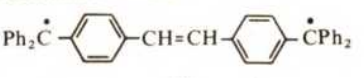
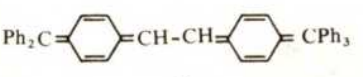
Georg Wittig — virtuoso of chemical synthesis

The 1979 Nobel Prize for Chemistry was awarded jointly to Georg Wittig and Herbert C. Brown. Here Robert Shaw describes Georg Wittig's achievements in synthetic and mechanistic chemistry.



GEORG Wittig was born on 16 June, 1897 in Berlin and after his *Abitur* hesitated between chemistry or music; luckily for chemistry he chose the former. His love of music has remained with him however, and in his earlier days he was an accomplished pianist. I should add that he has also been a keen mountaineer with many difficult ascents to his credit.

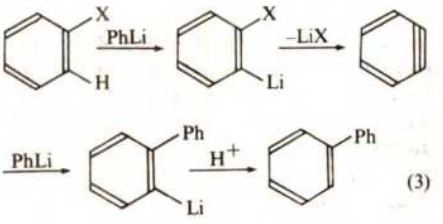
He commenced his study of chemistry at the University of Tübingen in 1916 but war service almost immediately intervened. He returned (on release from a prisoner of war camp in the UK) to the study of his chosen subject working under Karl von Auwers. In 1926 he obtained his *Habilitation* at the same university. From 1923-32 he was Teaching Assistant (first under von Auwers, then under Meerwein) at the Chemical Institute of the University of Marburg. In 1932, he went to the Technical High School in Braunschweig as *ausserplanmässiger* Professor. He stayed there until 1937, when he became *Extraordinarius* in Freiburg. In 1944 he became *Ordinarius* at the University of Tübingen and left there in 1956 to become Director of the Chemical Institute of the University of Heidelberg. In 1965 he became Professor Emeritus but continued to co-direct the Institute for Organic Chemistry in Heidelberg for a further two years. He has remained active since. This is a bare outline of a brilliant scientific career spanning half a century.



Georg Wittig has received many honours and it is appropriate that his long and distinguished career has been crowned by the award of the Nobel Prize — a recognition which was long overdue.

If the impact a scientist makes on his peers is measured by the achievements which carry his name Wittig has scored a hat-trick: the Wittig hydrocarbon, the Wittig rearrangement and the Wittig reaction — an achievement that has been matched by few.

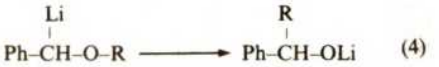
Wittig's scientific work began with studies on γ-pyrones. Investigations on free radicals then followed, in particular, of polyphenylated hydrocarbons. In an attempt to prepare a biradical (1), the Wittig hydrocarbon, bis[4-(diphenylmethylene)cyclohexadienyliden]ethane (2) was obtained in 1936.



(1)

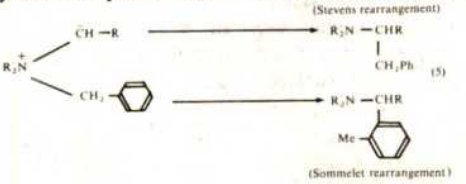
(2)

For these studies Wittig used phenyllithium, first used by him in 1931; this reagent recurs again and again in many of his most important discoveries. Wittig called it his *Wünschelrute* (divining rod). His work with organolithium compounds and related organometallic reagents (following earlier work by Schlenk and Bergmann) establishes him, together with Henry Gilman and Karl Ziegler, as one of the fathers of organometallic chemistry of the main group elements.



Phenyl-lithium is a very strong base and nucleophile. Both of these properties are of importance in its reaction with halogenobenzenes, PhX (X = F, Cl, Br) to give diphenyl, PhPh. The observation that fluorobenzene (X = F) was the most reactive in this series led to the following reaction scheme, including the postulate in 1942 of the then revolutionary idea of a dehydrobenzene (benzyne).

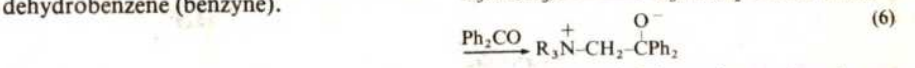
(3)



In the 1950s Wittig (and independently John D. Roberts) explored the synthetic and mechanistic aspects of benzyne. His studies were extended to other dehydroaromatics, dehydroheterocyclics and small-membered cycloalkynes in the 1960s. These short-lived intermediates were trapped as characteristic adducts with dienes or bases and this procedure led to novel syntheses. It may be an interesting aside that Wittig and Roberts believe that they are distantly related, as the name Dombrowski, occurred in both their families.

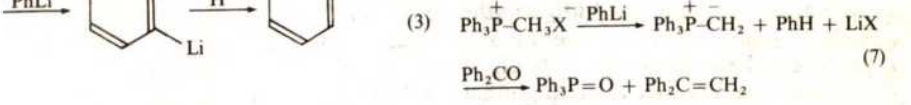
Much of Wittig's work was in the field of organic anionic chemistry. Here he carried out important investigations on metallated ethers (the Wittig rearrangement) in 1942

(4)

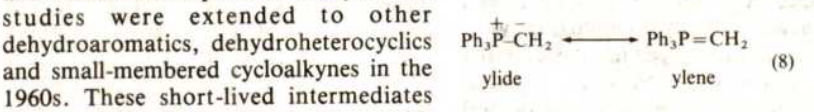


and ammonium ylides 2 years later

(5)

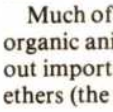


The zwitterionic ylides were obtained from the reaction of phenyl-lithium with quaternary ammonium halides and the unstable products converted with benzophenone to stable and easily characterised adducts.



(6)

Extension of this work to phosphorus compounds led to the discovery of the phosphonium ylides in 1953, and their reactions with aldehydes or ketones to give the famous olefin synthesis which carries Wittig's name.

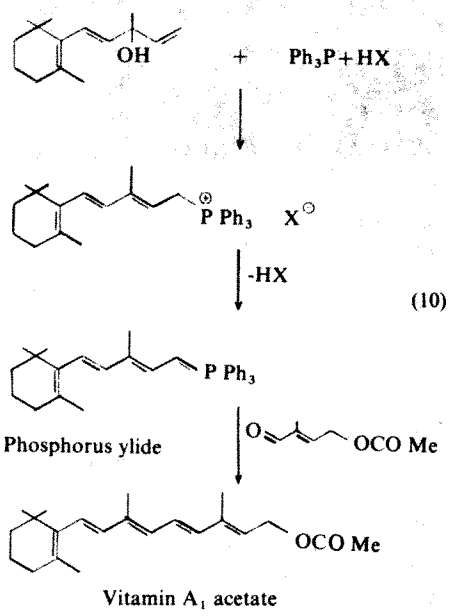


(7)

This ylide for which also the ylene canonical form is discussed

(8)

reacts *via* zwitterionic intermediates, usually unstable, but which can be isolated in special cases, to give olefins with a precisely defined location for the double bond.



(9)

This olefin synthesis proceeds under mild conditions and is thus ideally suited for the synthesis of natural products. Recent work allows considerable control of whether *cis* or *trans* olefins are formed. Amongst the

©1979Macmillan Journals Ltd

triumphs of this synthetic procedure are vitamin A_1, β-carotene, citranaxanthin (a food dye), vitamin D_2, progesterone, squalene, the sesquiterpenes α and β-sinensal (the aroma of orange oils), juvenile hormones (with potential in pest control), prostaglandin PGF_2, the Queen bee substance (a pheromone), an optical brightener (PALANIL^R Brilliant White R) for cotton and polyester fibres, and many more. In particular vitamin A_1 is now produced on a tonne scale by this method. The BASF process for its synthesis is outlined below.

Vitamin A_1 acetate

Another contribution by Wittig was the use of organolithium compounds and other strong bases to obtain carbenes in 1959, now widely recognised as important intermediates in many organic reactions. More recently carbenes have been observed in a variety of complex organometallic compounds, and some of these have been characterised by X-ray crystallography.

An α-carbon-hydrogen bond is essential for the formation of phosphorus ylides. Utilising the absence of such a structural feature in phenyl derivatives, Wittig synthesised pentaphenylphosphorane, Ph_5P.

$$Ph_4\overset{+}{P}\overset{-}{X} + PhLi \rightarrow Ph_5P + LiX \qquad (11)$$

By analogous routes pentaphenyl derivatives of arsenic, antimony and bismuth were obtained, as were tetraphenyl derivatives of sulphur, selenium and tellurium and a triphenyl derivative of iodine.

In addition to the above mentioned neutral organometallic compounds Wittig prepared numerous anionic derivatives, the 'ate'-complexes, and explored their chemistry. Two examples must suffice: sodium tetraphenylborate, $NaBPh_4$, used in the estimation of potassium and of some alkaloids, and lithium hexaphenylantimonate, $LiSbPh_6$.

Science may be impersonal — scientists certainly are not. So I cannot write about Georg Wittig the scientist without mentioning Georg Wittig the man. My first contact with Wittig was when, as a PhD student I wrote to him about a paper of his and Vidal's on the hydrocarbon fluorene and received a most courteous reply. I well recall the kindness with which he later received me and many other young scientists at his Institute in Heidelberg and his and his wife's generous hospitality. His Institute mirrored his personality, courteous and always kind, and was not one where continuous internecine warfare was current: his kindness made him an exceptionally effective teacher to those fortunate enough to have been his pupils. He was an inspiration to all those who came in contact with him.

His wife Waltraut, herself a PhD in chemistry, was his constant and trusted companion and her unexpected death last year was a severe blow to him. With firmness and kindness she stood by his side and shielded him from most of the more mundane cares of modern life leaving him free to concentrate on his scientific work. It must be a great sadness to him, as well as to those of us who knew her, that she did not live to see his work rewarded with the award of a Nobel Prize.

Georg Wittig's lasting achievements speak for themselves but two aspects deserve particular comment. Most of his work was done without the benefit of modern high technology instruments such as high field NMR spectrometers, four-circle diffractometer and so on. His most important 'instruments' were his vast chemical knowledge, his fine intellect and a superb chemical intuition. And much of his best work was done at an age when for many others the spring of scientific innovation has dried up. Good wine matures with age and Georg Wittig is undoubtedly of the best vintage. □

Robert A. Shaw is Professor of Chemistry at Birkbeck College, University of London.

Protean muscle

from Alan Weeds

MUSCLE is a highly adaptable and responsive tissue. Its physiological and biochemical properties accommodate to changes in functional requirements, altered patterns of nerve stimulus and hormonal variation. Dramatic changes are seen in the pattern of gene expression during embryological development and following denervation or local injury: such systems provide valuable models for unravelling the temporal sequence of these genetic events and elucidating their ontogeny. To what extent does the pattern of nerve impulses control muscle performance? How is this modified by use, hormones and other nutritional factors? What is the mechanism whereby these external influences affect the genetic programme of muscle? Is there a common messenger? These were some of the questions discussed at a recent meeting on Muscle Plasticity*.

Myosin changes during development

Probably the most controversial aspect of the meeting concerned the nature of myosin gene expression in developing muscle, a subject that has been debated in *Nature* recently (see **280**, 321; 1979). G. Gauthier (University of Massachusetts, Worcester) described the use of purified antibodies to fast and slow chicken muscle myosins to identify cross-reacting species in developing rat muscles by indirect immunofluorescence. In early post-natal development all fibres of extensor digitorum longus (EDL, which is fast-twitch in the adult) and soleus (slow-twitch in the adult) stained with both antibody preparations. Segregation of staining into the adult pattern occurred only later, probably coincident with the stage when the muscles cease to be polyneuronally innervated and are stimulated through a single axon. The experiments suggest the presence of both adult forms of myosin within the same fibre or may indicate a different myosin isoenzyme which cross reacts with both sets of specific antibodies. By contrast, N. Rubinstein (University of Pennsylvania, Philadelphia) argued that most of the fibres of both EDL and soleus muscles from 18-day rat embryos stained exclusively with antibodies to fast muscle myosin while only a few stained with antibodies to slow muscle myosin. At birth all the fibres still reacted with anti-fast myosin antibodies, but the level of staining was weaker in those fibres which also reacted with anti-slow myosin antibodies. These experiments, combined with two-dimensional gel electrophoresis of the myosin light chains suggest that only fast muscle myosin is synthesised in both fast and slow muscles at the earliest stages of development. Cultures derived from chick pectoralis and anterior latissimus dorsi muscles *in vitro* (fast and slow respectively) were also shown to synthesise only fast myosin by these criteria.

R. Whalen (Institut Pasteur, Paris) reported evidence for an embryonic form of myosin in developing rat muscles and also in bovine and chicken muscles. This was based on light chain patterns in two-dimensional gel electrophoresis and also on

*The International Symposium on Plasticity of Muscle was held at the University of Konstanz, Germany between 23 and 28 September and organised by Professor D. Pette. The proceedings of the meeting will be published in early 1980 by Walter de Gruyter, Berlin.

0028-0836/79/460232-02$01.00

gel fingerprints of chymotryptic fragments of the myosin heavy chains. Embryonic myosin is the predominant species in primary tissue culture cells after fusion and is present in newborn rat muscles as a minor species. Thus in soleus muscle of newborn rats, all three forms of myosin occur. J. Hoh (University of Sydney) also provided evidence for an embryonic form of myosin based on gel electrophoresis of the native protein.

While differences in the immunofluorescence results may reflect different techniques and variations in the response of the animals used to raise the antibodies, these different results are at variance, particularly those of Rubinstein, and will require further investigation. Nevertheless, the evidence for an embryonic myosin is persuasive and it is also clear from a number of systems that two or more myosin isoenzymes may coexist within the same fibre. But we do not know whether, if these myosins are synthesised simultaneously, polyneuronal innervation is required or whether this is part of the intrinsic developmental genetic programme. Part of the problem is to establish the precise times at which polyneuronal innervation becomes effective and is subsequently eliminated. Further experiments on the sorting of both myosin and troponin isoforms (discussed by S. Perry, University of Birmingham) are needed to elaborate the complex sequence of myofibrillar gene expression during differentiation and development. E. Kugelberg (Karolinska Institut, Stockholm) showed that there was a steady transformation of fibre motor units from fast to slow in soleus muscles from maturing rats, but whether the intermediate contraction times result from changed discharge frequencies of the motoneurones remains to be proved.

Innervation and regeneration

A related problem, discussed by R. Bischoff (Washington University, St Louis) and A. Kelly (University of Pennsylvania, Philadelphia) concerned muscle regeneration following denervation or local injury. Bischoff suggested two routes. Satellite cells located beneath the basement membrane may proliferate and fuse to form new myotubes or, under conditions where these are killed, dedifferentiation of myofibres occurs, which subsequently form immature myotubes leading to new myofibrils. This demonstrates once again the remarkable versatility of muscle tissue. Kelly argued that the programme of myosin gene expression during regeneration mimicked that occurring during development.

G. Vrbová (University College, London) presented evidence that polyneuronal innervation disappears when the animal starts moving and suggested that retraction of nerve fibres from the endplate might be due to the action of proteolytic enzymes, stimulated by acetylcholine and calcium ions. Thus maturation of muscle fibres depends not only on stimulation by a single motoneurone but also on muscle use. Other speakers also emphasised the importance of use. D. Goldspink (Queen's University Belfast, Northern Ireland) reported that limb immobilisation produced a marked increase in protein degradation and simultaneous decrease in synthesis, but atrophy was greater in the normally more active soleus muscle than in EDL. Stretching the muscles reduced the rate of atrophy through increased protein synthesis. H. Vandenburgh (National Institute of Mental Health, Bethesda) demonstrated increased protein synthesis in cultured muscle cells in response to stretch. He suggested that stretch activates the sodium/potassium ATPase, which might enhance amino acid transport. J. Etlinger (SUNY Downstate Medical Center, Brooklyn) showed effects of calcium ions as well as stretch on protein degradation and biosynthesis in rat muscles. Release of myofilaments during degradation is stimulated in the presence of calcium ions by way of proteolysis. Thus the application of mechanical force influences ion movements in muscle membranes which may be responsible for the observed changes in protein turnover.

The effects of a number of hormones on protein synthesis and degradation were reviewed by A. Goldberg (Harvard Medical School, Boston), emphasising the dynamic nature of muscle as providing 80% of available body protein for metabolism. C. Ianuzzo (York University, Toronto) and A. Montgomery (Newcastle General Hospital, Newcastle upon Tyne) showed the effects of altered thyroid hormone levels on the presence of fast-twitch fibres in rat soleus muscles. Thyroid status clearly influences the pattern of myosin gene expression in addition to its general effects on protein turnover.

Electrical stimulation

The other major area of discussion centred on altered patterns of electrical stimulation and use in adult muscles. Although denervation, spinal transection and cross-reinnervation have provided useful models, these surgical procedures are often complicated and the effects long term. Emphasis at this meeting was on the use of chronic electrical stimulation to investigate the influence of different firing rates on speed of shortening and metabolic enzyme levels. T. Lømo (University of Oslo, Norway) reported chronic stimulation experiments on rat muscles following nerve section, where the only stimulus reaching the muscles was the externally applied one. His most interesting findings were that infrequent 100 Hz pulses applied to slow muscles produced properties characteristic of fast-twitch muscles. But he found that the speed of contraction was regulated independently from the muscle's endurance. O. Hudlická (University of Birmingham) described effects of chronic stimulation in increasing blood flow and oxidative enzyme levels, while D. Pette (University of Konstanz, Germany) showed dramatic changes in metabolic enzyme activities, especially hexokinase, within 24 hours following stimulation of rabbit fast-twitch muscles at 10 Hz for 12 hours per day. C. Heilmann (University of Konstanz) examined effects on the sarcoplasmic reticulum and found reduced calcium uptake and ATPase activity within 2 days of applying artificial stimulation. In addition there were changes in the composition of phosphorylated proteins in the reticulum membrane. S. Salmons (University of Birmingham) showed an increase in the activity of enzymes involved in polyamine synthesis of nearly two orders of magnitude within 28 hours of applying the external stimulator, which might reflect increased levels of mRNA processing or translation in these muscles. Although this model was discussed extensively, Vrbová suggested that pharmacological agents and hormones might prove more valuable for the future because of the 'insulting' effects of this abnormal form of stimulation on the muscles.

The meeting represented somewhat of a watershed. I left with the feeling that the groundwork has been laid but that there was much more to achieve. Particularly important would be tissue culture systems which were free from the vagaries of whole animal models. A. Shainberg (Bar-Ilan University, Ramat-Gan, Israel) introduced us to novel experiments analysing acetylcholine receptors on myotubes following electrical stimulation. Although the importance of the membrane became increasingly clear as the meeting proceeded, relatively little attention has been paid to it in the past. Whatever the signals may be that control the genetic programme, the membrane acts as their gate. Our mercurial muscles have much yet to reveal. □

Life in a cold climate

from W. Nigel Bonner

THE Antarctic provides a testing environment for many forms of life. Severe climate, characterised by large temperature range and oscillations, with long periods of subzero temperatures, combine with extreme isolation to create a set of conditions where the critical response of an organism to its environment can often be simply expressed in terms of one or two key features. Studies of such responses allow the description of the adaptational strategy of certain polar organisms and are being undertaken by the British Antarctic

©1979 Macmillan Journals Ltd

Survey, (a component body of the Natural Environment Research Council). Some recent work was reported at a conference at the Linnean Society last month*.

The typical Cryptostigmatid mite, *Alaskozetes antarcticus,* which is an important component of the very sparse Antarctic terrestrial invertebrate fauna, is continually exposed to the risk of tissue freezing. Freezing is fatal to all stages of this mite. The risk of freezing is increased if the mites have been feeding, as food remains in the gut provide potential ice-nucleators when supercooled. W. Block and S.R. Young have found that *Alaskozetes* can to a great extent avoid freezing first by ceasing to feed in the autumn, so that the gut is emptied of potential ice-nucleating agents, and second by developing an ability to supercool to −26°C. Supercooling is enhanced by glycerol, which the mite can synthesise as a response to low temperature and low relative humidities, to allow survival to at least −31°C. Juvenile mites possess an even greater ability to tolerate cold than do adults. In this way juveniles and adults avoid tissue freezing in winter in their maritime Antarctic habitat. *Alaskozetes* maintains a metabolic rate some two to three times higher than that of comparable temperate mites over the range 0 to +10 °C. This elevation of metabolism or cold adaptation combined with its strategy for avoiding freezing allows large populations of mixed instars to survive the Antarctic winter and so use the short summer period for growth and reproduction. Life cycles of such species are necessarily long (up to 2-3 years) in the Antarctic.

Conditions are very different in the Antarctic sea. Here temperatures, although low, are stable in comparison with the terrestrial environment and freezing is a problem for relatively few organisms (notably fish and some shallow-water molluscs). More important is the great seasonal variation in food availability, caused by changes in light-climate and ice-cover. This results in a brief season of phytoplankton bloom, in which food is abundant, followed by a long period of scarce or erratic supply. Andrew Clarke suggested that Antarctic marine invertebrates, unlike *Alaskozetes,* are characterised by low basal metabolic rates, (regarding basal metabolism as the generation of ATP for protein turnover, for membrane pumps, and (with NADPH) for lipid turnover, plus the cost of circulation). Coupled with low basal metabolic rates are slow growth, reduced annual reproductive effort and by analogy with fish, low rates of protein synthesis. Together, these result in a reduction of the total food requirement, thus facilitating survival in an environment when food is limited for a large part of the year.

The absence of planktonic larval stages of benthic invertebrates is characteristic of the polar seas. In Antarctic prosobranch molluscs, for example, most forms produce a few large yolky eggs from which tiny but perfect snails emerge after a long development. This parallels the principal reproductive strategy of other polar benthic invertebrates and G.B. Picken argued that this style of early development, whether by means of egg capsules, brood protection or viviparity, has strong survival value in localities where low temperature and slow growth mean that planktonic larvae would be unable to exploit the brief abundance of phytoplankton during the summer bloom. The trend towards reduced fecundity, enhancing the survival of the large, well-developed juveniles in comparison with more numerous but smaller planktotrophic larvae, and the extreme isolation of shallow-water benthic habitats in the Antarctic, may be the principal factors responsible for the high level of species endemism found there.

Sea-birds also exploit the Antarctic environment. Being homeotherms, low temperatures are not primarily a problem for them, provided energy sources are adequate. During the breeding season, however, which is in general timed to take advantage of the high seasonal food availability, food demand is dramatically increased at those sites where the birds concentrate. South Georgia is such a site and J.P. Croxall and P.A. Prince have studied how the various species breeding there divide the food resources between them. In some cases chick-feeding periods are complementary between species pairs, so that direct competition for food between similar feeders is reduced. In others, there may be species differences in the frequency with which chicks are fed, allowing one species to exploit more distant feeding grounds than another. Most commonly, however, differences are found in the detailed composition of diets. The two very similar albatrosses, the Black-browed Albatross and the Grey-headed Albatross, for example, have as principal components of their diet krill and squid respectively. Because squid is less nutritious than krill Grey-headed Albatrosses rear their chicks more slowly and are unable to breed every year. However, in compensation their adult survival is substantially greater than in the Black-browed Albatross. □

Elephant Seal breeding beach. Studies on Elephant Seals at South Georgia by British Antarctic Survey have shown how this species has recovered from the effects of commercial sealing in the past. (Photograph by T.S. McCann.)

James Clerk-Maxwell—100 years later

Cyril Domb

King's College, University of London, Strand, London WC2, UK

This year is the centenary of the death of James Clerk-Maxwell, whose theory of the electromagnetic field provided the background essential to the development of Einstein's ideas. Einstein, at the commemoration of the centenary of Maxwell's birth in 1931, described the change in conception of reality in physics after Maxwell as "the most fruitful that physics has experienced since the time of Newton".

THE concept of electromagnetic radiation originated with Maxwell, and his field equations paved the way for the special theory of relativity. Newton, Maxwell and Einstein are in a class of their own among physicists, and it is remarkable that Einstein was born in the year that Maxwell died, as in many respects Einstein took over where Maxwell left off. The quantum theory also leaned heavily on Maxwell's ideas. Max Planck introduced his quantum hypothesis to account for the spectrum of 'black-body radiation' (electromagnetic radiation in thermal equilibrium with matter at a given temperature) and to resolve the UV catastrophe of the classical theory for which an infinite amount of energy was present in radiation of short wavelengths. In the subsequent development of the theory of the structure of atoms and molecules and of matter in general, the interaction between matter and radiation has a central role.

Maxwell also made fundamental contributions to other branches of physics, notably thermodynamics, the kinetic theory of gases (the idea of applying probability and statistics to molecules is due to Maxwell), colour vision and colour photography. In the nineteenth century there was no serious division between theoretical and experimental physics. Maxwell engaged in both throughout his life, and his best known appointment is that of first Professor of Experimental Physics in the University of Cambridge.

Contemporary assessment

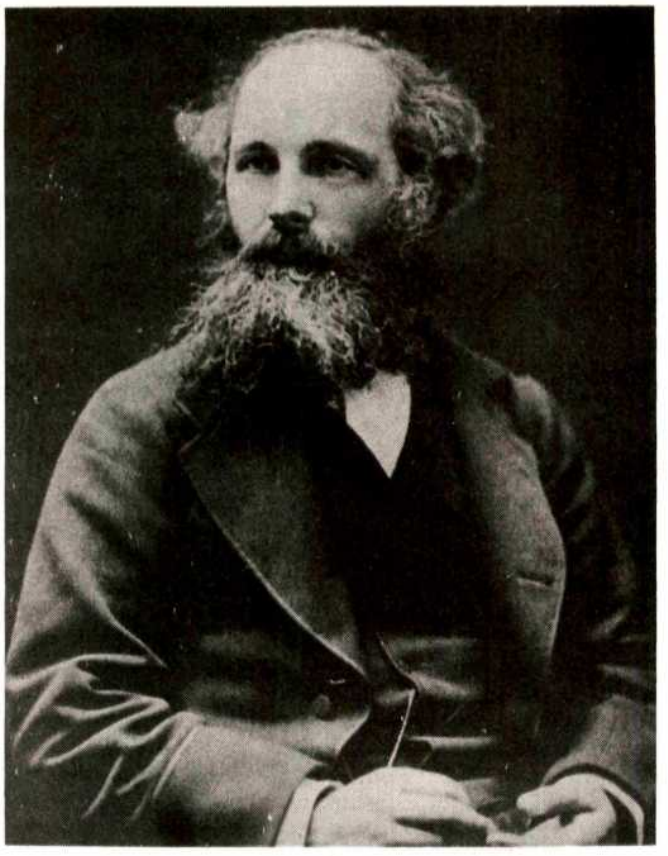
Maxwell's contemporaries did not think quite so highly of him. When the Cavendish Laboratory was initiated in 1871 Maxwell was only the third of those proposed for the appointment of director. The first was William Thomson (later Lord Kelvin). He did not wish to move from Glasgow and suggested Helmholtz who also refused to move from Berlin where he had just been appointed director of a new laboratory. Only then was Maxwell approached, and the letter of invitation by the Reverend E. W. Blore stated: "It has I believe been ascertained that Sir W. Thomson would not accept the Professorship. I mention this in case you should wish to avoid the possibility of coming into the field against him." When Maxwell did eventually take up the appointment at Cambridge the average attendance at his lectures was between two and three students!

His first academic teaching appointment was at Marischal College in the University of Aberdeen in 1856. In 1860 a merger took place between the two constituents of this University, King's College and Marischal College, and one of the two professors of Natural Philosophy became redundant; David Thomson of King's College was allowed to continue, ostensibly because of superior teaching ability, and Maxwell was declared redundant.

Maxwell applied for a vacancy at the University of Edinburgh but he was turned down in favour of his school friend Peter Guthrie Tait who was again considered a better teacher. Fortunately King's College London appointed him to the Chair of Natural Philosophy. The five subsequent years were undoubtedly the most fruitful of his career. He was elected to the Royal Society in 1861 aged 29. His two classic papers on the electromagnetic field were published in 1862 and 1864. In 1861 he delivered a lecture at the Royal Institution on the theory of three primary colours, and demonstrated the first colour photograph. The theoretical and experimental work on the viscosity of gases which took place during these years culminated in his Bakerian lecture to the Royal Society in 1866. He supervised the experimental determination of electrical units for the British Association's Committee; this work of measurement and standardisation led to the establishment of the National Physical Laboratory. He also measured the ratio of electromagnetic and electrostatic units of electricity, and confirmed that it was in satisfactory agreement with the velocity of light as predicted by his theory.

But even the association with King's College was described in negative terms by the College historian. Maxwell resigned his Chair in 1865 and retired to the family estate in Glenlair, Scotland. When the centenary history of the College was published in 1928 it claimed that Maxwell was asked by the Governors to resign because he could not keep order at lectures. There is, however, no hint of such a situation in the biography by Campbell, in the obituary notice in the Royal Society or in any of Maxwell's correspondence. I have recently investigated this claim and found it devoid of any substantial basis.

Maxwell emerged from retirement to take up the appointment at Cambridge in 1871, where he spent his final eight years; he died on 5 November 1879 aged only 48. He published just over 100 papers, received no public honours, and was buried quietly in a small churchyard in the village of Parton, Scotland. By contrast, his friend William Thomson lived on for nearly 30 years more, published 600 papers, received every possible honour and distinction, and was buried with great acclaim in Westminster Abbey.



The true quality of Maxwell's genius became apparent only with the development of twentieth century physics. In addition to the major contributions to science mentioned previously, several ideas which he put forward quite casually have proved extremely fertile, and have led to important advances.

Biographical notes

Fortunately Maxwell's lifelong friend, Lewis Campbell (together with the first Demonstrator in Physics at the Cavendish Laboratory, William Garnett) produced a definitive biography within a few years of his death. Other biographical essays have appeared, the most important of which (by C. W. F. Everitt) provides new biographical material, and reviews

From a portrait at King's College, London

James Clerk-Maxwell in his later years.

Maxwell's scientific achievements from the vantage point of the present day.

James Clerk-Maxwell came from a comfortable middle-class background. The original family name was Clerk, the additional surname Maxwell being added by his father because of the inheritance of the Middlebie estate from ancestors of that name. James, an only child, was born in Edinburgh where his father was a lawyer; his parents had married late in life and his mother was 40 years old at his birth. Shortly afterwards the family moved to Glenlair, the country house on the Middlebie estate.

James showed remarkable curiosity at an early age, and before he was 3 his mother wrote "he has great work with door locks, keys, etc. and 'show me how it doos' is never out of his mouth. He also investigates the hidden course of streams and bell wires. . . . As to the bells, they will not rest; he stands sentry in the kitchen, or he rings, and sends Bessy to see and shout to let him know, and he drags papa all over to show him the holes where the wires go through." He also had a phenomenal memory, and at the age of 8 he knew by heart the longest chapter of the Old Testament (Psalm 119 containing 176 verses).

Alas, his mother died in 1839 from abdominal cancer, the same disease to which he was to succumb at exactly the same age. A dull and uninspired tutor was engaged who claimed that James was slow at learning. Fortunately he was rescued by his aunt Jane Cay and was sent to school at the Edinburgh Academy. Among the other pupils were his biographer Lewis Campbell, and his friend Peter Guthrie Tait.

Maxwell's interests ranged far beyond the school syllabus, and he did not pay particular attention to examination performance. But he published his first scientific paper at the age of 14 describing a generalised series of oval curves which could be traced with pins and thread by analogy with an ellipse. This fascination for geometry and for mechanical models continued through his whole career, and was of great help in his subsequent research.

At the age of 16 he entered Edinburgh University where he read voraciously on all subjects, and published two more scientific papers. He went on to Cambridge in 1850, and here there is evidence that his exceptional powers began to be recognised. H. M. Butler (later Master of Trinity) wrote "When I came up to Trinity Maxwell was just beginning his second year. His position among us was unique. He was the one acknowledged man of genius among the undergraduates." Another friend W. N. Lawson wrote in his diary "Maxwell as usual showed himself acquainted with every subject on which the conversation turned. I never met a man like him. I do believe there is not a single subject on which he cannot talk, and talk well too, displaying always the most curious and out-of-the-way information."

A more discriminating appraisal came from his mathematics teacher, William Hopkins, the famous 'wrangler maker' of the period whose students included G. G. Stokes, William Thomson, Arthur Cayley, P. G. Tait and E. J. Routh. Of Maxwell he is reported to have said that he was the most extraordinary man he had met with in the whole course of experience; that it seemed impossible for him to think wrongly on any physical subject, but that in analysis he was far more deficient (other contemporaries testified to Maxwell's preference for geometrical over analytical methods). This shrewd assessment was borne out later by several important formulae advanced by Maxwell where the results have proved to be correct but the mathematical arguments are faulty.

In 1854 Maxwell was second wrangler and first Smith's prizeman; he was elected to a Fellowship at Trinity, but his father's health was deteriorating, and he wished to return to Scotland. In 1856 he was appointed to the Chair of Natural Philosophy at Marischal College Aberdeen; but unfortunately before the appointment was announced his father died. This was a great personal loss; he had a close relationship with his father, they had corresponded almost daily, and had always spent vacations together.

Maxwell must now have felt the need for his own family life, and in June 1958 he married Katherine Mary Dewar, daughter of the Principal of Marischal College. The union was childless, and is described as a "married life . . . of unexampled devotion". When Maxwell was away from home he would write to his wife every day, sometimes even twice a day, giving all details of his activities. When his wife was ill during their stay in Cambridge he did not sleep in a bed for three weeks. Reciprocally when Maxwell had an attack of smallpox at Glenlair in September 1860 his wife was left quite alone with him—the servants coming only to the door of the sideroom.

Later biographers have been less sympathetic to Mrs Maxwell. However, Everitt points out that the suggestion repeated by many writers (including Sir Edmund Whittaker) that she attempted to interfere with his scientific work, emanated from Mrs Tait, and should be completely discounted. For example, his wife helped him devotedly in his experiments on colour vision and the viscosity of gases.

Maxwell moved from Aberdeen to London in 1860. He took up residence in Kensington where he stayed until 1866. It was here that an experimental test was undertaken of his theoretical prediction that the viscosity of a gas should be independent of its density, his wife acting as stoker. He carried out many other experiments in a large attic which ran the whole length of the house. When he experimented at the window with the colour-box used for studies of colour vision (painted black, and nearly eight feet long) his neighbours thought him crazy to spend so many hours staring into a coffin.

After Maxwell retired to Glenlair, he continued to visit London every spring, and served as external examiner for the Mathematics Tripos at Cambridge. In the spring and early summer of 1867 he toured Italy; he had a good knowledge of French, German and Italian, the only language which gave him any difficulty being Dutch. But most of his energy during this period was devoted to writing his famous treatise on electricity and magnetism.

In 1871 when he was approached regarding the new Chair at Cambridge, Maxwell showed no enthusiasm for the position. In his reply to the Reverend E. W. Blore he said "I had no intention of applying for the post when I got your letter, and I have none now, unless I come to see that I can do some good by it." But after persuasion by G. G. Stokes, Lord Rayleigh and others he allowed his name to go forward and was duly elected.

He set about designing and superintending the erection of the Cavendish Laboratory. The building was not completed until 1874, and was not furnished with proper apparatus until 1877. Maxwell had few students, but they were of the highest calibre, and included W. D. Niven, Ambrose Fleming, R. T. Glazebrook, J. H. Poynting and Arthur Schuster.

At Cambridge Maxwell spent a great deal of time and effort editing the unpublished manuscripts of Henry Cavendish (who had donated the funds for the establishment of the Cavendish

The house which the Maxwells occupied during their stay in London (1860–66). The address was then 8 Palace Gardens Terrace, Kensington, but in 1869 the number was changed to 16. Experiments on colour vision and viscosity of gases, in which he was helped by his wife, took place in the attic.

Laboratory). Maxwell did a superb job, repeating key experiments, and establishing priority for Cavendish in the discovery of the inverse square law of electrostatics. But it cost all the spare time of the last five years of his short life, and surely his genius could have been put to more profitable use.

In the Easter term of 1879 Maxwell was ill on several occasions; he returned to Glenlair in June but his condition did not improve. On 2 October he was told that he had no more than one month to live. The religious faith which had characterised his whole life became even more manifest during his last few weeks. He returned to Cambridge, and expressed particular concern that proper arrangements should be made to look after his wife whose health had been poor. His mind remained clear to the end; in the words of Dr Paget who attended him "No man ever met death more consciously or more calmly".

Major contributions to science

Electromagnetism: It is Maxwell's researches on electromagnetism which have classified him with the great scientists of history. Maxwell always acknowledged his debt to Faraday, and in the preface to his *Treatise on Electricity and Magnetism* says that his major task was to convert Faraday's physical ideas into mathematical form, and hence to make them more widely accessible.

ON PHYSICAL LINES OF FORCE.

The velocity of light in air, as determined by M. Fizeau*, is 70,843 leagues per second (25 leagues to a degree) which gives

$$V = 314,858,000,000 \text{ millimetres}$$

$$= 195,647 \text{ miles per second} \quad \ldots\ldots\ldots\ldots\ldots\ldots (137).$$

The velocity of transverse undulations in our hypothetical medium, calculated from the electro-magnetic experiments of MM. Kohlrausch and Weber, agrees so exactly with the velocity of light calculated from the optical experiments of M. Fizeau, that we can scarcely avoid the inference that *light consists in the transverse undulations of the same medium which is the cause of electric and magnetic phenomena.*

Cambridge University Library

Extract from Maxwell's 1862 paper in the *Philosophical Magazine* in which he first formulated the electromagnetic theory of light.

His original contributions to electromagnetism are contained in three large sets of papers. The first, "On Faraday's Lines of Force", was published in 1856 during his first stay at Cambridge. Its aim was to derive all the standard results of electricity and magnetism using the 'medium' concept rather than that of action at a distance. The second, "On Physical Lines of Force", appeared in 1861–62. In attempting to illustrate Faraday's law of induction (that a changing magnetic field gives rise to an induced e.m.f.) Maxwell constructed a mechanical model and found that there would be a corresponding 'displacement current' in the dielectric medium. This medium could then be the seat of transverse waves, and on calculating the velocity of these waves he found that they were very close to the velocity of light. He concluded dramatically "we can scarcely avoid the inference that light consists in the transverse undulations of the same medium which is the cause of electric and magnetic phenomena". The final paper "A Dynamical Theory of the Electromagnetic Field", published in 1864, dispensed with the mechanical model, and formulated the field equations in the way in which they have been used subsequently.

Colour vision: To understand the theory of colour vision it is important to differentiate between the optical (or true) spectrum of a beam of light and the chromatic spectrum as seen by the eye. Beams of light with different optical spectra can have the same chromatic spectrum. Isaac Newton had shown that the optical spectrum of white light is very complex, but Thomas Young at the beginning of the nineteenth century proposed that any chromatic spectrum can always be analysed into three components corresponding to three receptors in the eye.

Maxwell's work on colour vision started when he was an undergraduate at Edinburgh and continued for many years afterwards. He chose red, green and blue as primary colours, and devised a colour top by means of which tinted papers of different colours could be mixed in varying intensities and the results determined. In this way he initiated 'quantitative colorimetry', analysing every hue into its appropriate components. Maxwell made the important observation that Young's hypothesis works only if negative as well as positive contributions are allowed. He also suggested that colour blindness corresponds to the absence of a red-sensitive receptor, and devised a pair of spectacles to enable a colour blind person to differentiate between red and green.

He invented a colour box in which beams of light of different colours could be mixed in variable proportions to match any given hue. With this apparatus he was able to achieve great accuracy in his experiments to chart the colour response of

different individuals, and to demonstrate that the colour discrimination of normal people is very good.

Colour photography: From the three-colour theory Maxwell concluded that by photographing through filters of three different colours, and then recombining the images, it should be possible to make a colour photograph of any object. He demonstrated this practically in a lecture to the Royal Institution in 1861 by photographing a tartan ribbon. This demonstration should not have worked, since the photographic emulsions available to Maxwell were not red-sensitive. The mystery was solved when a group of Kodak workers repeated Maxwell's procedure exactly, and found that the red filter also passed UV, and the red in the ribbon apparently also reflected UV.

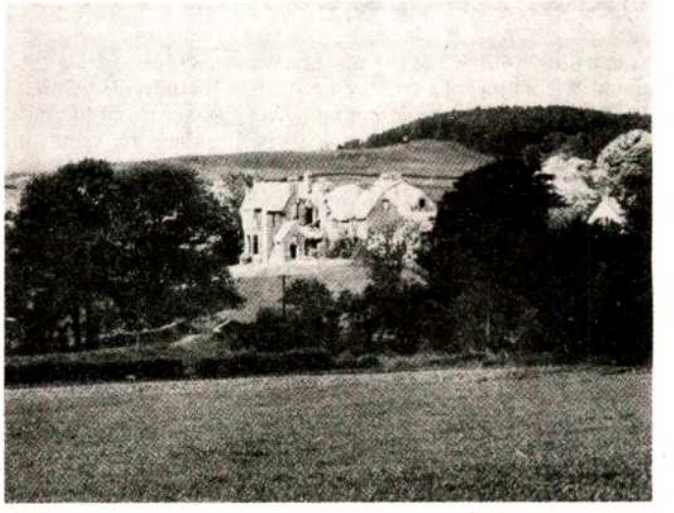
Saturn's rings: Whilst at Aberdeen Maxwell was able to demonstrate his mastery of classical physics in his Adams Prize Essay on Saturn's Rings, described by George Airy as one of the most remarkable applications of mathematics he had ever seen. Three alternative hypotheses were advanced for the constitution of Saturn's rings: (1) that the rings are solid, (2) that they are fluid or in part uniform, (3) that they consist of masses of matter not mutually coherent; it was necessary to examine for each hypothesis whether the conditions of stability are satisfied by the mutual attractions and motions of the planet and the rings. Maxwell concluded that the third hypothesis was the only one compatible with the stability of the rings. His investigation of this hypothesis laid the foundation for his subsequent work on the kinetic theory of gases.

Kinetic theory of gases

At the British Association meeting in Aberdeen in 1859 Maxwell pointed out that the velocities of molecules in a gas must follow a statistical distribution. Previously it had been naively assumed that they all had the same velocity. Maxwell derived a formula for this distribution at a given temperature and density, which has come to be known as the Maxwellian distribution. Although his derivation contained unwarranted assumptions, his result is valid and represents one of the most widely used formulae in statistical mechanics.

In later papers Maxwell investigated the transport properties of gases—the behaviour of viscosity, thermal conductivity and diffusion with change of temperature and pressure. He concluded that the viscosity of a gas should be independent of pressure, and found this result in reasonable agreement with experiment. He noted a particular simplification which occurs for molecules interacting with a repulsive force inversely proportional to the fifth power of their distance apart. In the last major paper of his life, published in 1879, he laid the foundations of the theory of rarefied gas dynamics.

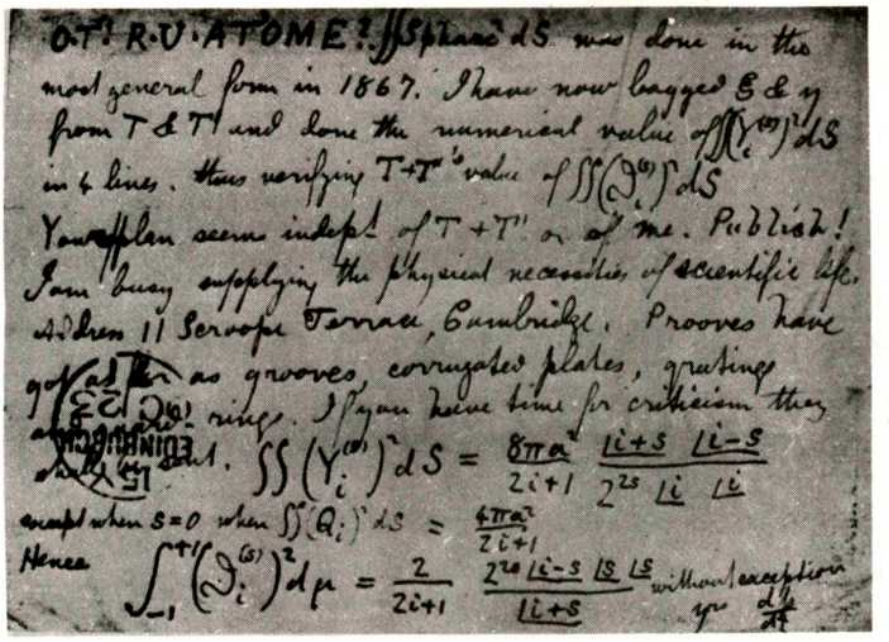
Fertile ideas



Several casual ideas of Maxwell have led to important developments. Perhaps the best known is the Maxwell Demon which he introduced near the end of his text-book *Theory of Heat*, published in 1871, to demonstrate the statistical character of the second law of thermodynamics. The demon was a hypothetical being who could follow the path of every molecule, and seated on a trapdoor between two vessels A and B, would open and close the door so as to allow fast molecules to go from A to B and slow molecules from B to A. Hence the temperature of B would be increased and A decreased without expenditure of work thereby contravening the second law of thermodynamics. The suggestion intrigued many distinguished scientists subsequently. If one could devise a practical realisation of the demon, the consequences could be very important. Clearly the demon's intelligence must be related in some way to entropy, and this correlation was given a mathematical formulation in Brillouin's theory of information which thereby demonstrated that the demon could not operate. Brillouin's interpretation of information as negative entropy, which was responsible for exorcising the demon, is a key concept in present understanding of the thermodynamics of biological systems.

In 1868, Maxwell provided the first analytical treatment of governors, devices which ensure that the velocity of the machine remains nearly uniform despite variations in driving power or resistance. Devices of this kind had been used by James Watt (to control his steam engine), James Thomson, C. W. Siemens, M. Foucault and others. Maxwell derived differential equations for the motion, introducing a term later to be characterised as negative feedback. He solved the equations, and determined conditions for the motion to be stable, and the governor to function. His paper laid the foundation of control theory, or cybernetics.

The Bakerian Lecture to the Royal Society in 1869 was delivered by Thomas Andrews, and described the classic experiments on carbon dioxide from which he derived the relationship between the liquid and gaseous states. Four years later Johannes van der Waals presented his thesis in which, starting from a plausible molecular hypothesis, he derived his equation of state for fluids. Maxwell was very impressed by this thesis, and made the effort of learning Dutch to be able to study it. He reviewed it in *Nature* in 1874, and in a lecture to the Chemical Society in 1875, where he supplied a crucial step missing in the van der Waals treatment. The argument which Maxwell used to justify his construction was heuristic rather than rigorous; it was only in the 1960s that this result was shown to be rigorously correct.



Whilst still a student at Cambridge in 1853 Maxwell undertook a study in geometrical optics "suggested by the contemplation of the structure of the crystalline lens in fish". He looked for a medium in which focusing would be perfect—all rays proceeding from any point in the medium would meet accurately in another point; and using a method deduced by analogy from Newton's *Principia* he arrived at a mathematical description of the medium. Nearly a century elapsed before Rudolf Luneberg revived the subject, and found other instances of perfect imaging devices.

A striking example of the casual way in which Maxwell produced original ideas is provided by the theory of propagation of light in a dispersive medium. A formula for the refractive index was put forward by Sellmeyer in 1871. Twenty years after Maxwell's death, Lord Rayleigh published a note in the *Philosophical Magazine* pointing out that Maxwell had considered the question before anyone else. But Sellmeyer could hardly have been expected to know of Maxwell's work as it was contained in a question set for the Mathematical Tripos examination on 21 January 1869.

Photographed by R. A. R. Tricker

Glenlair, the country house which Maxwell inherited and to which he moved when he resigned from King's College in 1865. He left in 1871 to become the first Cavendish professor at Cambridge. (The interior of the house was destroyed by fire in 1929.)

Cambridge University Library

One of the postcards sent by Maxwell to his friend Peter Guthrie Tait. William Thomson (Lord Kelvin) is referred to as T, P. G. Tait as T', and Maxwell signs himself dp/dT in accordance with the thermodynamic relation dp/dT = JCM. The term T & T' used in lines 3 and 4 refers to the famous nineteenth century text by Thomson and Tait, *Elements of Natural Philosophy*.

Maxwell and Einstein

Maxwell regarded the ether as the seat of electromagnetic waves, and after developing his electromagnetic theory, he devoted much thought to the problem of the 'ether drift' or how much the velocity of light would be changed by the motion of the emitter. He convinced himself that in a terrestrial experiment it was necessary to measure the time which has elapsed in a go and return journey and the effect would be of the order of v^2/c^2 (where v is the velocity of the emitter and c the velocity of light) which would be too small to measure. But in the last year of his life he wrote to the astronomer D. P. Todd suggesting that he look for a change in the periodicity of the satellites of Jupiter as the planet changed its position relative to the Earth; this periodicity should depend on the ether velocity along a line joining the Earth and the planet. These considerations were an important stimulus to the famous Michelson–Morley experiment which played such a crucial role in Einstein's development of special relativity.

Maxwell maintained a close scientific friendship with William Thomson (later Lord Kelvin) and Peter Guthrie Tait. For many years the three exchanged postcards, the former being referred to as T and the latter as T', and Maxwell as dp/dT (this was based on the thermodynamic relation dp/dT = JCM giving Maxwell's initials, where p is the pressure, T the temperature, J Joule's constant, C Carnot's function T^{-1}, and M the rate of increase of heat in an isothermal change of volume). One of the most influential text books of the period was Thomson and Tait's *Treatise on Natural Philosophy*. When Tait sent a preliminary draft to Maxwell he wrote back criticising them for confusing mass and weight: "You may place the two masses in a common balance (which proves their weight equal), you may then cause the whole machine to move up or down. If the arm of the balance moves parallel to itself the *masses* must also be equal."

The identity of mass-like and weight-like properties of matter is a coincidence in Newton's theory, and constituted one of Einstein's major criticisms of the theory.

In his classic 1864 paper "A Dynamical Theory of the Electromagnetic Field" Maxwell tried to consider the formulation of a field theory of gravity which also satisfies an inverse square law of force. But the change of sign in the interaction and the requirement that energy must be positive led to the conclusion that an enormous intrinsic energy must be associated with the medium. "As I am unable to understand in what way a medium can possess such properties I cannot go further in this direction in searching for the cause of gravitation." Maxwell clearly wanted to go in the Einstein direction, but the necessary basic equipment was lacking.

Finally in a lecture delivered to the Chemical Society in 1875 Maxwell calculated the specific heat of a gas of molecules with n degrees of freedom. He found that the ratio γ of C_p the specific heat at constant pressure, to C_v the specific heat at constant volume, should be of the form $(2+n+e)/(n+e)$, where e is a positive quantity of unknown value relating to the stored energy of the molecule. For a monatomic molecule $n=3$, $e=0$ (no stored energy), $\gamma = 5/3$, a value which agrees well with experiment. For a diatomic molecule $n=6$, and the largest possible value of γ (corresponding to $e=0$) is 1.33; but the experimental values for several gases are found to be 1.408. Maxwell continued "I have now put before you what I consider to be the greatest difficulty yet encountered by the molecular theory".

The difficulty was resolved only by Planck's quantum hypothesis; and it was Einstein who first applied the hypothesis to the calculation of specific heats, and showed that the energy of an oscillator became frozen at sufficiently low temperatures.

Maxwell's versatility

This record by no means exhausts Maxwell's contributions to science and to general culture. This would require a much larger and more comprehensive article. He showed considerable ability as a poet, particularly for semi-humorous verse on scientific themes. He was concerned with scientific terminology, for example, coining the term curl which is now used almost universally in vector analysis. Amongst other scientific innovations he produced a theorem on reciprocal diagrams in frameworks which he later extended to continuous media, and which was of importance in the development of ideas on strength of materials. He devoted much time and effort trying to popularise the Gibbs approach to thermodynamics.

Maxwell's papers are full of novelty and interest. In 1854 he discusses what happens when a slip of paper falls through the air, noting that its general path is not in the vertical direction but inclined to it at an angle which remains nearly constant, its fluttering appearance due to a rapid rotation around a horizontal axis. He then advances reasons for this behaviour.

In the words of the late Charles Coulson "there is scarcely a single topic that he touched upon which he did not change almost beyond recognition".

An absorption feature in the spectrum of the pulsed hard X-ray flux from 4U0115+63

A spectral feature, apparently an absorption line, has been observed at an energy of 20.1 ± 0.5 keV in the pulsed flux of 3.61 s X-ray pulsar 4U0115+63 using the UCSD/MIT instrument on HEAO 1. The line strength, expressed as equivalent width, is 3.1 ± 0.5 keV. Although essentially unresolved, the feature has a depth more than 60% of the continuum flux. If the feature arises by cyclotron resonance absorption near the magnetic poles of the neutron star, it implies a magnetic field of between ≈1.8 and ≈2.5 × 10^{12} G depending on the gravitational redshift (≲5–40%).

ALTHOUGH standard models (see ref. 1) of the pulsating binary X-ray sources as rotating, accreting magnetised neutron stars require magnetic fields B of the order of 10^{12}–10^{13} G, the discovery by Trümper *et al.*[2] of a strong pulsed 58 keV feature in 1976 and 1977 balloon observations of the spectrum of Her X-1 raised the important possibility of direct measurements of B. Trümper *et al.*[2] have argued that the feature they observed may result, as suggested earlier on theoretical grounds by Basko and Sunyaev[3], from cyclotron emission quantised in a field of ≈5.3 × 10^{12} G (uncorrected for redshift). The UCSD/MIT experiment on HEAO 1 confirmed the existence of this feature in the spectrum of Her X-1 on several occasions in 1978 (refs 4, 5).

The 1978 outburst[6,7] of 4U0115+63 led to discovery of its 3.61 s pulsations[6–8], accurate measurement of its position[9,10], and discovery of its binary nature[11], 24-d orbit[12], and 15th mag B-type optical counterpart[13], as well as the determination of X-ray spectra and pulse profiles from 0.9 to 40 keV[14,15]. Here we present details of the evidence for the 20 keV feature previously reported[16], but defer a complete discussion of the 12–180 keV spectral and temporal behaviour of the source. We caution that despite the attractiveness of the cyclotron interpretation of the feature, pending better understanding of the complex physics of radiation transfer in the magnetised, semi-relativistic atmosphere of an accreting neutron star, we cannot exclude the possibility that the observed phenomenon results from some quite different cause.

Observations

HEAO 1 pointed at 4U0115+63 (ref. 17) on 16 January 1978, when the source was near its peak brightness, for ≈3 h centred at ≈15.00 UT. Each of the two low energy detectors (LED1 and LED2) of the UCSD/MIT hard X-ray and low energy γ-ray experiment[18] had a ≈0.3 cm thick, actively shielded NaI 'phoswich' scintillation detector of area ≈100 cm² collimated to a 1.2° × 23° (FWHM) field-of-view by slat collimators with an energy resolution of ~6 keV (FWHM) at 20 keV. X-ray events in the 12–180 keV range are analysed in the 64-channel linear pulse height analyser (PHA) and transmitted event-by-event over a single telemetry channel shared among seven detectors. The mean residence time of events in the telemetry buffers determines the time resolution of about 0.05 s, binned here to 0.32 s. After elimination of Earth-blocked data and correction for electronic and telemetry dead times, each detector yielded about 6,000 s of useful data.

Fourier transforms and folds gave a best geocentric period of 3.61361 s during the observation, consistent with the SAS 3 ephemeris[12]. Figure 1 shows the data from LED2, folded modulo the pulse period and summed over the 12–66 keV interval in which we observe a significant pulsed flux. Comparison of this 'template' pulse shape with the data in individual PHA channels (Fig. 2) shows no strong variation of pulse profile with energy, but a marked reduction in pulse amplitude in the 19.3–24.8 keV band. In these circumstances it becomes possible to discuss the data in terms of a simple two-component model, in which we represent the observations as a sum of pulsed and steady fluxes. To determine the spectrum of each of these two components we fit the folded data in each PHA channel by the sum of two functions of the pulse phase—the first a constant, and the second given by the template. The smooth curves of Fig. 2 show the resulting fits. These smooth curves all have the same shape and phase alignment, which are those of the template. Only their amplitudes have been adjusted to fit the data. Because of minor differences in time and energy resolution and gain between the two detectors, we fit each independently, obtaining the spectra shown in Fig. 3.

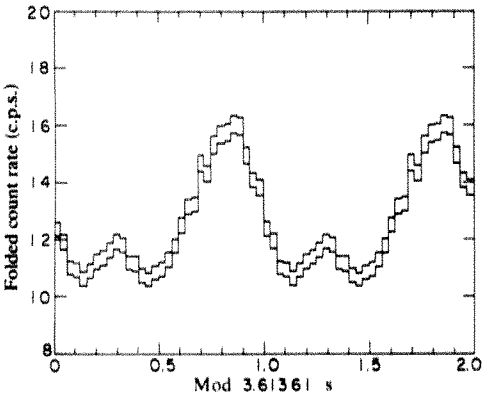

Fig. 1 Counting rates (12–66 keV) in low energy detector 2 (LED2) folded modulo the pulse period. LED1 shows a virtually identical profile. The upper and lower histograms show the data $\pm 1\sigma$, for two complete pulse periods. The data at any energy from 12 to 66 keV can be well represented by a sum of constant and a pulse of this shape. The plot includes a background count rate of 3.7 counts per second (c.p.s.). Phase 0 refers to JD 2443525.1134055.

The two lower sets of points (Fig. 3) show the pulsed spectrum in each detector, where we define the pulsed flux as the excess flux above the minimum of the fitted pulse profile, averaged over one 3.61 s cycle. Because the background is unpulsed, these spectra required no background subtraction, and their error bars reflect only counting statistics. This also allowed us to include data with the Earth's horizon in the field of view, which increases the useful exposure from the ≈3,800 s included in the total spectrum (and in our preliminary report[16]) to ≈6,000 s.

The large dip in the pulsed LED2 spectrum in PHA channels 9 and 10 corresponds to the low amplitude of pulsation noted in the 19.3–24.8 keV band of Fig. 2. The smaller dip in LED1 results partly from poorer resolution (since the feature is essentially unresolved—see below) in that detector, ≈33% (FWHM at 20 keV) as against ≈29% for LED2, and, we must conclude, partly from a statistical fluctuation. By a series of detector response calculations, detailed below, we have established that the combined probability (taking both detectors into account) that the observed feature could have arisen by a statistical fluctuation from a smooth continuum is very small ($\chi^2 = 50$ for $\nu = 7$ d.f.) but that adding a narrow absorption line to the model gives an improved χ^2 of 9.6 ($\nu = 5$) for the model of best fit. Because of the difference (in the depth the feature) between the two detectors, more complicated model photon spectra cannot be expected to improve χ^2 very much, so we accept the fit. For the model of best fit we obtained an absorption line energy $E_0 = 20.1 \pm 0.5$ keV and a line strength, expressed in terms of the equivalent width of continuum absorbed, of $\Delta E = 3.1 \pm 0.5$ keV. Independent fits to each detector separately yielded $\Delta E = 2.0 \pm 0.7$ keV for LED1 and $\Delta E = 4.1^{+1.1}_{-0.7}$ keV for LED2. Such an absorption line must have a depth exceeding 0.6 of the continuum level (95% confidence), which corresponds to a maximum actual width of about 5 keV (=3.1 keV/0.6). Systematic uncertainties, principally due to the idealised two-component analysis and to imperfections in the detector response models, may increase the absolute errors for E_0 and ΔE from the purely statistical errors quoted.

Experiments with different methods of analysis from those reported here, and with reasonable modifications of the detector response models, lead us to estimate the maximum likely increase in these errors to be less than a factor of two.

In these calculations we used response models for the two detectors based on pre-launch calibrations. We compared the expected counts for given input photon spectra with the actual data by a χ^2 test which treated the two detectors as a single experiment, summing χ^2 over the data from the five PHA channels nearest the feature in each detector. Systematic errors in the HEAO 1 attitude determination during the observation required independent normalisations for LED1 and LED2. Since we are concerned here only with the immediate vicinity of the feature, it was sufficient to use a simple form for the continuum, and we chose $dN/dE = A \exp(-E/E_\lambda)$. For the hypothesis of no feature we fitted for the continuum slope E_λ and the two normalisations, obtaining $\nu = 7$, and for the line hypothesis fits we added E_0 and ΔE, obtaining $\nu = 5$. We determined the single parameter, 1σ statistical errors in E_0 and ΔE, and the constraint on the line depth, using criteria discussed by Avni[19].

As the feature appears in the 3.61 s pulsed spectrum, it is very difficult to understand as an artefact of the instrument or analysis. It appears neither in the background nor in the unpulsed spectrum of 4U0115+63, nor in any other source spectra observed with the same instrument and analysed in the same way, whether pulsed (such as Her X-1, GX1+4, 4U0900−40 and 4U1626−67)[4,5,18] or total (Crab Nebula, Cyg X-1). We have divided the data into two halves, and the dip appears in each of them.

The two-component analysis which leads to the pulsed spectra of Fig. 3 has the important feature that, in the language of signal processing, it filters the data with the expected signal shape (the template), which yields optimal sensitivity. However, if there is a strong variation with energy of pulse profile or phasing this

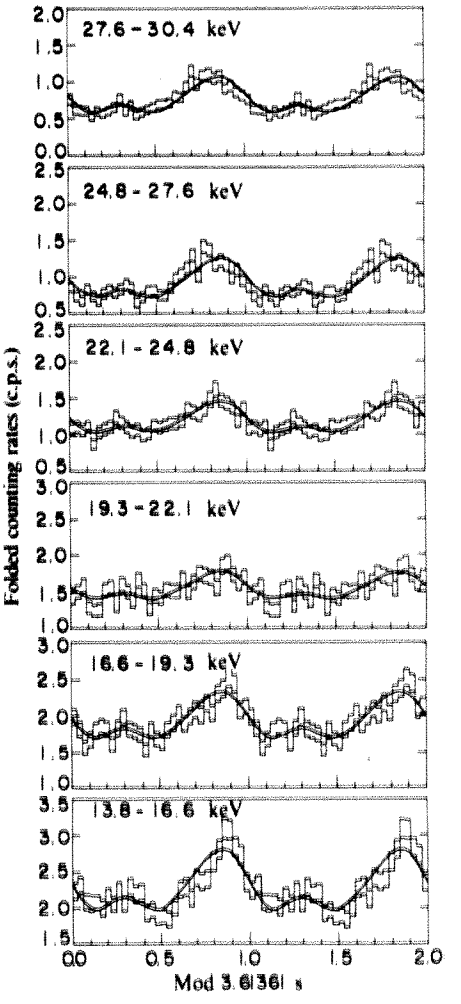

Fig. 2 Folded counting rates from LED2 in PHA channels 7–12, displayed similarly to Fig. 1, all to the same scale. The 19.3–24.8 keV channels (PHA 9 and 10) are noticeably less strongly pulsed than adjacent channels, possibly due to cyclotron resonance absorption. The continuous curves show fitted pulse profiles derived as described in the text, only smoothed for clarity by omission of all but the first three Fourier frequencies. Background rates for PHA channels 7 to 12 of 0.48, 0.37, 0.30, 0.26, 0.23 and 0.24 (c.p.s.), respectively, are included.

analysis could introduce spurious features. Data taken simultaneously by the Goddard Space Flight Center experiment on HEAO 1 show rapid changes in overall pulse shape with energy below about 10 keV (ref. 21) but examination of the data above 13 keV and the fits in Fig. 2 shows only small changes in pulse profile, which do not change the general shape or phase of the pulse, even in the channels with the dip, and do not account for the reduction in pulse amplitude there. A χ^2 test of the data in each PHA channel against the hypothesis of no pulsation gave $\chi^2 = 90$ (for 31 d.f.) in the channel with the dip, but $\chi^2 = 150$–190 at both higher and lower energies, which establishes the reality of the feature independent of any assumptions about pulse shape. Pravdo *et al.*[22] pointed out that incautious subtraction of physically different 'on-pulse' and 'off-pulse' spectra could produce an apparent absorption feature with no underlying physical significance. While one can never rigorously exclude such an explanation, the deep and narrow feature observed make it artificial in this case. We observe a pulse that varies strongly in amplitude but very little in shape as a function of energy. For such behaviour the picture of independent emission spectra with pulse phase offers no natural interpretation.

The two upper sets of data in Fig. 3 show the total (pulsed plus unpulsed) spectrum in each detector. In the analysis of these total spectra we used only data in which the Earth lay completely outside the collimator field of view in order to avoid large systematic background variations. We estimated the background from ≈4,000 s of sky exposure in each detector obtained in eight roughly equal intervals from the two orbits of scanning data adjacent to the observation; the errors shown for the total spectra include the effects of systematic variations in the background as estimated from the scatter among these eight intervals. Figure 4 shows the photon spectrum for LED2 corresponding to the total count spectrum of Fig. 3*b*, derived by dividing by detector efficiencies determined from the instrument response to the Crab Nebula. The spectrum is close to a power law with number spectral index ≈3.9 or to $\approx 10^8$ K thermal bremsstrahlung. A correction of 0.85 for the collimator transmission averaged over small aspect variations during the point was applied.

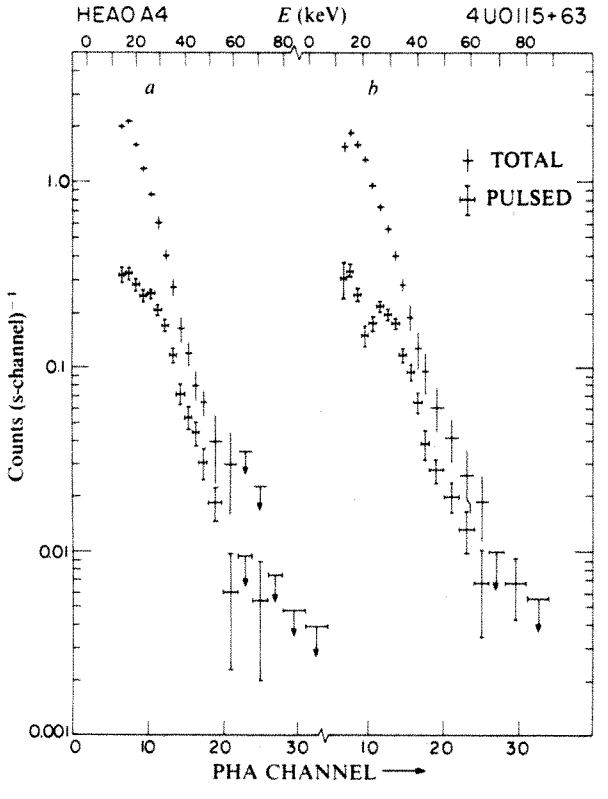

Fig. 3 Pulse height spectra of the total (upper) and pulsed (lower) counts in: *a*, LED1; and *b*, LED2. The 20 keV feature shows most clearly in LED2 in PHA channel 9. If it results from cyclotron resonance absorption, it corresponds to a surface magnetic field B of ~ 1.8–2.5×10^{12} G, (depending on the gravitational redshift), probably near the poles of the neutron star.

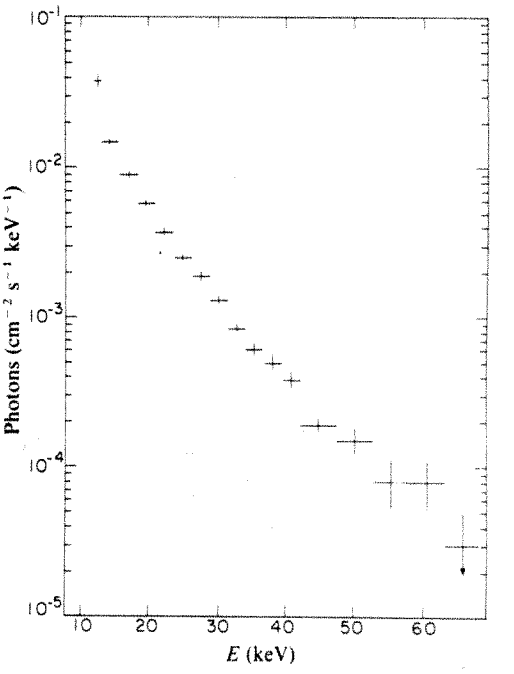

Fig. 4 Photon spectrum of the total flux (pulsed plus unpulsed), using the data from Fig. 3*b*, and based on a calibration using the Crab Nebula.

Discussion

Our results are consistent with all the other data known to us. However, the UCSD/MIT observation obtained about an order of magnitude more counts in the 20 keV range than any other instrument of comparable energy resolution. Hence no detailed confirmation of the 20 keV feature seems likely until further observations can be obtained.

Figure 3 shows that the pulse fraction, defined here as the ratio (pulsed flux)/(total flux), decreases from ≈50% at 60 keV to ≈17% at 15 keV. Johnston *et al.*[14] have found that it continues to decline to below 2.5 keV. Because the pulsed spectrum is harder than the total spectrum, the spectrum must harden near the peak of the pulse, behaviour generally similar to that seen from 0.9 to 18 keV by others[14,15]. However, the main peak observed below about 10 keV occurs at a different phase, about 0.5 instead of our 0.85.

Note that we use the term 'absorption' to include 'cyclotron resonance scattering'. The concavity of the total flux (Fig. 4) near 20 keV is sufficient to accomodate either absorption, which would entirely remove photons, or scattering, which could merely redistributate them in direction and thus pulse phase. However, as scattered photons could be beamed in directions never seen by Earth-bound observers, the two are essentially indistinguishable observationally.

The results for Her X-1 due to Trümper *et al.*[2] can be interpreted as absorption at energies below ≈42 keV as well as emission at ~58 keV. The data presented here, because of the deep and narrow feature, favour absorption/scattering as the correct interpretation for 4U0115+63 but cannot rule out an emission line explanation, in which the broad (about twice the instrument energy resolution) hump around 28 keV in the pulsed spectrum results from an emission blend seen over a steeply falling continuum. If due to cyclotron emission, our data would indicate a correspondingly higher and less uniform magnetic field. As we expect a cutoff in cyclotron emission corresponding to the maximum surface field near the magnetic

poles, the observed extension of the pulsed flux above the feature suggests an additional hard component of the continuum. No full theoretical treatment predicting the relative likelihood of cyclotron emission or absorption/scattering has yet appeared, though each has been briefly considered in the literature[3,23,24]. Dimensional estimates tend to support scattering/absorption over emission (F. Lamb, personal communication). Clear evidence for higher (or lower) harmonics could settle this question, but it does not appear in these data.

Assuming that the 20 keV feature arises near the surface of the neutron star, a gravitational redshift of ≤ 5–40% (ref. 25) gives 20–28 keV as the surface energy corresponding to a 20 keV line. If, following Trümper *et al.*[2] we interpret this as due to cyclotron absorption from the ground state ($j=0, s=-1$) to the first excited state ($j=1, s=-1$) or ($j=0, s=+1$) and assume negligible change in the electron momentum parallel to the magnetic field B, we obtain $B \approx (1.8 \text{ to } 2.5) \times 10^{12}$ G, probably near the base of the accretion column near the magnetic pole. The narrowness of the line implies it must arise in a region of fairly uniform field, since $\Delta B/B \approx \Delta E/E \leq 0.25$. Because the radial extent Δr of the absorbing region must satisfy $\Delta r/r \leq \frac{1}{3}(\Delta B/B)$ (ref. 2), if $r \approx 10$ km, then Δr must be <1 km. Since redistribution of photons in energy would tend to fill in a narrow absorption line, its width and strength limit the amount of reprocessing matter that can lie along the line of sight. Thus, this source does not seem to be observed through a cold magnetospheric shell of the type proposed for Her X-1 (refs 26, 27), as discussed in detail by Weaver[28].

As we have already constrained the height of the emission region to <1 km, any future improvements in resolution will begin to show whether it is more like the size of the accretion hot spot (≈ 1 km) or the atmospheric scale height (≈ 1 m). Thermal motions along the magnetic field line should also contribute to the linewidth. Since this effect depends on the cosine of the angle between the field and the line of sight, observation of the broadening as a function of pulse phase could eventually give both the temperature of the absorbing electrons and the geometry of the system.

We thank members of the HEAO project and the people in the HEAO Operations Control Center for their work on making the pointed observation successful. We also thank L. A. Rose and S. Pravdo for comments and for results from the GSFC experiment prior to publication, and J. Trümper, L. Cominsky, J. McClintock, B. Rossi and J. van Paradijs for helpful comments. This work was supported by NASA contracts 8-27974 and 8-27975.

Plasma acceleration at the Earth's magnetopause: evidence for reconnection

A characteristic of magnetic field reconnection is the acceleration of plasma as it flows across a rotational discontinuity. At the Earth's magnetopause this effect has only been observed recently during a few magnetopause crossings by the ISEE satellites. For one example analysed in detail the results show good agreement with theoretical predictions.

MAGNETIC reconnection or merging is thought to have a fundamental role in the conversion of energy stored in magnetic fields, and may occur in many cosmic situations. The concept of reconnection was introduced into magnetospheric physics by Dungey[1] who proposed that reconnection should be operative at the dayside boundary of the Earth's magnetic field, the magnetopause, as well as in the geomagnetic tail. A detailed description of the process was first provided by Petschek and coworkers[2,3] who demonstrated that reconnection may occur at substantial rates and that it leads to high-speed plasma jetting away from the reconnection site. Jets of plasma possibly associated with reconnection have been observed in the tail[4,5] but never at the magnetopause. This negative result has added to the controversy over the nature and efficiency of the reconnection process, despite substantial indirect evidence for its occurrence[6]. Recent measurements from the dual-satellite International Sun–Earth–Explorer Mission[7] (ISEE) have now shown the occasional presence of high-speed plasma at the magnetopause. We report here on one of these cases in which the observations agree in considerable detail with theoretical predictions.

The basic reconnection configuration for the magnetopause[3,8] is illustrated in Fig. 1. In this model, the magnetopause is a standing Alfvén wave emerging from the X-shaped centre of the

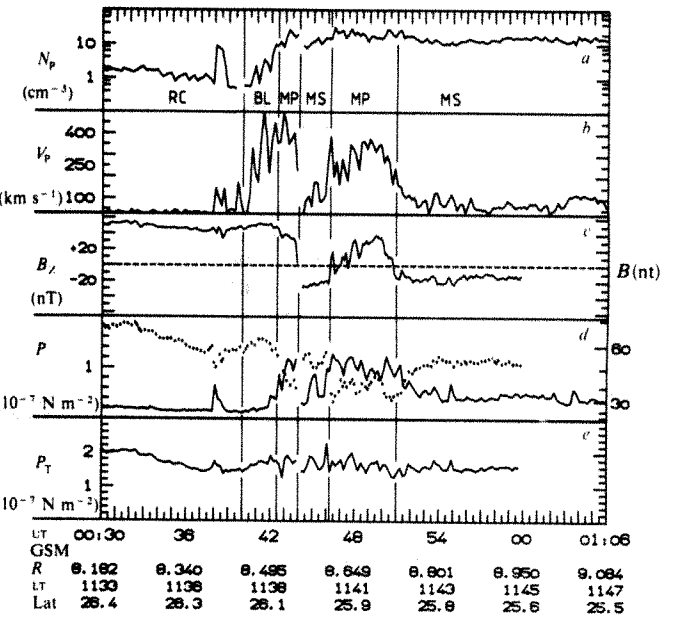
reconnection site, referred to as the diffusion region. The magnetic fields on the two sides of the magnetopause current layer, which separates the magnetosheath and terrestrial fields, are not entirely tangential to that layer, but are connected and consequently have a small normal magnetic field component B_n. The magnetosheath plasma flows towards and across the magnetopause, or equivalently, there is a tangential electric field $\mathbf{E}_t$. As the plasma crosses the current sheet, its momentum changes abruptly under the action of the tangential components of the Maxwell stresses. Picturing the sharply bent field lines at the magnetopause as elastic bands acting on the plasma, the process may be likened to a magnetic slingshot, which ejects the plasma at high speed in poleward-directed jets just inside the magnetopause. The energy added to the plasma in this manner is extracted from the electromagnetic field[9] at the rate $\mathbf{E}_t \cdot \mathbf{I}$, where $\mathbf{I}$ is the total magnetopause current.

Observations

Figure 2 shows plasma and magnetic field observations which demonstrate the behaviour described above. The plasma data were obtained with the LASL/MPE quadrispherical analysers[10], which measure the three-dimensional distribution function of ions and electrons with very good time resolution. Full distributions are obtained in three spacecraft revolutions, or



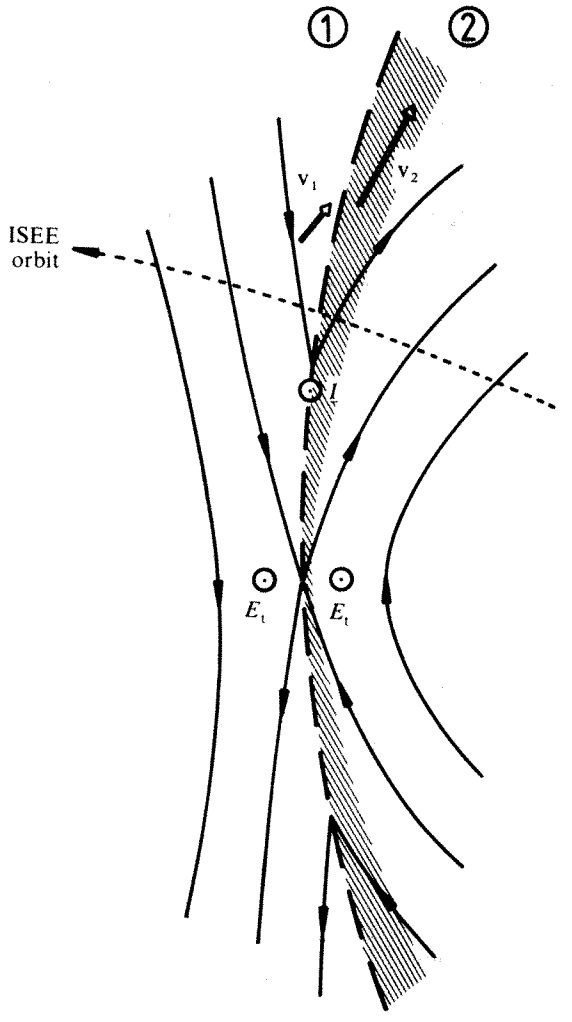


Fig. 2 Plasma and magnetic field data for the ISEE 1 magnetopause crossings on 8 September 1978. *a*, *b* and *c* show the proton density N_p, the proton flow speed v_p, and the magnetic field component B_z, perpendicular to the ecliptic. In *d* the solid line indicates the plasma pressure P, defined as $N_p k(T_p + T_e)$, where k is the Boltzmann constant and T_p and T_e are the proton and electron temperatures, respectively. The dotted line represents the magnetic field strength B, when using the scale on the right, or the magnetic field pressure $B^2/2\mu_0$ with the scale on the left. *e*, The total pressure $P + B^2/2\mu_0$. Plasma parameters are spaced 12 s apart, magnetic field quantities 8 s apart. During the 36 min shown, ISEE 1 moves from a radial distance, R, of 8.2 to 9.1 Earth radii. The local time, LT, is slightly pre-noon throughout the period, the latitude, Lat, stays near 26° (all coordinates in the geocentric solar magnetospheric, GSM, system). Initially ISEE 1 is located in the outer magnetosphere or ring current (RC) region. It then traverses a thin boundary layer (BL) of magnetosheath-like plasma. Due to boundary motions there are multiple magnetopause (MP) encounters before the satellite exits into the magnetosheath (MS). The magnetopause encounters are identified by the transitions in B_z from northward (positive) in the magnetosphere to southward in the magnetosheath.

Fig. 1 Reconnection configuration for southward-directed external magnetic field. Solid lines denote magnetic field lines. The dashed line marks the magnetopause, and the shaded area the boundary layer. Magnetosheath and magnetosphere are located to the left and right of the magnetopause, respectively. The normal magnetic field component B_n is negative at the ISEE orbit.

~9 s, and repeated every 12 s. This time resolution which is absolutely necessary in magnetopause studies, is achieved at the expense of energy/angle resolution. For ions, measurements are made over an energy range between 70 eV and 40 keV per charge in 16 channels, covering elevation angles between +55° and −55° in four segments, and 360° of azimuth in eight and four equidistant sectors for the inner and outer elevation segments, respectively. The plasma data are shown as moments of the measured distribution functions[11]. Data from the UCLA triaxial fluxgate magnetometer[12] are presented here as 12-s averages overlapped by two-thirds so that there is one sample every 4 s.

The data shown in Fig. 2 are from an outbound traversal of the subsolar magnetopause region at a latitude of ~25°. If we assume that the diffusion region of the reconnection configuration was located near the subsolar point, the measurements were made along a path indicated in Fig. 1. Magnetopause (MP) encounters are identified by the changes in field orientation (B_z panel). Due to motions of the magnetopause, the first, complete crossing is followed by another, incomplete one, before the satellite finally exits into the magnetosheath (MS).

A magnetopause speed of 10 km^{-1} s relative to the spacecraft is derived for the first crossing from the time difference between the ISEE 1 and ISEE 2 crossings, the latter spacecraft being 1,820 km further away from the Earth. Using 10 km s^{-1}, a magnetopause thickness of 900 km is deduced, which is large compared with an ion gyro radius (~100 km). Figure 2*a* shows that the plasma number density, N_p, was within a factor of 1.5 of the average magnetosheath value during the magnetopause encounters. However, earthwards of the inner edge of the first

crossing, the density dropped gradually to the low values of the outer magnetosphere. This period, denoted BL, corresponds to the low-latitude plasma boundary layer[13,22]. The density peak within the magnetosphere presumably represents an early partial entry into the boundary layer.

The plasma pressure P and the magnetic field magnitude B show substantial variations during the magnetopause crossings. However, as Fig. 2*e* shows, the total pressure $P_T = P + B^2/2\mu_0$ remained approximately constant as expected.

The most significant feature shown in Fig. 2 is the extremely large plasma flow speed, V_p, observed during each magnetopause encounter and persisting throughout most of the boundary layer. These high speeds, which were also seen by ISEE 2, peak at 450 km s^{-1}, whereas values in the adjacent magnetosheath fall in the range 50–100 km s^{-1}. The latter speeds are consistent with the prediction of gas-dynamic models for this location[14]. As already mentioned, enhanced flow speeds at the magnetopause are characteristic of reconnection.

Comparison with theoretical expectations

We now compare the observations quantitatively with the predictions of the reconnection model of the dayside magnetopause[3,8]. In this model the magnetopause is described as a rotational discontinuity—a current layer which possesses a normal magnetic field component and across which the tangential field changes direction by an arbitrary angle. For such a sheet the following relations hold[15]

$$\mathbf{v}_{t2} - \mathbf{v}_{t1} = \pm((1-\alpha_1)/\mu_0\rho_1)^{1/2}[(\rho_1/\rho_2)\mathbf{B}_{t2} - \mathbf{B}_{t1}] \quad (1)$$

$$\rho_2/\rho_1 = (1-\alpha_1)/(1-\alpha_2) \quad (2)$$

$$v_n = \pm B_n((1-\alpha)/\mu_0\rho)^{1/2} \quad (3)$$

$$\alpha \equiv (P_\parallel - P_\perp)\mu_0/B^2 \quad (4)$$

Here **B**, **v** and ρ are the magnetic field vector, plasma flow velocity and mass density, respectively, and the subscript pairs (n, t) and (1, 2) refer to components normal (n) or tangential (t) and exterior (1) or interior (2) to the magnetopause surface; $P_\parallel$ and $P_\perp$ are the pressures parallel and perpendicular to the magnetic field, respectively, and α is the pressure anisotropy factor. Equation (3) shows that the plasma flows across the sheet with the modified Alfvén speed. Thus, a rotational discontinuity is in fact a large amplitude Alfvén wave. Density changes across such a wave occur only when the anisotropy factor changes, as indicated by equation (2). Finally, equation (1), multiplied by ρv_n, expresses the balance of tangential stresses in the current sheet. The left-hand side is the rate of change of tangential momentum of the plasma as it flows across the layer while the right-hand side, using equations (2) and (3), is seen to represent the sum of the net tangential Maxwell stress $\tau_M = (B_n/\mu_0)(\mathbf{B}_{t2} - \mathbf{B}_{t1})$ and pressure anisotropy stress $-\alpha\tau_M$. Assuming $v_n < 0$ (see Fig. 1), the positive and negative signs in equations (3) and (1) refer to $B_n < 0$ and $B_n > 0$, respectively.

Equation (1) forms the basis for our test of the hypothesis that the plasma inside the magnetopause received its high velocity from the magnetic slingshot. We apply it across the first magnetopause crossing, using only data points immediately adjacent to the current sheet. The number density, although it had a substantial maximum within the sheet, had nearly identical values (~10 cm^{-3}) on the two sides. Equation (2) then indicates that α also should have been the same. For $\rho_2 = \rho_1$ equation (1) predicts that the tangential velocity difference vector should be parallel ($B_n < 0$) or antiparallel ($B_n > 0$) to the magnetic difference vector, and that its magnitude should equal the modified Alfvén speed based on the magnetic difference field. Figure 3 shows the behaviour of **v** and **B** throughout the first magnetopause crossing. The two difference vectors may be imagined as extending from points ① to points ② on the left in Fig. 3. They are seen to be nearly parallel, forming an angle of

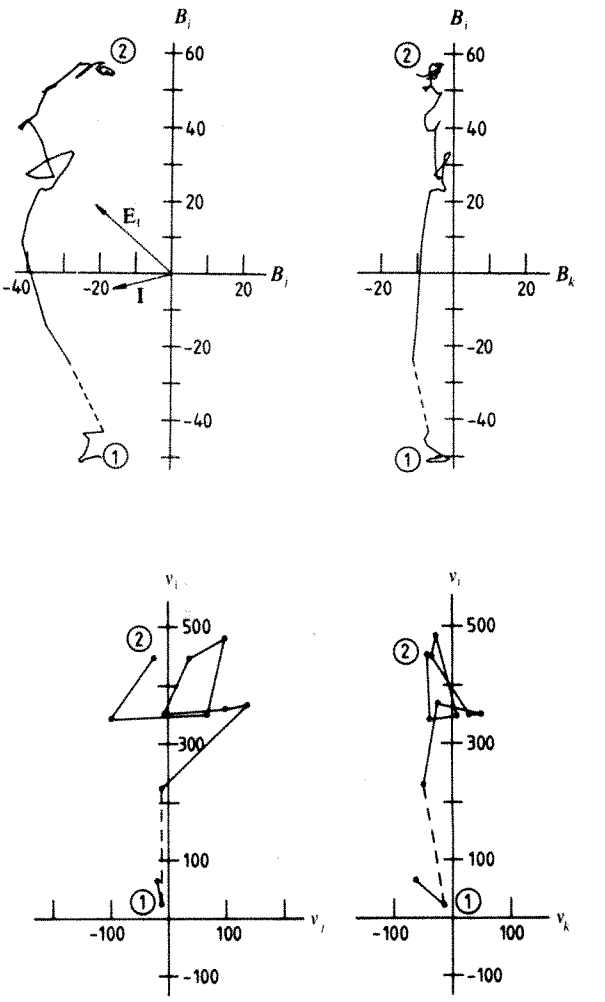

Fig. 3 Polar plots of the magnetic field **B** (nT) and plasma flow velocity **v** (km s^{-1}) for the first magnetopause crossing of Fig. 2 in the principal axes coordinate system obtained from minimum variance analysis. The k axis is in the direction of minimum variance of the magnetic field and is interpreted as the outward-directed normal to the magnetopause. The (i, j)-plane is tangential to the magnetopause, with the i and j axes approximately due north and west, respectively. Direction cosines with respect to the solar ecliptic x, y, z axes are (−0.59; −0.37; 0.72), (−0.12; −0.84; −0.53) and (0.80; −0.40; 0.45) for the i, j, k axes, respectively. The points marked 1 and 2 refer to the magnetosheath and magnetosphere sides of the magnetopause. Magnetic field and plasma data points are separated by 4 and 12 s, respectively. Data gaps are shown as dashed line segments. Also shown are vectors representing the magnetopause current **I**, and the electric field $\mathbf{E}_t$.

only 12°. Given the uncertainties associated with temporal variations and with the plasma measurements, this value is not significantly different from zero. The fact that the vectors are parallel rather than antiparallel indicates $B_n < 0$, as expected for a crossing in the Northern Hemisphere (see Fig. 1).

The magnitude of the measured tangential velocity difference is 427 km s^{-1} whereas for $\alpha = 0$, a number density of 10 cm^{-3}, and a 5% abundance of α particles in the proton plasma, the Alfvén speed based on the difference magnetic field is 580 km s^{-1}. We conclude that the difference between these two numbers is not significant. First, gain degradation of the plasma detectors may have led to a systematic underestimation of the density of up to 20% and therefore to an overestimation of the difference Alfvén speed of up to 10%. More importantly, the limited angular resolution of the measurements will lead to an uncertainty (normally an underestimate) of the flow velocity of up to 30% if the flow is inclined ~45° with respect to the ecliptic, as in the present case[11]. Finally, the presence in the magnetopause region of α particles beyond the assumed level and/or of small numbers of heavier ions of ionospheric origin may reduce the difference Alfvén speed further.

Figure 2 shows that high velocity plasma is present, not only in the boundary layer but throughout most of the magnetopause itself, both for the main crossing and for the partial ones. As the magnetopause thickness was large compared with an ion gyro radius, we may compare all of the velocity measurements with equation (1) as follows: We suppress the subscript 2 in that equation and let the corresponding quantities represent conditions at an arbitrary point. Subscript 1 will represent average magnetosheath conditions. Equation (1) then predicts a linear relationship, with slope

$$m = [(1-\alpha_1)/\mu_0\rho_1]^{1/2} \quad (5)$$

between $(\rho_1/\rho)\,\mathbf{B}_t$ and $\mathbf{v}_t$. As Fig. 3 shows, the main dynamical effect is associated with the 'i' components of these two vectors. A scatter plot of $\mathbf{v}_i$ against $(\rho_1/\rho)\,\mathbf{B}_i$ is shown in Fig. 4. Linear regression analysis of these data yields a correlation coefficient of 0.90 and a slope of 4.4 ± 0.3 (km s^{-1} nT^{-1}). On the other hand, the slope obtained from equation (5) with $\alpha_1 = 0$ and an average magnetosheath particle density ρ_1 (see Fig. 2) of 12.8 cm^{-3}, is $m = 5.6$ (km s^{-1} nT^{-1}). In view of the uncertainties discussed previously, the difference between the two slopes is not significant. We conclude that the entire set of data is compatible with the slingshot acceleration hypothesis.

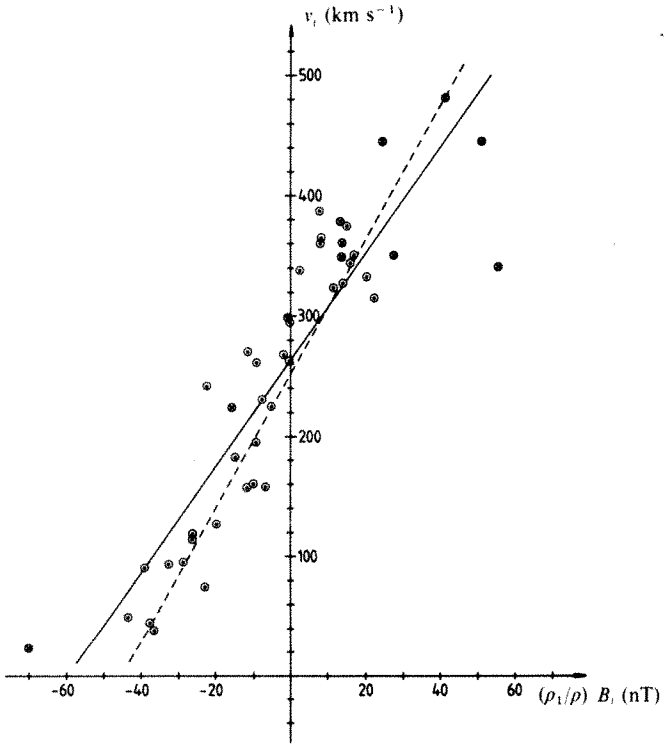

Fig. 4 Scatterplot of v_i against $(\rho_1/\rho)\,B_i$ for the magnetopause encounters of Fig. 2. ⊗, 00.42.20–00.44.20 UT interval; ⊙, 00.45.56–00.52.56 UT interval. v_i and B_i are the components of $\mathbf{v}_t$ and $\mathbf{B}_t$ along the i axis in Fig. 3. The index 1 refers to average magnetosheath conditions ($\rho_1 = 12.8$ cm^{-3}). Index-less symbols refer to measurements in the intervals above. The solid line is a fit to the data using a linear regression analysis, the dashed line marks the slope predicted by equation (5) with $\alpha_1 = 0$ and $\rho_1 = 12.8$ cm^{-3}.

As already mentioned, the slingshot acceleration process requires the presence of a magnetic field component B_n perpendicular to the magnetopause. Furthermore, the direction change of the tangential plasma velocity in the event discussed here corresponds to a negative value of B_n. To check this prediction, we have calculated the normal vector $\mathbf{n}$ and the average normal magnetic field component $\mathbf{B}_n$ directly from the magnetic data during the first crossing by the minimum variance technique[16,17]. The results depend on the precise time interval chosen, with B_n ranging from −3 to −9 nT. The normal coordinate system used in Fig 3, and the subsquent calculations of v_n and E_t are based on the results from a time segment with $B_n = (-5.4 \pm 2.9)$ nT. This value is close to the average and has the smallest absolute error. With $B_n = -5.4$ nT, an average density $N_p = 15$ cm^{-3} and $\alpha = 0$, we find (equation (1)) $v_n = -28$ km s^{-1} for the first magnetopause crossing. Because of the inward motion, at 10 km s^{-1}, of the magnetopause relative to the satellite, the predicted normal plasma velocity is −38 km s^{-1}. As shown in Fig. 3, the measured velocity component v_k is in fact negative on the average, albeit with large fluctuations. Figure 3 illustrates the difficulty of establishing the presence or absence of plasma flow across the magnetopause by direct examination of v_k.

In a time-dependent one-dimensional magnetopause, the tangential electric field $\mathbf{E}_t$, measured in the frame moving with the magnetopause, should remain constant during a crossing. This field may be obtained from the simplified Ohm's law[18]:

$$\mathbf{E}_t = -\mathbf{v}_n \times \mathbf{B}_t - \mathbf{v}_t \times \mathbf{B}_n \quad (6)$$

The largest correction term to equation (6) would be the Hall term[18]. However, for a thick layer this term contributes very little. Using the values of B_n and v_n derived previously, we find $E_t = 1.8 \pm 0.5$ mV m^{-1} during the first crossing. The electric field vector forms an angle of $56° \pm 10°$ with the total current $\mathbf{I}$, which was deduced from the jump in $\mathbf{B}_t$ (see Fig. 3). This result supports Cowley's[19] conclusion, arrived at from theoretical considerations, that the two vectors need not be parallel during reconnection.

The dissipation rate $\mathbf{E} \cdot \mathbf{I}$, with $I = 0.073$ A m^{-1}, is found to be 78 ± 24 W km^{-2}. Both the electric field and the dissipation rate are comparable to those obtained from the d.c. electric field experiment[20] on ISEE 1 for another crossing[21]. Unfortunately, that experiment was in an unfavourable mode during the present event, so that no comparison is possible.

Conclusions

Our observations provide the first evidence for the occurrence of the plasma acceleration at the magnetopause intrinsic to the reconnection process. So far two more examples of this kind have been found in the ISEE data. However, in most cases with favourable magnetic field orientation no plasma acceleration is observed. This means either that reconnection occurs rarely and in conditions which are not yet understood, or that the process is small-scale and non-stationary, and therefore has a low probability of being observed locally.

Rare earth element mobility associated with uranium mineralisation

Scott M. McLennan & S. R. Taylor

Research School of Earth Sciences, The Australian National University, Canberra A.C.T. 2600, Australia

Extreme rare earth element mobility has been discovered, associated with uranium mineralisation in metasedimentary rocks of the Lower Proterozoic Pine Creek Geosyncline, Australia. The rare earth element patterns and other geochemical evidence point to movement of the rare earth elements and uranium by carbonate complexes in a low temperature, oxidising and alkaline solution.

MOBILITY of rare earth elements (REEs) in rocks is of interest as these elements are often used as petrogenetic indicators. The REEs seem to be immobile in most metamorphic conditions[1-3]. Some light rare earth element (LREE, La–Sm) mobility has been detected during hydrothermal alteration (submarine weathering), spilitisation and lower greenschist metamorphism associated with hydrothermal activity[4-6]. Collerson and Fryer[7] suggested heavy rare earth element (HREE, Gd–Lu) mobility due to carbonate complexing associated with granulite metamorphism and granite production in Archean terrains. Several studies have related HREE mobility to complexing (mainly carbonate complexing) in hydrothermal conditions[8-13]. The present study examines the relationship between REE and uranium mineralisation in the Cahill Formation[14] of the Pine Creek Geosyncline, Northern Territory, Australia.

Geological setting

The following summary of the geology and geochemistry of the Pine Creek Geosyncline is based on information given at the International Uranium Symposium on the Pine Creek Geosyncline, Sydney, 3–8 June, 1979.

The Pine Creek Geosyncline (Fig. 1) comprises up to 14 km of mainly Lower Proterozoic metasedimentary rocks (clastics and carbonates)[15]. These rocks were deposited between age limits of 2,400 and 1,870 Myr (ref. 16).

Most of the important uranium deposits in the eastern part of the Pine Greek Geosyncline are contained within the Cahill Formation (Fig. 1). This unit consists primarily of quartzo-feldspathic and micaceous metasedimentary rocks. A lower member (which contains most uranium-deposits) contains abundant carbonate and carbonaceous metasedimentary rocks[15]. The exact age of the Cahill Formation is in some doubt. Most workers[14,15,17] suggest it is of Lower Proterozoic age. Consideration of metamorphic assemblages[18], however, indicates that these rocks may have been buried deeper than can be explained by the known Lower Proterozoic sedimentary thickness and that an age as old as Archean cannot be excluded.

Uranium mineralisation, for the most part, is strata-bound and occurs in breccia matrix and vugs. In most samples, chlorite is ubiquitous, primarily as an alteration product[19]. The favoured model is that uranium deposition occurred from a low temperature fluid within collapse structures (caves, cavities) of an impure carbonate stratum which has undergone extensive solution and development of karst terrain[20]. Alternative models have been described by Binns *et al.*[21] and Crick and Muir[22]. Ore deposition probably occurred between about 1,800 and 1,700 Myr (refs 20, 23).

Most samples analysed in this study probably represent the insoluble residue (plus alteration products, ore minerals and so on) after carbonate had been removed. Samples include fine-grained metasedimentary schists with a wide range of uranium concentrations (1.4–48,230 p.p.m.). The least altered sample (PCG132) is a muscovite–biotite–quartz schist (SiO_2 = 77.44%). Modal mineralogy of the altered samples is rather variable although chlorite (primarily as an alteration product) and quartz are always dominant. Muscovite, graphite and haematite are also occasionally present, in most samples. One sample of massive, impure uraninite (uraninite + fourmarierite + secondary U and Pb minerals) was also analysed.

REE, Th and U data

Four samples were analysed for REE (excluding Pr + Ho) by an ion-exchange/X-ray fluorescence technique and the remainder by spark source mass spectrometry. Details of techniques have been reported previously[24,25]. Uranium and thorium concentrations on samples PCG52, PCG57 and PCG148 and U concentration on sample 75080180 were made available by John Ferguson of the Bureau of Mineral Resources, Canberra, Australia. Results of REE, U and Th analyses are given in Table 1.

As most of these rocks were originally sedimentary, it is convenient to compare REE data to typical sedimentary rocks. Figures 2 and 3 plot the REE data normalised to Post-Archean Average Australian Sedimentary rock (PAAS)[26].

Sample PCG132 has a U concentration (1.4 p.p.m.) and Th/U ratio (4.7) well within the range of typical sedimentary rocks and may be considered a normal, unmineralised sample. The REE pattern of this sample (Fig. 2) is nearly parallel to PAAS, although lower in total abundances by a factor of about 0.5–0.7. Minor HREE depletion is apparent and there is no anomalous Eu behaviour relative to PAAS. The normal distribution of REE in clastic sedimentary rocks is extremely uniform and similar to PAAS[26]. It is therefore likely that PCG132 is fairly typical of unaltered samples in the Cahill Formation.

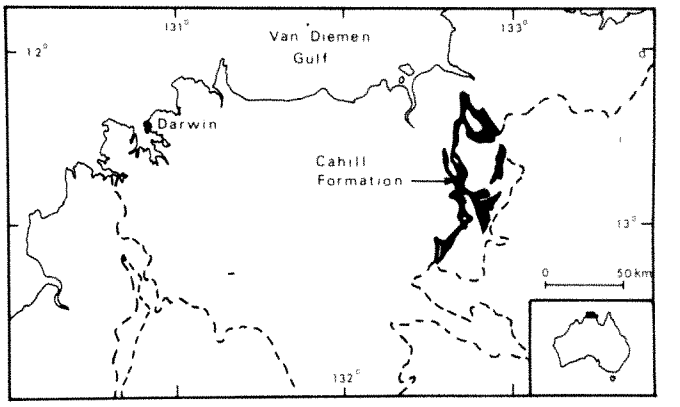

Fig. 1 Location map of the Pine Creek Geosyncline, N.T., Australia. The approximate limits of the geosyncline are marked by dashed lines and the Cahill Formation is shown in black.

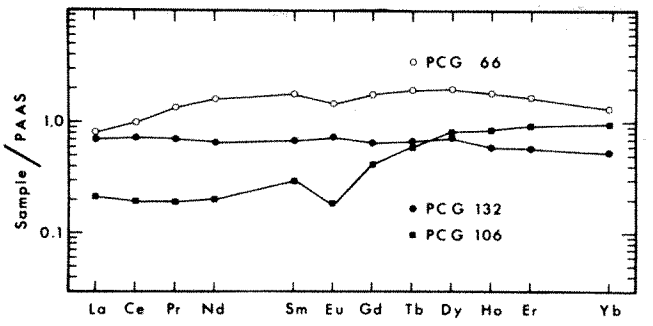

Fig. 2 REE patterns, normalised to post-Archean average Australian shales (PAAS)[26,36], for samples with low and intermediate U content.

Samples with intermediate U content (PCG66, PCG106) show REE patterns (Fig. 2) which differ substantially from PAAS but there is no consistent trend. PCG106 is notable for LREE depletion and a negative Eu anomaly. Samples enriched in U(PCG57, PCG148, PCG52, 75080180) show consistent REE trends (Fig. 3). They are depleted in LREE and enriched in HREE. These samples show a PAAS-normalised maximum in the vicinity of Tb–Dy.

The impure uraninite sample (75080260) has a REE pattern which parallels the U-rich samples (Fig. 3). Uraninite alone, however, cannot account for the REE concentrations of the other samples. Mixing calculations between PCG132 and 75080260 result in about an order of magnitude excess in total REE (ΣREE) for most samples with U concentrations comparable to those resulting from the mixing proportions. Also, LREE depletion cannot be achieved by such mixing.

For all metasedimentary rock samples, there is an inverse correlation between U content and La:Yb ratio (Fig. 4). Samples with U ≥ 1,900 p.p.m. show a correlation between U content and ΣREE (see Fig. 3). Another interesting feature of these rocks is the complete lack of coherence between U and Th, as indicated by the strong inverse correlation between U content and Th:U ratio (Fig. 5). This is in strong contrast to the general behaviour of Th and U in most igneous and sedimentary rocks[27].

The remarkable correlation between REE and U content, in these samples, has not been previously observed. The REE patterns in the U-rich samples (Fig. 3) are unlike any terrestrial[3] or extraterrestrial[28] rock. Common rock forming minerals such as garnet and zircon do display HREE enrichment[3], but they are not present in significant proportions and could not explain these REE patterns. No REE minerals have been identified in these samples which could explain such patterns and it is possible that much of the REE content was associated with the original clay minerals and alteration products (now chlorite, biotite, muscovite, and so on). Significant adsorption of REE on clay minerals has been documented for Quaternary clays of Norway[29].

REE mobility

The above observations indicate that massive REE mobility related to U movement, resulting in depletion of LREE and enrichment of HREE, occurs relative to the parent rock. The

§ PAAS—Post-Archean average Australian sedimentary rock; values from Nance and Taylor[26].

LREE depletion shows that REE were leached from the sedimentary rocks themselves. The HREE were selectively deposited with the U or selectively incorporated into the ore depositing solution. A HREE-depleted parent lithology has not been identified but slight HREE depletion was apparent in PCG132, the supposedly unaffected sample. If large volumes of parent rock were involved, a notable HREE depletion may not occur.

The nature of the solution which carried the REE and U can be determined from several lines of evidence. The lack of Th–U coherence (Fig. 5) strongly suggests that U was primarily transported in solution as U^{6+}. Complexes of uranous ions with chlorides, sulphates, phosphates or fluorides are thus unlikely transporting mechanisms[27,30]. Transport of U as uranyl ions (UO_2^{2+}), carbonate complexes, uranyl fluoride complexes or uranyl phosphate complexes are all possible[30]. Although several secondary uranium sulphate and uranium phosphate minerals have been reported from this area, lack of correlation between U and S, F or P^{32} suggests that sulphate, fluoride and phosphate complexes were unimportant.

REE mobility, under hydrothermal conditions, is also best accomplished by soluble complexes. The most common forms of complexing are sulphate, fluoride and carbonate[8]. Sulphate complexing generally results in major hydrothermal sulphate deposits[8]. Pseudomorphs after sulphate minerals have been recognised in this region but are thought to be of evaporitic origin[22]. The lack of correlation between REE (La, Ce, Y) and F or S^{32} indicates that these complexes were probably unimportant.

It seems most likely that U and REE were transported together in a hydrothermal fluid as soluble carbonate complexes. Typical forms would be $[UO_2(CO_3)_3]^{4-}$ and $[REE(CO_3)_3]^{3-}$. Transport of U as simple uranyl ions may also have occurred but is not considered important since this species only predominates at relatively low *p*H[30]. The shape of the REE patterns for the U-rich samples is easily explained by such a mechanism since complexes of the HREE tend to be more soluble than LREE[8].

Strong supporting evidence for this mechanism is available from fluid inclusion studies[33]. Inclusions in quartz, thought to be associated with the main stage of U-mineralisation (Type II inclusions of Ypma and Fuzikawa[33]) contain CO_2 as a major phase (along with H_2O and CH_4). The temperatures of such fluids are difficult to determine but very low (meteoric?) values have been suggested[20]. REE and U carbonate complexes of the type suggested here would be best formed under alkaline ($pH \geq 7.5$) and oxidising ($E_H \geq 0.2$ V) conditions with temperatures below about 100 °C (refs 8, 30).

The conditions in which deposition occurred are more speculative. Lowering of *p*H, E_H and carbonate activity are all efficient mechanisms[8]. The activity of CO_2 would be effectively

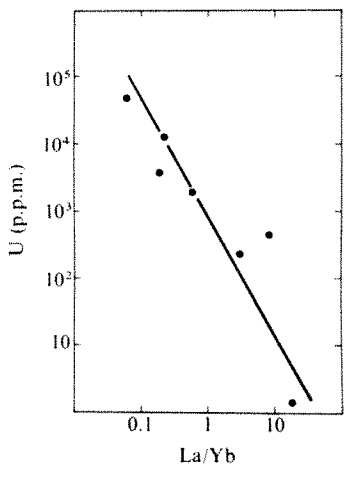

Fig. 4 Plot of U content against La/Yb for whole rock samples.

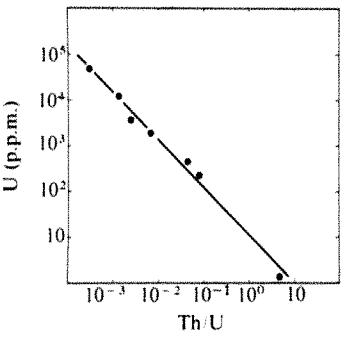

Fig. 5 Plot of U content against Th/U for whole rock samples.

decreased by the lowering of total pressure on entrance of the ore-bearing solutions into cavities[8]. Such a mechanism would be in accordance with the karst environment suggested for these ores[18,19].

Most other studies which have appealed to carbonate complexes for mobilisation of REE have dealt with HREE depletion[7,13]. These studies, however considered fairly high temperature regimes. In a study of the Precambrian Sokoman iron-formation, Fryer[12] suggested REE mobility by carbonate complexes during diagenesis to explain HREE enrichment. It seems that HREE are preferentially retained in hydrothermal solutions and only removed in late stage and/or low temperature deposits. This is consistent with present understanding of chemistry of REE carbonate complexes[8,9].

A final point which deserves comment is the behaviour of Eu in these rocks. If soluble carbonate complexes are controlling REE distribution in these rocks, the Eu^{2+} would be expected to behave very differently than REE^{3+}. This should result in anomalous Eu behaviour with increasing U-content; this clearly does not occur (Fig. 3). It seems unlikely that a second major complexing agent was present (such as halogens and phosphates) allowing transport of Eu^{2+} (see above discussion). Equally unlikely is the possibility that Eu^{2+} was oxidised to Eu^{3+} by the ore-forming fluid since other evidence[20] suggests that the fluid varied only from moderately reducing to moderately oxidising. An intriguing possibility is that the source material contained only Eu^{3+}. If the source were sedimentary it may indicate that Eu^{2+} can be oxidised to Eu^{3+} during sedimentary processes and still preserve a memory of Eu-anomalies inherited from the igneous precursors[26,34–36].

These results have important implications for a wide range of geochemical problems. It is now quite clear that the REEs can be transported as soluble carbonate complexes in fluid phases. REE studies on rocks which have been significantly affected by fluid migration and alteration must take this factor into account.

We thank J. Ferguson for samples and several U and Th analyses, Brian J. Fryer for four REE analyses and P. E. Oswald-Sealy, J. M. G. Shelley, H. N. C. Cutten and W. Sinclair for technical assistance.

Vesicularity and CO_2 in mid-ocean ridge basalt

James G. Moore
US Geological Survey, Menlo Park, California 94025

Vesicles and included CO_2 are enriched in deep-sea basalts that are also enriched in light rare earth and incompatible elements. This enrichment probably results from a unique deep mantle origin of such melts but may have been modified by CO_2 bubbles rising in shallow magma chambers.

THE primary control on the vesicularity of subaqueously erupted basalt is the depth (and hydrostatic pressure) of eruption[1,2]. Shallower eruption produces more (and larger) vesicles not only because exsolved volatiles expand with lower pressure, but also because exsolution of volatiles dissolved in the melt is more complete. However, basalt composition also affects the vesicularity of submarine basalt. Alkalic basalt seems to be more vesicular (at the same depth) than tholeiitic basalt[3], although fresh submarine alkalic basalt sample suites are rare and data limited. Fresh tholeiitic basalt from the same general area on a mid-ocean ridge such as the Mid-Atlantic Ridge at 37 °N shows a variation in vesicularity that can be related to major element variations, such as K_2O (ref. 4).

In addition to these vesicularity controls, important variations have been noted between tholeiitic basalts from different mid-ocean ridges which seem to be independent of depth or major element chemistry[5]. These variations are of such magnitude that individual suites from mid-ocean ridges can be characterised by their vesicularity.

Analyses of the gas contained in vesicles from four localities on spreading ridges indicates that >95% of the remaining gas is CO_2 (ref. 6). Hence the vesicularity of submarine basalts (except for those that are shallower than about 1 km) is a measure of the CO_2 content of the lava (other than that dissolved in the glass).

In this study, vesicularity has been determined by point counting standard thin sections of the outermost 1–1.5 cm of pillows and slabs, most of which include at least some sideromelane glass. More than 1,000 points were counted, and the vesicularity is reported in volume per cent of vesicles in glass (or microcrystalline material) excluding phenocrysts and microphenocrysts. More than 200 samples have been analysed from 13 ridge segments in the Atlantic and Pacific oceans (Table 1).

Results

The measurements of the volume per cent vesicles at any locality vary widely, particularly in rocks with a low vesicle content, but show a rough log-normal distribution (Fig. 1). For lava suites with ~10% vesicles, the variation is about one-half order of magnitude, but for suites of low vesicularity, the variation is as much as 1.5 orders (Fig. 1). This is partly a measurement problem, as only one point out of 1,000 would fall on a vesicle for a rock giving 0.1% vesicles. In practice, counting was continued on the very vesicle-poor rocks until at least one point fell on a vesicle. Because of the log-normal distribution, the logarithmic mean is used as a measure of the vesicularity of a given suite (Table 1). Among lavas collected (and presumably erupted) at about the same depth, the logarithmic mean vesicularity between sample suites varies by an order of magnitude (Figs 1, 2 and Table 1). The extremes in the variation are clearly real and not a result of measurement problems (compare Figs 1 and 2).

The effect of depth of eruption on vesicularity can be partly evaluated by comparing the vesicularity averages with the trend line established independently from samples collected at known depth on the east rift zone of Kilauea volcano and the south rift zone of Mauna Loa volcano, Hawaii. Thirty-five samples were analysed from 16 dredge hauls through a depth range of 490–5,190 m. The least-squares fit of the data on a log plot is shown in Fig. 2. The straight line on the log plot is defined by $\log V = 6.25 - 1.88 \log D$ where V is the volume per cent vesicles and D is the depth in metres. Hence V is very nearly proportional to D^{-2}. Such a relationship is consistent with the increase of V towards shallower depth resulting from both the Boyle's law increase in vesicle size (due to reduction of pressure) and

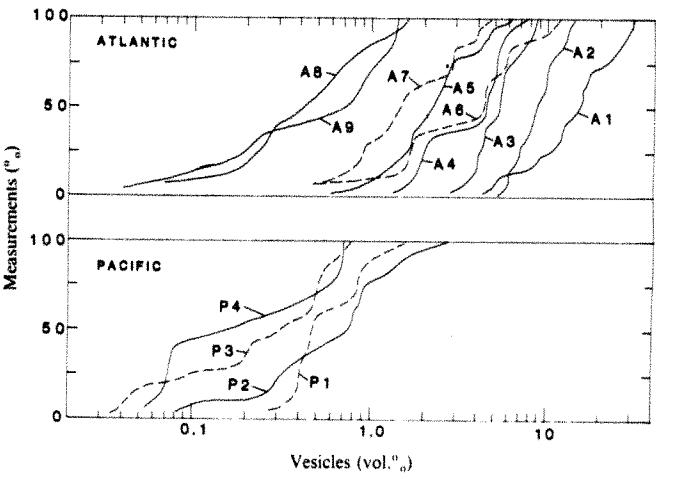

Fig. 1 Cumulative curves of volume per cent vesicles for the outermost 1–1.5 cm of basalt lava flows from 13 ocean ridge segments (see Table 1).

© 1979 Macmillan Journals Ltd.

exsolution of an additional gas phase whose mass is proportional to the reduction in pressure[6]. Therefore, the logarithmic mean vesicularity of sample suites has been projected to a common depth of 3 km parallel to a line with a slope of $V = 1/D^2$ (Table 1, Fig. 2).

The logarithmic mean vesicularity at 3 km ranges from 0.17 to 2.9%, and the Atlantic suites are consistently higher (>0.55%) than those of the Pacific. The adjusted average vesicularity for the Reykjanes Ridge suites (A1, A2, A3) is least reliable because they are shallow and have been extrapolated through the greatest depth range.

The presence of the high-vesicle suites in the Atlantic suggests that they may be favoured by the slower spreading which prevails in the Atlantic. A plot of vesicularity adjusted to 3 km relative to spreading rate (Fig. 3) indicates a rough inverse correlation. Pacific suites range from 0.17 to 0.51% vesicularity and 3 to 8 cm yr^{-1} half spreading rate. Atlantic suites range from 0.56 to 2.9% vesicularity and all spread at about 1 cm yr^{-1}.

Schilling[7] has noted that spreading ridge basalts enriched in the volatile elements Cl, F and Br are also enriched in other incompatible elements, the light rare earth elements (LREE), and show high $^{87}Sr/^{86}Sr$ ratios. The chrondrite normalised ratio La/Sm, which is a measure of LREE enrichment, has been previously determined in rocks from 11 of the 13 segments (see references of Table 1). Samples analysed for rare earth elements are partly the same samples analysed for vesicles, and partly samples which were obtained from localities close to those analysed for vesicles. The LREE enrichment factor (La/Sm)EF shows a moderately good correlation with adjusted vesicularity (Fig. 3). The so-called 'normal ridge basalts' with (La/Sm)EF of about 0.6 show log-mean vesicularities adjusted to 3 km depth <0.7%, and areas enriched in the halogens with higher (La/Sm)EF range in vesicularity up to 2.9% (Fig. 3).

The variation in adjusted vesicularity can be regarded as a measure of the CO_2 content of the rock in excess of saturation as CO_2 is the predominant gas in vesicles. The vesicle CO_2 in the rocks ranges from about 70 p.p.m. for the Galapagos samples (P3) to 1,200 p.p.m. for samples collected from 45° N on the Mid-Atlantic Ridge (A4) assuming a rigid temperature of the basalt glass of 1,000 °C.

The size of the vesicles ranges widely in a single thin section, but vesicles in the matrix glass (excluding glass inclusions in phenocrysts) show a distinct minimum diameter of 3–4 μm. This minimum diameter may be controlled by the surface tension of the melt. The logarithmic median diameter decreases with depth. It is 40–45 μm at 2.5 km depth and 20–25 μm at 5 km depth, but even at this depth, some vesicles attain 100–200 μm in diameter. Hence, a small population of small vesicles must exist in the upper part of magma chambers a few kilometres beneath oceanic spreading ridges.

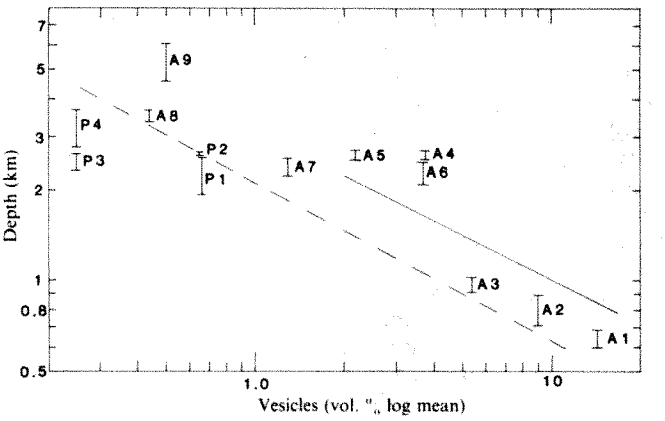

Fig. 2 Logarithmic mean vesicularity relative to depth range for 13 suites of mid-ocean ridge basalt samples. Dashed line is least-squares logarithmic trend line for Hawaiian rift zone samples. All sample suites have been projected parallel to solid line to estimate mean vesicularity at 3 km depth (see Table 1).

Vesicularity controls

The control of the vesicularity of submarine lava is complex because of the transient nature of gas bubbles in melt and the many processes that can operate to enrich, remove, or disperse vesicles. Bubbles tend to rise and concentrate or escape more rapidly than heavy phenocrysts of the same size which would sink because of their greater density contrast with the melt. The processes that control vesicularity may be divided into three general groups depending on their location: (1) during and after eruption on the ocean floor, (2) within magma chambers before

eruption and within feeding dykes during eruption, and (3) within the source region where magma is generated.

(1) During eruption, the rapid quenching and solidification of pillow basalts on the sea floor is believed to inhibit both the loss of volatiles by bubbles escaping from the lava and the interaction of lava with ocean water. However, recent discoveries on the Galapagos spreading ridge[18] reveal large fluid, non-pillowed lava flows which commonly pond in depressions. Chimneys around the margins of these flows suggest that water trapped beneath was heated and jetted up through the flow, possibly adding to the water content and vesicularity of the flow.

Collapse (or uplift) of the axial zone of a spreading ridge may have occurred after eruption. Such tectonic movements would invalidate the assumption that the depth of collection of submarine lava is the same as the depth of eruption. Collapse of the sea floor from a depth of 2.5 km down to 3.5 km, which is possible on a slow-spreading ridge with a kilometre-deep rift valley, could bring lavas with a vesicularity of 0.9% down to a region where a vesicularity of 0.45% would be reasonably expected.

(2) Since vesicles are ubiquitous in submarine lavas and volatile-rich inclusions are common in phenocrysts, the melts in magma chambers are close to volatile saturation, and some small bubbles are probably present at least in the upper part of shallow magma chambers. If the chamber is non-convecting, such bubbles will tend to rise and collect near the ceiling. If the ceiling is wide and relatively flat, they will be distributed over a wide zone, and most will be incorporated in the solidifying roof rocks marginal to the central region tapped by erupting dykes. If the ceiling is narrow and peaked, then bubbles may accumulate and become enriched in the central apex tapped by dykes.

Other factors might control the distribution of volatiles within the chamber. Processes of liquid diffusion may concentrate volatile components near the cooler ceiling and walls of the chamber or near the ceiling where lower pressure conditions prevail. The content of volatile components in the melt can be enhanced by the digestion and assimilation of hydrothermally altered rocks at the top or upper margins of the chamber and by the crystallisation of early-formed minerals.

The length of feeding dykes, that is, the depth of the magma chamber beneath the ocean floor, will affect the vesicularity of erupted basalt because of the rapid pressure change on eruption. If the volatile content is the same in the upper part of different magma chambers, then lava erupted from a deeper chamber through longer dykes would be more vesicular than that erupted from a shallower chamber, because the greater pressure drop would enhance the growth of existing bubbles and cause exsolution of new bubbles.

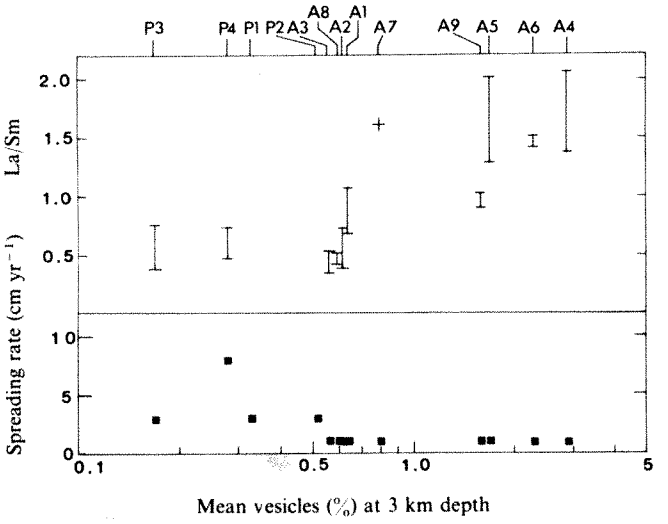

Fig. 3 Logarithmic mean vesicularity adjusted to 3 km depth relative to spreading rate and chrondrite normalised La/Sm ratio for 13 suites of mid-ocean ridge basalt.

(3) The vesicularity of the melt erupted from a magma chamber may be established by differences in the volatile content of magma fed into the bottom of the chamber from the mantle possibly induced by heterogeneities within the mantle, by the mixing of melts from different sources, or by the style of melting.

Discussion

The possibility of lava flows interacting with seawater, thereby increasing vesicularity during eruption and flow on the ocean floor, is believed to be minor because of the general low water content of submarine basalt, which when compared with experimental studies suggests that the melts are undersaturated with water[3]. Moreover, analyses of ridge basalt from four of the regions included in this study (A2, A5, A9, P2) indicate that the predominant vesicle gas is CO_2, not H_2O. Locally, however, water may be added to basalt melt by the chimney activity described by Ballard[18].

The mechanism of collapse of the ocean floor after eruption of the analysed lava cannot be eliminated and indeed tends to increase the vesicularity in the rifted valleys of slow-spreading ridges. However, the anomolously high vesicularity of some of the sample suites cannot be explained by this process unless collapse amounted to 1,400 m (for suites A8 and A4). Furthermore, there is no evidence in the lavas from suite A5 that lavas of different age show a significant difference in vesicularity.

The higher vesicularity of Atlantic spreading ridge basalt suites compared with those from the Pacific (Fig. 3) suggests that some feature of the shallow storage chambers feeding eruptions may control the vesicularity of erupted lava. Pacific spreading ridges generally spread faster (Fig. 3) and consequently the magma chambers are presumably larger and shallower[19,20]. The larger chambers are more likely to contain convecting magma which will inhibit the rise of vesicles and collection near the top. Furthermore, the shallower character of fast-spreading chambers would cause them to be tapped by shorter dykes[20] subjecting the melt to a smaller pressure drop (as compared with the deeper slow-spreading chambers) thus producing less vesicular erupted lava assuming that the tapped melt had the same volatile content. Finally, the narrow and more peaked aspect of slow-spreading chambers may tend to concentrate rising volatiles towards the top centre of the chamber where they will be tapped by dykes and erupted as more vesicular lava on the ocean floor. In the broader flat-topped chambers of fast-spreading ridges, volatiles will be concentrated over a broader zone of the ceiling, where a higher proportion will be incorporated in the solidifying roof rocks marginal to the fluid central zone tapped by erupting dykes.

Such an explanation cannot account for differences in the vesicularity of Atlantic suites, all of which occur where spreading rates are low and close to a half rate of 1 cm yr^{-1}. However, Cann[20] has suggested that because spreading rates of much less than 1 cm yr^{-1} have not been found, this may mark a lower limit of spreading, where the magma chamber is very narrow[19] and perhaps discontinuous along strike and through time. In such chambers, volatile concentrations of erupted lava may be especially enriched in favourable places by the processes discussed.

The vesicularity contrasts may also be caused by differences in the composition of magma fed into magma chambers from the mantle. Schilling and coworkers[7,8] have amassed data showing that significant concentrations of trace elements occur in ocean ridge basalts from certain areas where magmas are apparently derived from deep mantle plumes. Such plume-derived lavas are enriched in the halogens, LREE, $^{87}Sr/^{86}Sr$, and other incompatible elements of varying volatility, including K, Ba, Rb and Cs. In the Atlantic, such plume areas include Iceland (A1) and the Azores region (A4, A5, A6, A7), which this study demonstrates are also enriched in vesicles and CO_2. Hence the plume areas may represent sites of upwelling of partial melt from a deep mantle source relatively undepleted in volatiles, and other incompatible, large ion elements. In contrast, the basalts of

so-called normal ridge segments such as A8 and the Pacific suites that were sampled are derived from a shallower mantle zone previously depleted in these constituents.

CO_2 is the primary discrete volatile phase in melts erupted on the ocean floor and no doubt exists also as a discrete phase as bubbles in subjacent magma chambers, where it is commonly entrapped in phenocryst minerals. Hence spreading ridge magma chambers which may exist for millions of years will be subjected to a constant flux of upward-streaming CO_2. The extent to which this CO_2 is concentrated in favourable places and is able to concentrate other trace elements and affect isotopic ratios is poorly known. Much of the evidence suggests that the unique chemistry of plume-type basalt is derived from a different, deeper mantle source. But the high CO_2 content of these basalts indicates that their composition may have been substantially altered by the CO_2 flux.

It is clear from Fig. 2 that high-vesicle lavas have a much better potential for building islands than do low-vesicle lavas. If we contrast extreme areas with an adjusted average vesicularity at 3 km of 2% with one of 0.30%, then projecting parallel to the Kilauea curve, these values increase at 2 km depth to 4.4 and 0.65%, and at 1 km depth to 17 and 2.5%. If the same amount of melt was erupted from each centre, the high-vesicle lava would build up more rapidly and its rate of buildup would accelerate more rapidly. Hence the presence of islands such as the Azores and Iceland near regions of high-volatile lavas may partly result from this process.

Biomass burning as a source of atmospheric gases CO, H_2, N_2O, NO, CH_3Cl and COS

Paul J. Crutzen, Leroy E. Heidt, Joseph P. Krasnec, Walter H. Pollock & Wolfgang Seiler*

National Center for Atmospheric Research, PO Box 3000, Boulder, Colorado 80307

Biomass burning can contribute extensively to the budgets of several gases which are important in atmospheric chemistry. In several cases the emission is comparable to the technological source. Most burning takes place in the tropics in the dry season and is caused by man's activities.

THE potential importance of deforestation and biomass burning for the atmospheric CO_2 cycle has received much attention and caused some controversy[1–3]. In this article we will show the probable importance of biomass burning as a trace gas source, which is caused by man's activities in the tropics. We used the results of our global biomass burning analysis[4] to derive some rough estimates of the sources of the important atmospheric trace gases CO, H_2, CH_4, N_2O, NO_x (NO and NO_2), COS and CH_3Cl from the worldwide burning of biomass. Table 1 shows the results of our study for different activities and ecosystems.

Our approach has been to relate the emission quantities of these gases to those of CO_2 in fire plumes. We have determined such emission ratios during two major forest fires. The first was from a forest fire ~12.5 km south-west of Meeker, Colorado. The crown fire was fuelled by pinon and juniper timber, but most of the material burned consisted of annual and perennial grasses, shrub juniper, and sagebrush in the undergrowth. The dense plume rose to a height of ~4 km before flattening and moving horizontally. Samples were collected in stainless steel containers during flights through the smoke plume at different altitudes. Background samples were also collected, at plume altitude, 6 km before reaching the sampling area and again when leaving the fire area.

The second fire occurred in the Wild Basin area of the Rocky Mountain National Forest, not far from the Meeker site, in a mature spruce and fir forest in which there was much dead woody material on the ground and much less green vegetation than in the Meeker fire. In this case samples were taken on ground level. CO_2, CO, CH_4, H_2, COS and CH_3Cl were analysed by gas chromatography; N_2O was determined by mass spectrometry. To check for nonlinear gas-chromatographic responses at high concentrations in the samples, a volumetric measurement of CO_2 was also performed.

Some information on emissions from wood burning can also be derived from earlier field and laboratory experiments[5–9]. the emission ratios are shown in Table 2 which includes only collections with CO_2 concentrations at least 10% above background. At this stage we have not been able to measure gaseous emissions in tropical ecosystems. This is clearly a disadvantage, but it should not invalidate our main conclusions. Biomass burning has previously been considered unimportant as a global source of atmospheric trace gases[10]— our analysis shows that this is not the case.

Importance of trace gases in the atmosphere

Some of the trace gases such as CO_2, N_2O and CH_4 considered in this study contribute to the atmospheric greenhouse effect by their absorption of terrestrial thermal radiation[11].

Other trace gases such as carbon monoxide (CO) strongly affect the tropospheric concentrations of the highly reactive

hydroxyl (OH) radical through the reaction

$$CO + OH \rightarrow CO_2 + H \quad (1)$$

It has, therefore, been proposed that a growth in tropospheric CO from industrial activities would lead to a decrease in tropospheric OH concentrations[12]. As the only significant tropospheric sink for many gases (especially hydrocarbons and chlorinated hydrocarbons) is reaction with OH, a rise in the tropospheric CO content would cause enhanced concentrations of these gases in the troposphere and a greater transfer to the stratosphere, with possible effects on stratospheric ozone. Other gases which affect the concentration of OH in the stratosphere include methane (CH_4) and molecular hydrogen (H_2).

Although the oxidation of methane (CH_4) is important, molecular hydrogen (H_2) can also add to the reservoir of stratospheric water vapour. This will affect the formation of stratospheric OH, with further consequences on the chemical and thermal balance of the stratosphere[13].

Little of the nitric oxide (NO) emitted at ground level can reach the stratosphere because of the efficient precipitative scavenging of its oxidation products NO_2 and HNO_3. The presence of NO in the troposphere affects the formation of ozone, through the oxidation of carbon monoxide, methane and other hydrocarbons[14]. It is therefore conceivable that increasing industrial inputs of CO and NO in the atmosphere will lead to increasing levels of tropospheric ozone[14].

As nitrous oxide (N_2O) does not react in the troposphere, it will have a long tropospheric residence time and reach the stratosphere where its oxidation leads to the formation of NO and NO_2. These gases appear in catalytic cycles of reactions leading to less ozone above 25 km and more ozone below this altitude[15].

Carbonyl sulphide (COS) and methyl chloride (CH_3Cl) have similar importance in stratospheric chemistry. During periods of little volcanic activity it is possible that the photodissociation of COS is the main source of sulphur in the stratospheric sulphate layer. Although little is known about the sources of COS there may be a growing anthropogenic input of it[16]. The decay of CH_3Cl in the stratosphere releases Cl and ClO, which are extremely efficient in limiting stratospheric ozone by catalytic reactions. An important source of methyl chloride is its emanation from the oceans, but its production by biomass burning has also been proposed[17].

Global source estimates

The data collected in Table 2 show an encouraging uniformity. Individual average emission ratios for several gases do not deviate more than a factor of 6 from each other. The largest variations in emission ratios are found for N_2O, COS and CH_3Cl. This is not surprising as one may expect these emissions to be particularly dependent on the type of material being burned. For example, the relative nutrient content in the green parts of the biomass is much larger than in stemwood[18]. We are not aware of any published emission data for the gases N_2O, H_2, CH_3Cl and COS. With the exception of the lower values obtained by Darley *et al.*[5] and Boubel *et al.*[7], the CO/CO_2 emission ratios have all been determined to be in the range of 12–20%.

Because of the uniform CO/CO_2 ratios reported, we can give a reasonable indication of the magnitude of the CO emissions. The same may apply to CH_4 and H_2. It is clear, however, that any estimations are much less reliable for NO_x, N_2O, COS and CH_3Cl. However, we can still indicate the potential importance of biomass burning as a source of these gases to the atmosphere.

If the data on total worldwide CO_2 emissions from wood burning of $2–4 \times 10^{15}$ g C yr^{-1} from Table 1 are accepted, we can discuss its possible implications for the budgets of CO, H_2, CH_4, NO_x, N_2O, CH_3Cl and COS. The wood burning contribution can then be compared with previously derived estimates of the sources of these gases from other anthropogenic or natural processes. Note that our estimates on the global extent of biomass burning are substantially smaller than those of other workers such as Wong[2] and Woodwell *et al.*[3]. We cannot defend the data compiled in Table 1 here due to lack of space, however, acceptance of higher biomass burning rates will clearly lead to larger estimates of trace gas emission rates.

Adopting an average relative CO/CO_2 volume emission factor of 14% from the data collected in Table 2, the average estimated input of CO would be 8.4×10^{14} g CO yr^{-1}, with a range of about $2.4–16.6 \times 10^{14}$ g CO yr^{-1}. Seiler[19] has estimated that the technological input of 6.4×10^{14} g CO yr^{-1} is the dominant source of atmospheric CO, and a global CO emission of 2.9×10^{14} g yr^{-1} from burning has been estimated by Bach[20]. Clearly, the CO input form fires is probably also important for the global CO budget and for the interpretation of the global CO distribution.

With a relative H_2/CO_2 emission ratio of 3.3%, the production of H_2 would amount to 15×10^{12} g H_2 yr^{-1}, with an estimated range of $9–21 \times 10^{12}$ g H_2 yr^{-1}. Schmidt[21] estimated the total worldwide source of H_2 to be 36.5×10^{12} g yr^{-1}, including an anthropogenic contribution of 25.5×10^{12} g yr^{-1}. Although our analysis shows that fires are probably important no such contribution was considered in his budget.

Assuming an average CH_4/CO_2 emission ratio factor of 1.6%, the global source of CH_4 can be calculated as

Table 1 Summary of data for the annually burned area and biomass

Activity	Burned and/or cleared area	Total biomass cleared	Biomass exposed to fire	Annually burned biomass	Dead below-ground biomass	Dead unburned above-ground biomass
Burning due to shifting agriculture	21–62 (41)	31–92 (62)	24–72 (48)	9–25 (17)	7–20 (14)	16–72 (44)

Range	2.9–3.5	1.0–2.2	5.5–21.6	0.02–0.50	0.28–0.65	5.4–28.6	4.4–57.2

The forest fire plume data were obtained from wild fire observations. The remaining data were obtained from controlled fires or laboratory measurements.

6×10^{13} g yr^{-1} with a range of $2.5–11\times10^{13}$ g CH_4 yr^{-1}. The combustion vegetation could contribute to the CH_4 budget of the atmosphere, which has an estimated input of $40–83\times10^{13}$ g CH_4 yr^{-1} (ref. 22). However, methane is not the only hydrocarbon gas emitted from the burning of vegetation: emissions of many reactive hydrocarbons, including acetylene (C_2H_2) have also been detected[5] and for some of these gases wood burning may be an important source.

As explained above, the derivation of global source estimates for N_2O, NO_x, COS and CH_3Cl is not trivial. The resulting fluxes which we will derive for these gases are, therefore, less reliable than those derived for CO, H_2 and CH_4. The simplest way of estimating the flux would be to apply the same procedure as for CO, H_2 and CH_4. With an approximate N_2O/CO_2 emission factor of 0.22%, the estimated nitrous oxide source would be 20×10^{12} g N_2O yr^{-1}. Similar calculations would yield a source of 14×10^{12} g N yr^{-1} for NO_x, 1.1×10^{11} g S yr^{-1} for COS, and 1.9×10^{11} g Cl yr^{-1} for CH_3Cl.

Although this approach indicates the potential importance of emission strengths, it is a dubious estimation. An upper limit to the NO_x emissions can be obtained by estimating the mass of bound nitrogen in the burned plant material and by assuming that almost all bound nitrogen is emitted as NO_x—an assumption consistent with other experimental studies[8,23,24]. The average of eight experimental slash fires gave relative volume emission ratios NO_x/CO_2 of 4% for duff and 2.1% for needles. These ratios are close to the values that can be expected if essentially all bound nitrogen in the plant material were volatilised as NO_x. No NO_x emissions were detected during the combustion of cellulose materials, presumably because burning temperatures were too low to allow appreciable NO_x production from atmospheric N_2 and O_2. The relative volume yield NO_x/CO_2 from an entire fire (in which about 55% of all available fuel was consumed) was estimated to be 0.65%[8]. In living plants the nutrients N and S are mainly concentrated in those parts which are most easily burned, such as leaves, small twigs and bark. Before burning, however, much plant tissue is dry and dead, and has actually lost nutrients. Using the information in our Table 1 and Tables 53 and 54 in the compilation by Rodin and Bazilevich[18], the average maximum global N/C ratio in the burned biomass can be roughly estimated to be between 1.5 and 2.5%. Given this information we derive a maximum global average NO_x emission of 50×10^{12} g N yr^{-1} from biomass burning, with a range of $20–100\times10^{12}$ g N yr^{-1} if most bound nitrogen is indeed emitted as NO_x. The mean estimate is about equal to that mentioned previously by Delwiche and Likens[25].

The assumption that all fixed nitrogen is released as NO_x is far from established. A study by Clements and McMahon[26] confirms that most of the NO_x released during burning arises from fuel nitrogen. They conclude that environmentally significant amounts of NO_x are formed by the burning of forest fuels. However, this study also indicated that the NO_x yield is not 100% and that it actually increases with the nitrogen content of the fuel: a rough average of the NO_x yield observed in their studies is about 30%. From a mass-balance perspective it is therefore conceivable that other trace gases besides NO_x are released by biomass burning. These could include N_2O, NH_3 and HCN. NH_3 is an important gas involved in the atmospheric nitrogen cycle. HCN has not so far been observed in the atmosphere, but it could be rather stable as it is not removed photochemically in the troposphere.

If we assume that our maximum observed N_2O/CO_2 emission ratio of ~0.4% is produced from the burning of the nutrient-rich portions of the vegetation (such as the needles and leaves, which have an average N/C composition ratio of 4–6%), we may guess that the N_2O volume emissions could be ~8% of those of NO_x. Consequently we may estimate an average global N_2O source of $\sim13\times10^{12}$ g N_2O yr^{-1}. Finally, comparing the relative emission ratios of COS and CH_3Cl to those of N_2O obtained from the Wild Basin fire in Colorado, the global emission rate of COS can be roughly extrapolated to be 2.4×10^{11} g S yr^{-1} (3×10^7 molecules cm^{-2} s^{-1} at the Earth's surface) and that of CH_3Cl to be 4.2×10^{11} g Cl yr^{-1} ($\approx4\times10^7$ molecules cm^{-2} s^{-1}). Judging from these estimates, biomass burning could produce much more COS than is destroyed in the stratosphere[16]. This may indicate the presence of another sink for COS in the troposphere or at the Earth's surface. On the other hand, the production of CH_3Cl from biomass burning seems to be an order of magnitude lower than its destruction in the troposphere by reaction with OH[27]. Therefore, from this limited analysis it seems that the oceanic source of CH_3Cl should be more important[17].

The indicated emissions of NO_x and N_2O both seem very important from a global perspective. A NO_x source strength of several times 10^{13} g N yr^{-1} is comparable to or larger than the other two major sources of NO_x (industrial processes[28] and lightning[29]). The production of NO_x by the burning of vegetation during the dry season has been clearly demonstrated by Lewis and Weibezahn[30], who measured an increase in rainfall acidity by 10^4 from the beginning to the end of the dry season in the Aragua Valley in Venezuela. According to these authors the release of NO_x by seasonal vegetation burning and its conversion to HNO_3 were responsible for this phenomenon. The S/N ratios in plant material are too low for H_2SO_4 to be nearly as important as HNO_3 in the acidification of the precipitation. The observations by Lewis and Weibezahn[30] supported our method of extrapolation from mid-latitude to tropical conditions.

The indicated production rates of N_2O by burning are comparable to the removal rate in the stratosphere, which is still

the only well-documented sink for nitrous oxide. The large oceanic source of N_2O once derived by Hahn[31] is now strongly disputed and more recent observations point to a much smaller source[32,33]. It seems, therefore, that vegetation burning as a source of N_2O could be of a similar substantial importance.

Note that in our source calculations for the atmospheric trace gases, we did not consider the potential release from the heating of the topsoil organic matter or from the $40–80 \times 10^{14}$ g C of matter which is exposed to fire but left behind as dead, unburned above-ground biomass (see Table 1). The topsoil organic matter is especially rich in nutrients and may make imporant contributions to the cycling of atmospheric trace gases and nutrient elements. The latter has already been pointed out by Lewis[34].

The analysis of emissions from the burning of vegetation has also revealed substantial yields of aldehydes, hydrogen peroxide (G. Kok, personal communication), and reactive and oxygenated hydrocarbons[7,35,36]. Because of the simultaneous production of NO, there may be a significant production of ozone in the fire-affected air. Such production of ozone has been observed[37].

Despite the limited amount of observations, we must conclude that biomass burning, especially in the tropics where the rates of biomass production and biomass burning are unparalleled, has the potential to contribute in an important way to the global budgets of several major atmospheric trace gases. We also need to consider that tropical emissions occur in a photochemically very active and dynamically important region, in which substantial transfer of tropospheric air to the stratosphere takes place.

Observations of biomass burning in the tropics are needed which will enable us to assess far more reliably the role of biomass burning in biogeochemical cycles and in atmospheric chemistry. This research is especially important in view of the increasing use of forest resources in the developing countries.

We thank Drs W. Lewis and C. McMahon for valuable comments. The National Center for Atmospheric Research is sponsored by the NSF.

A modified RNA polymerase transcribes a cloned gene under sporulation control in *Bacillus subtilis*

William G. Haldenwang & Richard Losick

The Biological Laboratories, Harvard University, Cambridge, Massachusetts 02138

A modified form of RNA polymerase from Bacillus subtilis *selectively transcribes a cloned gene under early sporulation control. This RNA polymerase lacks σ factor but contains a newly identified subunit of molecular weight 37,000, termed P^{37}. P^{37} could be a regulatory protein that controls, at least in part, an early stage of spore development.*

THE formation of dormant endospores in *Bacillus subtilis* is a simple developmental process that proceeds through a series of well defined morphological stages (for reviews see refs 1, 2). During the earliest developmental stages, the sporulating cell partitions itself by invagination of the plasma membrane into a forespore compartment and a mother cell or sporangium. Then, after engulfment of the forespore by the mother cell membrane, the developing spore acquires a cortex and a tough protein coat. Finally, a mature, dormant spore is liberated by lysis of the mother cell. Mutations in a variety of sporulation or *spo* genes arrest this process at different stages of spore development[1].

What mechanisms govern the expression of sporulation genes during this developmental sequence? To help answer this question, this laboratory previously cloned a *B. subtilis* gene whose transcription is activated at an early stage of spore development[3]. This gene, which maps near the origin of replication of the *B. subtilis* chromosome (between *spo0J* and *spo*IIE20, ref. 4, and W.G.H., C. Banner, J. F. Ollington, R.L., and A. L. Sonenshein, unpublished results) encodes an RNA of about 400 bases and referred to as the '0.4-kilobase gene'. This gene is known to be under sporulation control because its transcription is severely restricted in mutants blocked at the earliest stage of development (*spo0A*, *spo0B*, *spo0E*, *spo0F* and *spo0H* mutants; ref. 3 and unpublished results). Here we report the isolation from early sporulating cells of a form of *B. subtilis* RNA polymerase that transcribes this developmentally regulated gene *in vitro*.

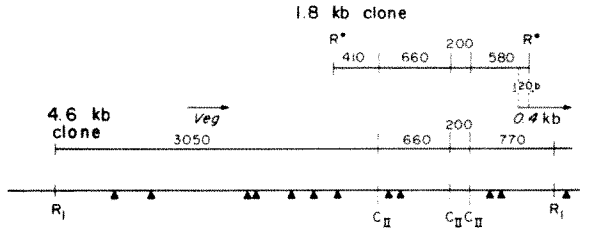

Fig. 1 Endonuclease restriction map of cloned *B. subtilis* DNA in the vicinity of the 0.4-kilobase gene. The lower line is a map of the cleavage sites for the restriction enzymes *Hpa*II (▲), *Eco*RI (as indicated) and *Hin*cII (as indicated) and is a composite of the maps of several overlapping cloned DNAs. The middle line is a map of one cloned DNA of 4.6 kilobases that terminates at an *Eco*RI site within the 0.4-kilobase gene, and the top line is a map of a cloned 1.8-kilobase DNA that terminates at an *Eco*RI* cleavage site within the 0.4-kilobase gene. The two heavy arrows show the location and direction of transcription of the 0.4-kilobase gene and the vegetative (*veg*) gene. The numbers on the middle and top lines show the size in base pairs of fragments generated by *Hin*cII cleavage of the 4.6- and 1.8-kilobase DNAs (see Figs 2, 4). The dashed lines show the position of the 120 base run-off RNA (see Fig. 4). Documentation for the information in this figure will be presented elsewhere (J. F. Ollington, W.G.H. and R.L., manuscript in preparation).

Detection of a specific transcribing activity

Figure 1 presents an endonuclease restriction map of cloned *B. subtilis* DNA in the vicinity of the 0.4-kilobase gene. The 0.4-kilobase gene, as depicted, is transcribed from left to right with its startpoint for transcription located about 300 base pairs from an internal *Eco*RI cleavage site (J. F. Ollington, W.G.H. and R.L., in preparation). At 2.7 kilobases to the left of the 0.4-kilobase gene, there is a sequence that is transcribed during growth and sporulation and referred to as the 'vegetative' gene.

We devised a specific hybridisation assay to search for an activity that would transcribe the 0.4-kilobase gene. A hybrid plasmid containing a 4.6-kilobase insert defined by the two *Eco*RI sites in the map was cleaved with the restriction enzymes *Hin*cII and *Eco*RI. This generated fragments of 3,050 and 2,200 base pairs that contained the vegetative gene and a 770-base pair fragment containing the promoter-proximal portion of the 0.4-kilobase gene as well as several other fragments of *B. subtilis* and vector DNA. (The 2,200-base pair DNA is a secondary cleavage product of the 3,050-base pair fragment that is generated from an *Eco*RI* site near the left end of the 4.6-kilobase DNA; see Fig. 2 legend). These fragments were separated electrophoretically and transferred to nitrocellulose by the method of Southern[5]. Radioactive RNA from cells pulse-labelled early in sporulation hybridised to fragments containing the vegetative gene and the 0.4-kilobase gene (ref. 3 and J. F. Ollington, W.G.H. and R.L., in preparation). In contrast, radioactive RNA from several different stage 0-blocked mutants annealed only to 3,050- and 2,200-base pair fragments containing the vegetative gene.

To test for transcription of the 0.4-kilobase gene *in vitro*, we hybridised radioactive RNA copied from hybrid plasmid DNA to the electrophoretically separated fragments. The experiment of Fig. 2 shows that RNA polymerase holoenzyme (lane 1) and core RNA polymerase (containing a trace of σ polypeptide) purified from vegetative cells (lane 2) selectively transcribed the vegetative gene region of the hybrid plasmid although neither form of polymerase copied RNA from the 770-base pair region that contained the 0.4-kilobase gene. Thus, purified vegetative RNA polymerase failed to recognise the sporulation-controlled sequence.

To search for a form of RNA polymerase that would copy the 0.4-kilobase gene, we examined extracts of cells collected early (T_1) in sporulation. We identified such an activity in enzyme partially purified by phase partitioning, gel filtration and phosphocellulose chromatography. Lane 3 of Fig. 2 shows that partially purified sporulation enzyme actively copied RNA from the 770-base pair region as well as from the vegetative gene-containing fragments. Some transcription of two plasmid vector fragments (2,400 and 2,210 base pairs) could also be detected. Transcription of hybrid plasmid DNA was not random, as we could detect no hybridisation to the 660- and 200-base pair fragments preceding the 0.4-kilobase gene or to a vector fragment of 950 base pairs.

As a further test of recognition of the 0.4-kilobase gene, we examined the strand selectivity of transcription from the 770-base pair region. DNA strands of the 770-base pair fragment were separated by gel electrophoresis of denatured DNA and then transferred by the Southern[5] procedure to nitrocellulose. Hybridisation of radioactive 0.4-kilobase RNA synthesised *in vivo* identified the slow-migrating DNA as the DNA coding strand (Fig. 3, lane 3). (Other work showing that the 5'-end of the slow-migrating strand is at the *Eco*RI end of the 770-base pair fragment established the direction of transcription as shown in Fig. 1). Figure 3 (lane 2) shows that RNA synthesised *in vitro* from hybrid plasmid DNA annealed selectively to the slow-migrating strand. Combining this result with the result of Fig. 2, we conclude that the RNA polymerase activity from early sporulating cells initiated transcription within the 770-base pair region and copied RNA asymmetrically from the coding strand of the 0.4-kilobase gene.

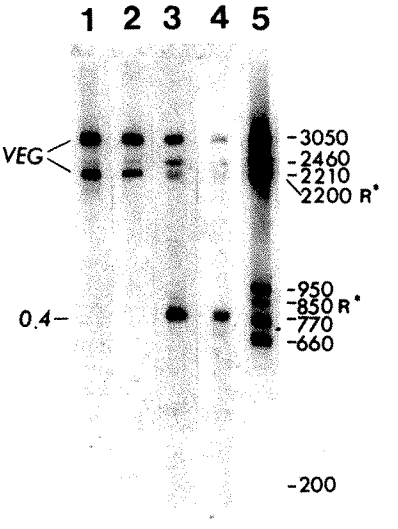

Fig. 2 Southern hybridisations to electrophoretically separated restriction fragments of hybrid plasmid DNA. A pMB9 hybrid plasmid containing the 4.6-kilobase insert of *B. subtilis* DNA[3] described in Fig. 1 was cleaved with the restriction enzymes *Eco*RI and *Hin*cII, generating plasmid vector fragments of 2,460 2,210 and 950 base pairs and *B. subtilis* DNA fragments of 3,050, 770, 660 and 200 base pairs. (In addition, *Eco*RI cleavage generated small amounts of two fragments of 2,200 and 850 base pairs that arise by secondary cleavage of the *B. subtilis* 3,050-base pair fragment at an *Eco*RI* site located 850 base pairs from the left end of the 4.6-kilobase DNA. *Eco*RI* is an altered form of *Eco*RI of reduced recognition specificity[11].) The fragments were separated electrophoretically and transferred to nitrocellulose by ascending chromatography as described by Southern[5]. The nitrocellulose strips (0.5 μg DNA per strip) were then incubated in hybridisation conditions (5 × SSC, 50% formamide; 18 h at 37 °C) with radioactive RNA that had been copied *in vitro* from hybrid plasmid DNA. RNA was synthesised *in vitro* by the following protocol: 0.1 units [a unit incorporates 1 nmol of AMP into RNA with poly(dA-T) as template] of RNA polymerase holoenzyme[12] (lane 1), core RNA polymerase[12] (lane 2), phosphocellulose-purified sporulation polymerase (fraction 20 of Fig. 5; lane 3) or DNA-cellulose-purified sporulation polymerase (fraction 36 of Fig. 6, lane 4) were separately allowed to pre-bind for 10 min at 37 °C with 2.5 μg of pMB9–4.6-kilobase hybrid plasmid DNA (representing an enzyme to template ratio of about 0.5–1.0) in 50-μl reaction mixtures[6] lacking ribonucleotides but containing 20% glycerol. Next, ribonucleotides (0.15mM CTP, GTP and ATP and 0.4 μm (5 μCi) [α^{32}P] UTP) were added. After 4 min incubation, unlabelled UTP (0.15 mM) was added. The reactions were stopped after 2 min and RNA was isolated for hybridisation as described elsewhere[6]. After the hybridisation reactions were completed, the Southern strips were washed, treated with RNase and exposed to X-ray film (Kodak SB-5) to visualise hybrids. Lane 5 shows the position of plasmid vector and *B. subtilis* DNA fragments as visualised by annealing a nitrocellulose strip (that had been treated by the Denhardt[13] procedure) with hybrid plasmid DNA that had been radioactively labelled *in vitro* by the 'nick-translation' activity[14] of DNA polymerase I.

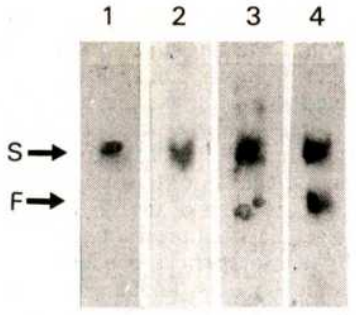

Fig. 3 DNA strand selectivity of transcription. The 770-base pair fragment (containing the 0.4-kilobase gene) was isolated by electrophoresis of pMB9–4.6-kilobase hybrid plasmid DNA that had been cleaved with *Hin*cII and *Eco*RI (see Fig. 1). The strands of the 770-base pair fragment were then separated by electrophoresis of denatured DNA through a 5% polyacrylamide gel as described by Hayward[15]. The separated DNA strands (0.05 μg per strip) were then transferred by the Southern[5] procedure to nitrocellulose. Nitrocellulose strips containing separated DNA strands were then incubated in hybridisation conditions (see Fig. 1 legend) with: lane 1, 120-base run-off RNA from the experiment of Fig. 4; lane 2, RNA transcribed *in vitro* from pMB9–4.6-kilobase hybrid plasmid DNA by phosphocellulose-purified sporulation polymerase from the experiment of Fig. 2; lane 3, *in vivo* synthesised 0.4-kilobase RNA isolated from ^{32}P-labelled sporulating cells as described previously[3]. After hybridisation, the strips were washed, treated with RNase and exposed to X-ray film to visualise hybrids. Lane 4 shows the position of the slow-migrating (S) and fast-migrating (F) strands as visualised by annealing a nitrocellulose strip with radioactively labelled hybrid plasmid DNA (see Fig. 2 legend).

Initiation of transcription at a unique site

Does sporulation enzyme initiate transcription at a unique site within the 770-base pair region? To answer this question we used a cloned subfragment of 1.8 kilobases that contained the promoter-proximal region of the 0.4-kilobase gene and entirely lacked the vegetative gene. The right-hand end of the 1.8-kilobase fragment is an *Eco*RI* cleavage site that falls within the 0.4-kilobase gene at 100–150 base pairs from the startpoint of transcription. We therefore reasoned that, if polymerase was initiating at a unique site near the promoter for the 0.4-kilobase gene, the RNA polymerase from sporulating cells with 1.8-kilobase DNA as template should generate a discrete-sized 'run-off' RNA of 100–150 bases.

This expectation was confirmed by the finding, shown in Fig. 4, that sporulation enzyme generated an RNA of 120 bases from hybrid plasmid DNA that had been cleaved with restriction enzyme to free the 1.8-kilobase insert from the vector. The size of this transcript was apparently dependent on run-off termination at an end of the cut DNA template, as the 120-base RNA was not generated during transcription of uncut plasmid template (Fig. 4). To prove that the 120-base RNA was copied from the 0.4-kilobase region of the hybrid plasmid, *in vitro* synthesised transcript was eluted from a slice of polyacrylamide gel containing the RNA band and from surrounding slices and annealed to electrophoretically separated fragments of the hybrid plasmid. Figure 4*b* shows that hybridisation to the 580-base pair (Fig. 1) fragment containing the 0.4-kilobase gene promoter region was only observed for the slice that contained the 120-base RNA. Finally, hybridisation to separated DNA strands (Fig. 3, lane 1) showed that the 120-base RNA was complementary to the DNA coding strand for the 0.4-kilobase gene. Thus, we conclude that sporulation enzyme initiated transcription at a unique site close to or identical with the promoter for the 0.4-kilobase gene.

Isolation of a modified RNA polymerase

Using cloned DNAs as probes for specific RNA synthesis, we extensively purified a modified form of RNA polymerase that transcribes the 0.4-kilobase gene. Figure 5*a* shows the polypeptide profile of proteins eluted from phosphocellulose with a linear salt gradient. As judged by hybridisation of *in vitro* synthesised RNA to the 770-base pair fragment (Fig. 5*b*) and by the production of the 120-base RNA (Fig. 5*c*), transcription of the 0.4-kilobase gene was preferentially associated with RNA polymerase eluting just past the centre of the gradient at 0.43 M KCl.

Although RNA polymerase was impure at this stage, the subunits of core RNA polymerase ($\beta'\beta\alpha_2$) were readily visualised in fractions across the gradient. In addition, those fractions that transcribed the 0.4-kilobase gene seemed to contain preferentially polypeptides of molecular weight (MW) 37,000 (P^{37}) and 36,000 (P^{36}).

Fractions 20–22 (containing RNA polymerase that preferentially transcribed the 0.4-kilobase gene) were pooled and subjected to DNA-cellulose chromatography. Gradient elution resolved two forms of RNA polymerase (Fig. 6*a*). In addition to the subunits of core RNA polymerase, proteins eluting at lower ionic strength (0.30 M KCl) included the P^{36} polypeptide and a

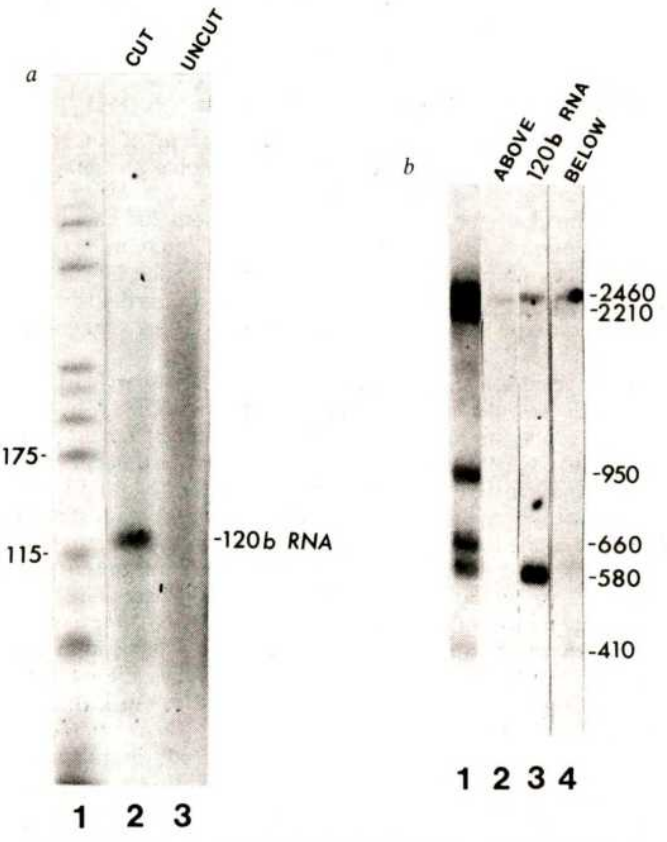

Fig. 4 Synthesis of a 120-base run-off RNA. *a*, RNA was copied *in vitro* using 0.2 units of phosphocellulose-purified sporulation polymerase (fraction 20 of Fig. 5) from a pMB9 hybrid plasmid containing the 1.8-kilobase *Eco*RI* fragment described in Fig. 1 legend. The conditions of RNA synthesis were as described in Fig. 2 legend except that heparin (30 μg) was added 30 s after the addition of ribonucleotides to block re-initiation of transcription. The template (2.5 μg) for *in vitro* transcription was either uncut hybrid plasmid DNA (lane 2) or hybrid plasmid DNA that had been cleaved with *Eco*RI to separate the 1.8-kilobase insert from vector DNA (lane 3). (Even though the 1.8-kilobase DNA was defined by two *Eco*RI* restriction sites, when cloned into the *Eco*RI site of pMB9, the resulting *Eco*RI–*Eco*RI* hybrid site was readily cleaved in *Eco*RI conditions.) *In vitro* synthesised RNA was then subjected to electrophoresis through a 5% polyacrylamide gel containing 7 M urea. As MW standards, lane 1 displays denatured *Hae*III fragments of ^{32}P-labelled pMB9 DNA. The numbers on the left of *a* give the size in bases of two fragments. After electrophoresis, the polyacrylamide gel was exposed to X-ray film (Kodak SB-5) to visualise *in vitro* synthesised RNA and the radioactive standards. *b*, After visualisation of the 120-base RNA (*a*, lane 2) 0.5-cm slices were cut from the polyacrylamide gel from positions above (lane 2), coincident with (lane 3) and below (lane 4) the run-off RNA. The slices were crushed and then incubated in hybridisation conditions (see Fig. 2 legend) with Southern strips containing electrophoretically separated fragments of pMB9–1.8-kilobase hybrid plasmid DNA that had been cleaved with *Eco*RI and *Hin*cII (see Fig. 1). These *Eco*RI–*Hin*cII fragments were visualised in lane 1 of *b* by reaction of a Southern strip with ^{32}P-labelled hybrid plasmid DNA (see Fig. 2 legend).

high molecular weight polypeptide. Proteins eluting at the higher ionic strength (0.41 M KCl) included P^{37}, and this polypeptide was present in a stoichiometry of approximately one per RNA polymerase core molecule. As measured by hybridisation to the 770-base pair fragment (Fig. 6*b*) and by the synthesis of the 120-base RNA (Fig. 6*c*), transcription of the 0.4-kilobase gene was strongly correlated with fractions containing P^{37}. Moreover, RNA polymerase in P^{37}-containing fractions exhibited a marked preference for the 0.4-kilobase gene; as shown in the hybridisation experiment of Fig. 2 (lane 4), enzyme in the peak fraction (fraction 36) for P^{37} content copied RNA with high selectivity from the sporulation-controlled sequence and generated less RNA from the vegetative gene or other regions of the hybrid plasmid.

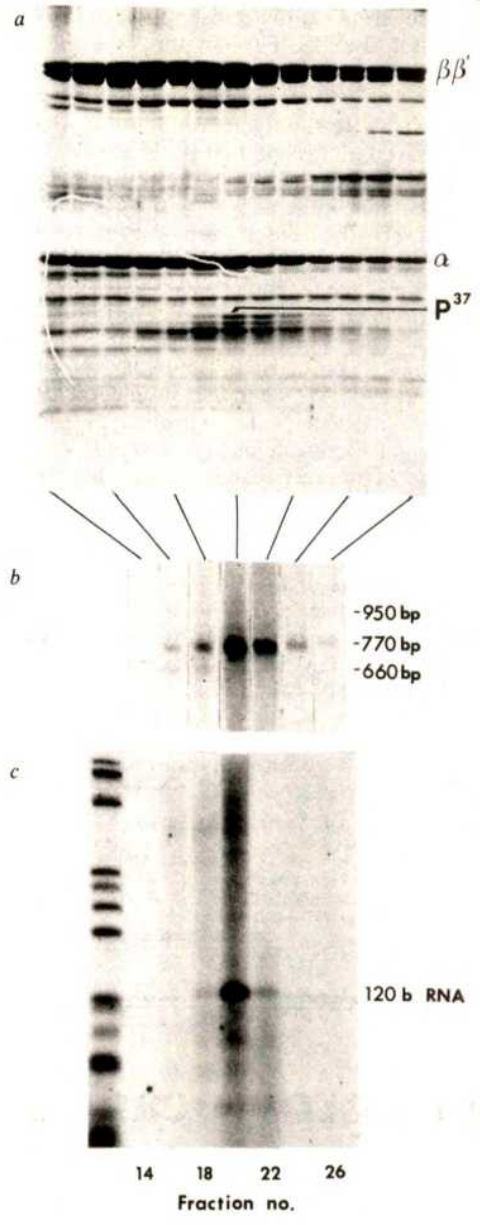

Fig. 5 Gradient elution of RNA polymerase from phosphocellulose. 100 g of *B. subtilis* cells (strain SMY) were collected at the first hour (T_1) of sporulation in Difco sporulation medium[16]. The cells were disrupted by two passages through a French pressure cell (8–10,000 p.s.i.) and RNA polymerase was partially purified by phase partitioning and gel filtration as described by Shorenstein and R.L.[12]. Next, 10 mg of gel-filtration-purified enzyme was applied to a phosphocellulose column (5 × 1.5 cm) and eluted with a 0.2–0.8 M linear gradient of KCl in 100 ml of buffer C(0.05 M Tris, *p*H 8.0, 20% glycerol, 0.3 mM dithiothreitol, 1 mM EDTA). Fractions of 2 ml were collected. *a*, Samples of 100 μl from each fraction were subjected to electrophoresis through a 23-cm-long slab gel containing SDS in a Tris-glycine buffer and a 10–20% gradient of acrylamide[17]. The gel was stained with Coomassie brilliant blue. *b*, RNA was generated *in vitro* from pMB9–4.6-kilobase plasmid DNA in reaction mixtures containing 2.5-μl samples from every other fraction along the gradient and annealed with Southern strips containing *Eco*RI–*Hin*cII fragments of hybrid plasmid DNA. Hybrids were visualised by autoradiography. The panel displays hybridisation in the region of the Southern strips containing *B. subtilis* fragments of 770 and 660 base pairs and a pMB9 fragment of 950 base pairs. Methods for this experiment were described in Fig. 2 legend. The 120-base run-off RNA was synthesised as described in Fig. 4 legend in reaction mixtures containing 2.5-μl samples from every other fraction from the gradient. The products of *in vitro* RNA synthesis are displayed by polyacrylamide gel electrophoresis and autoradiography. MW standards (see Fig. 4) are displayed on the left.

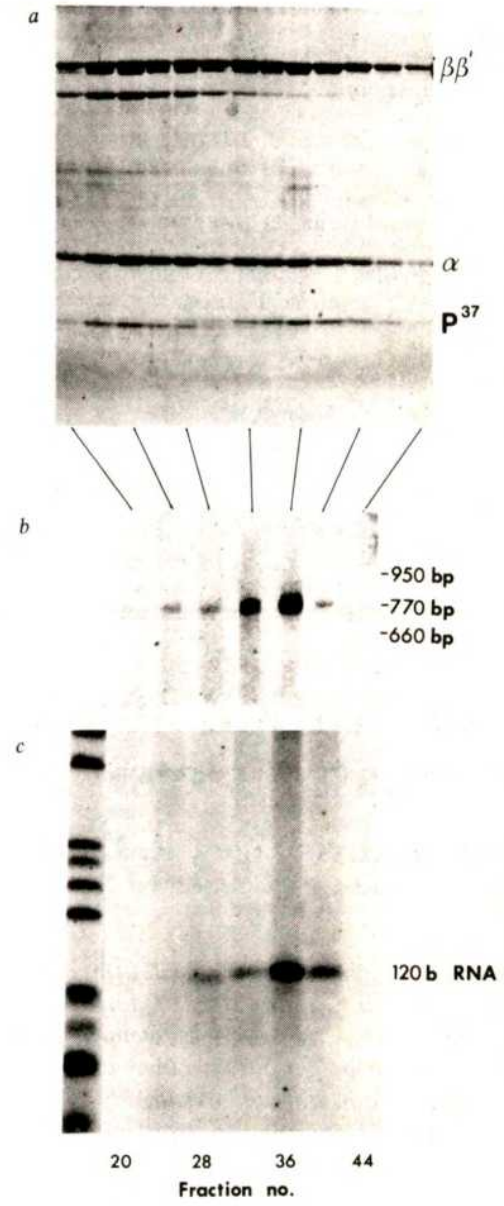

Fig. 6 Gradient elution of RNA polymerase from DNA-cellulose. Phosphocellulose-purified RNA polymerase in fractions 20–22 from the experiment of Fig. 5 were pooled and applied to a calf thymus DNA cellulose column (2 × 1 cm). Enzyme was eluted with a 0.2–0.7 M linear gradient of KCl in 50 ml of buffer C (Fig. 5 legend) and fractions of 1.0 ml were collected. *a*, Displays by SDS gel electrophoresis the pattern of polypeptides in 300-μl samples from every other fraction from the gradient. *b*, Displays the pattern of hybridisation to Southern strips of RNA synthesised *in vitro* by 5-μl samples from every fourth fraction from the gradient. *c*, Displays by polyacrylamide gel electrophoresis the *in vitro* synthesis of 120-base run-off RNA from 5-μl samples from every fourth fraction from the gradient. Procedures for the experiments of *a*, *b* and *c* are as described for the corresponding panels of Fig. 5.

Initiation of spore development

We have isolated a form of RNA polymerase that transcribes a cloned gene[3] (the 0.4-kilobase gene) that is activated at an early stage of sporulation in *B. subtilis*. As evidence of specific transcription, this RNA polymerase copied RNA selectively and asymmetrically from the 0.4-kilobase gene, initiating at a unique site close to the apparent startpoint for RNA synthesis *in vivo*. Nucleotide sequencing should now enable us to define this site precisely.

Purified RNA polymerase capable of transcribing the 0.4-kilobase gene was associated with a polypeptide of MW 37,000, termed P^{37}. P^{37} co-purified with the 0.4-kilobase gene transcribing activity during gradient elution from both phosphocellulose and DNA-cellulose. It therefore seems likely that this species confers on RNA polymerase the ability to recognise and transcribe the 0.4-kilobase gene. This possibility can now be tested directly by reconstructing the enzyme complex from purified P^{37} and core RNA polymerase. If P^{37} is, in fact, a transcriptional determinant, we would suppose that, acting in the apparent absence of σ factor, it is itself a σ-like regulatory subunit of polymerase that directs recognition of the 0.4-kilobase gene promoter. As a precedent, a regulatory subunit of RNA polymerase encoded by *B. subtilis* phase SP01 causes core RNA polymerase to bind at the promoters for phage SP01 'middle' genes[6].

The initiation of sporulation in *B. subtilis* is controlled by at least five or six genetic loci known as the stage 0 genes[1]. Mutations in stage 0 genes *spo0A*, *spo0B*, *spo0E*, *spo0F* and *spo0H* block sporulation at its earliest morphological stage (stage 0) and severely restrict transcription of the 0.4-kilobase gene *in vivo* (ref. 3 and J. F. Ollington, W.G.H. and R.L., in preparation). Based on these and other observations[7-9], we believe that the stage 0 gene products turn on early sporulation genes by modifying RNA polymerase. It is tempting to suppose that P^{37} is involved in this and that P^{37} is itself the product of a stage 0 gene. In recent experiments, however, we find that P^{37} is present in vegetative cells as well as in sporulating bacteria. Possibly, P^{37} directs the transcription of several classes of genes but its involvement in sporulation RNA synthesis is specifically controlled by the stage 0 gene products. This could be investigated by identifying the structural gene for the P^{37} protein.

The isolation from sporulating cells of an RNA polymerase which transcribed a sporulation gene *in vitro* is consistent with suggestions that spore development in general[10] and the 0.4-kilobase gene in particular[3] are controlled, at least in part, by one or more regulatory proteins that bind to RNA polymerase. It will now be of interest to determine whether temporally controlled classes of sporulation genes are transcribed by different forms of RNA polymerase containing distinct regulatory subunits.

We thank members of the Losick-Pero group who contributed reagents and advice and J. Pero and A. L. Sonenshein for assistance with the manuscript. This work was supported by NIH research grant 5 RO1 GM 18568 to R.L. and NIH postdoctoral fellowship 5 F32 GM 06401 to W.G.H.

Identification and processing of proglucagon in pancreatic islets

C. Patzelt, H. S. Tager, R. J. Carroll & D. F. Steiner

Department of Biochemistry, The University of Chicago, 920 East 58th Street, Chicago, Illinois 60637

Immunoprecipitation and tryptic peptide analysis of newly synthesised proteins from rat islets have identified an 18,000 *molecular weight (MW) protein as proglucagon. Conversion of this precursor was kinetically similar to the conversion of proinsulin and resulted in the formation of both pancreatic glucagon and a* 10,000*-MW protein lacking this hormonal sequence.*

AFTER the detection of proinsulin in 1967 (ref. 1) the search for a biosynthetic precursor of glucagon became the subject of considerable investigation. Several investigators have found larger immunoreactive forms of glucagon in extracts of pancreas[2,3], of gastric and intestinal mucosa[4,5], of salivary glands[6], and in plasma[7]. Estimates of the molecular weights of these various forms range from 4,500 to 70,000, but only a few forms have been characterised. Thus, we isolated a peptide which carried a C-terminal extension of eight amino acids on the sequence of pancreatic glucagon[8]. Because of its small size (MW 4,500) and because of the identification of low amounts of larger forms, this peptide seemed to represent a fragment or intermediate cleavage form of proglucagon. More recently, a larger form has been isolated from porcine intestine and has been partially sequenced. This peptide, glicentin[9], consists of 100 amino acid residues and has a molecular weight of 12,000. The glucagon moiety in this molecule is also extended at the C-terminus by a sequence of eight amino acids very similar to that of the 4,500-MW proglucagon fragment. More recently, 12,000 and 8,000-MW glucagon-containing peptides of intestine have been found to have identical counterparts in pancreatic tissue[10].

Although the above findings have not established the precursor nature of any of the larger forms of glucagon, biosynthetic studies in isolated fish islets have indicated that proglucagon has a molecular weight of 12,000 (refs 11, 12). In the present study we have used the high resolving power of SDS–polyacrylamide gel-electrophoresis and the sensitivity of fluorographic methods to examine the biosynthesis of glucagon in pancreatic islets of

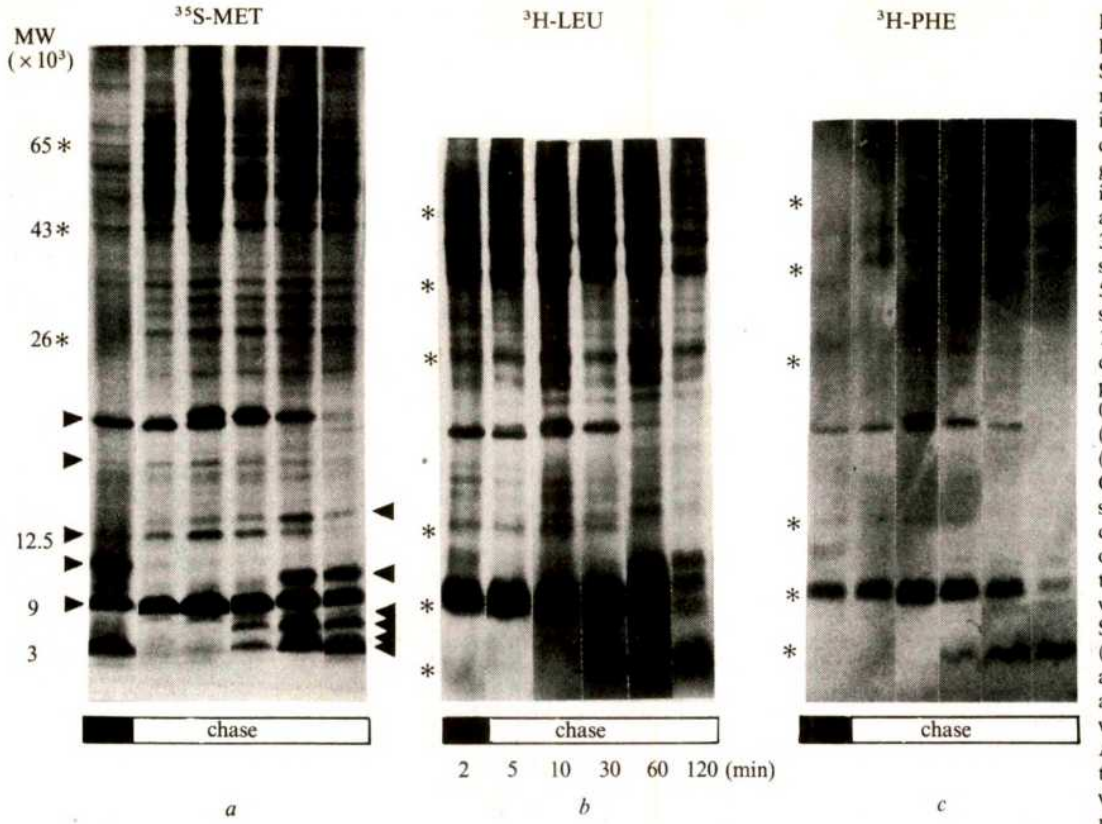

Fig. 1 Pulse-chase labelling of islet proteins. Samples of 100 isolated rat islets[30] were incubated in 50 μl Hanks' buffer containing 2.5 mM glucose and 50 μCi of the indicated radioactive amino acid for 2 min at 37 °C. Pulse-labelling was stopped by the addition of 5 ml Hanks' buffer supplemented with 10^{-3} M of the respective cold amino acid. Chase periods, in minutes, were 0 (lane 1), 3 (lane 2), 8 (lane 3), 28 (lane 4), 58 (lane 5) and 118 (lane 6). Chase-incubation was stopped by chilling, centrifugation and boiling of islets in 12.5 μl denaturing solution[20]. Samples were electrophoresed on SDS-polyacrylamide gels (0.1% SDS/16% acrylamide/0.25% bisacrylamide[16,31]) and dried gels were fluorographed[32,33]. Asterisks show the position of marker proteins whose sizes are indicated numerically on the left. Arrowheads to the left of a point (from top to bottom) to proglucagon (MW 18,000), an unidentified prohormone-like protein (MW 16,000), prosomatostatin (MW 12,500) (unpublished), preproinsulin[16], and proinsulin. Arrowheads at the right point to conversion products.

the rat. Immunoprecipitation, tryptic peptide analysis and kinetic studies of formation and processing have all identified an 18,000-MW peptide as pancreatic proglucagon.

Prohormone-like proteins in pancreatic islets

To identify proteins having prohormone-like kinetics of formation and processing[13–15], pulse-chase experiments were carried out with isolated rat islets using various radioactive amino acids of high specific activity. The slab gel electrophoretic system was optimised by adjusting the concentrations of acrylamide and bisacrylamide[16] for resolution of proteins in the molecular weight range of 10,000–30,000, a size range in which new prohormones might be expected to occur[17]. In the pulse-chase experiments shown in Fig. 1 proinsulin was the predominant labelled band and was used as an internal standard for the detection of other proteolytically processed proteins. The most conspicuous protein which exhibited prohormone-like behaviour was a relatively highly labelled band of MW about 18,000, which appeared immediately after a pulse of 2 min. However, unlike proinsulin, this 18,000-MW protein underwent a small post-translational increase in its molecular size. It later disappeared after a chase period of 30–120 min. This period for post-translational processing is consistent with prohormone conversion, as indicated by the fading of the labelled proinsulin band and the appearance of smaller insulin-like conversion products (Fig. 1). These results suggested that the 18,000-MW band might represent a precursor to one of the other major islet hormones such as glucagon or somatostatin. Faintly labelled proteins showing similar labelling kinetics, though without early post-translational enlargement, could also be found consistently with MW 12,500 and, in the case of experiments *a* and *b* of Fig. 1, with 16,000 MW.

Proteins appearing later in the course of a chase-period are likely to represent intermediates or endproducts of the conversion process. Thus a 13,000-MW protein and one of MW 10,000 are, on the basis of their relative abundance, both likely to be derived from the 18,000-MW precursor (Fig. 1). Furthermore, up to four labelled peptides smaller than proinsulin were resolved as indicated by arrowheads in Fig. 1*a*. These proteins were included, together with the above-mentioned candidate prohormones, in the surveys for proteins involved in the biosynthesis of glucagon described below. The 12,000-MW protein was identified as the prohormonal form of somatostatin (unpublished), whereas the 16,000-MW band has not yet been related to any known islet hormone.

Identification of glucagon-related proteins

For the identification of proglucagon and its conversion products islets were pulse-labelled for 2 h with ^{35}S-methionine. Islet lysates were electrophoresed and fluorographed as described in Fig. 1 legend and prohormones and conversion products were eluted from the dried gels for immunoprecipitation. Two types of glucagon-antisera were used for this study: the first is a tissue nonspecific antiserum (designated NS) known to be directed toward the central and N-terminal regions of glucagon and known to be reactive with larger forms of glucagon; the second is an antiserum specific for pancreatic glucagon (designated CTS, that is C-terminus-specific) which recognises the amino acid sequence at positions 24–29 of the glucagon molecule but which does not react with forms carrying a C-terminal extension in the radioimmunoassay[10]. Such an extension has been reported to be present in a proglucagon fragment isolated from commercial glucagon preparations[8], in glicentin[9], and in 12,000 and 8,000-MW glucagon-containing peptides of both pancreas and intestine[10]. It can be removed by combined treatment with trypsin and carboxypeptidase B. The authentic C-terminal tryptic fragment of glucagon cleaved out of a larger molecule by this enzymatic treatment would also be recognised by this specific antibody[10].

The data in Fig. 2 shows that the two proteins of MW of 18,000 are the only candidate prohormones which exhibited significant reactivity with the glucagon antisera. In addition, a

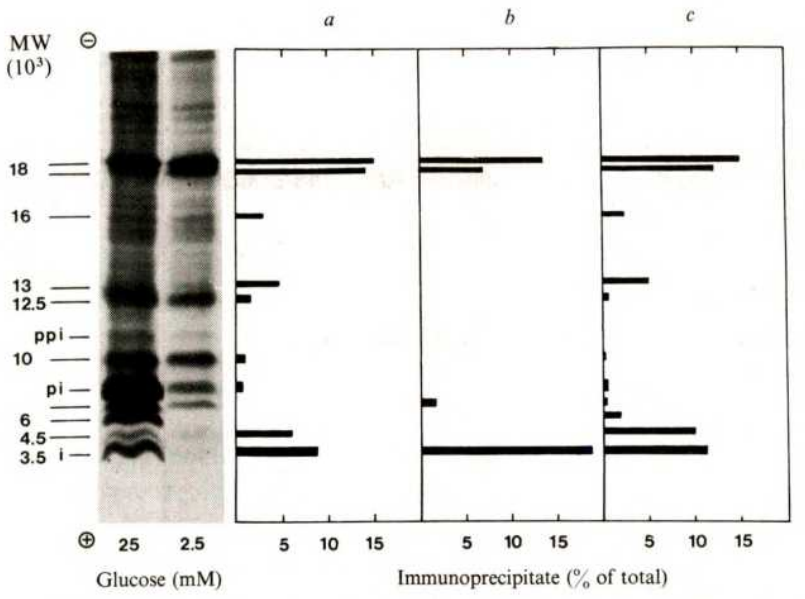

Fig. 2 Immunoprecipitation of newly synthesised islet proteins with various glucagon antisera. Islets (1,200) were incubated in Hanks' buffer containing 2.5 mM glucose and 600 μCi ^{35}S-methionine (Amersham) for 2 h at 37 °C. Islets were dissolved in 150 μl denaturing solution with boiling, the sample then being distributed to 12 slots of an SDS-polyacrylamide-gel[7,16] slab for electrophoresis and subsequent fluorography. The lower molecular weight range of one lane of the resulting fluorograph is shown at the left side in comparison to a sample incubated at 25 mM glucose. Protein bands as indicated at the margin (see also Fig. 1*a*) were eluted from excised gel pieces, either by shaking for 48 h at 37 °C in 2 × 2 ml of 0.01 M NH_4HCO_3 (proteins < 6,000-MW), or by shaking in 2 × 2 ml 25 mM Tris/200 mM glycine/0.1% SDS (proteins > 6,000-MW). Bovine serum albumin (BSA) (200 μg) was added to all samples as carrier. SDS was removed by dialysis against the SDS-free buffer for 72 h. Concentration of the samples was achieved by precipitation in 10% TCA or by lyophilisation (fractions < 6,000-MW). All fractions were finally dissolved in 0.7 ml NH_4HCO_3 (0.1 M). For immunoprecipitation 50-μl samples were incubated after addition of 150 μl of 0.1 M Tris-HCl, *p*H 7.6, 0.05 M NaCl, 0.01 M EDTA, 0.1% BSA with 1 μl glucagon antiserum NS (*a*) or CTS (*b*). Samples for set *c* were pretreated at analogous amounts with 2 μg tosylphenylalanine chloromethyl ketone-treated trypsin (Worthington) for 12 h at 37 °C in 0.5 ml 0.1 M NH_4HCO_3/2 mM $CaCl_2$. Reaction was stopped by addition of 5 μg phenylmethylsulphonyl fluoride (in absolute ethanol) and 10 μg carboxypeptidase B (Boehringer) was added for a further incubation period of 12 h at 37 °C. Reaction was finally stopped by boiling, samples were lyophilised and prepared for immunoprecipitation with antibody CTS as described above. Controls to which 10 μg of glucagon were added before the addition of the antiserum were always included. All samples were run as duplicates. After 24 h incubation the appropriate anti-IgG serum was added for double-antibody precipitation. Precipitates were washed in excess buffer containing 1% Triton X-100. Pellets were finally dissolved in 0.2 ml 3 M acetic acid and counted in 10 ml Aquasol (New England Nuclear). Data represent means of two different experiments (except for the 13,000 and 16,000-MW proteins). ppi, Preproinsulin; pi, proinsulin; i, insulin.

low molecular weight fraction co-migrating with iodinated glucagon (MW 3,500) and a somewhat slower migrating peptide (MW 4,500) exhibited immunoreactivity; to a lesser extent the 13,000-MW protein was also precipitated with antiglucagon serum. Whereas the 3,500-MW fraction reacted with the C-terminus specific antibody without enzymatic pretreatment (Fig. 2*b*) the 4,500 and 13,000-MW proteins showed such reactivity only after trypsin plus carboxypeptidase B-treatment (Fig. 2*b* versus *c*) and may thus carry a C-terminal extension on their glucagon moieties. On the basis of its estimated size and its immunological behaviour, the 3,500-MW peptide is regarded as intact glucagon, whereas the 4,500-MW glucagon-like component probably represents the proglucagon fragment described earlier[8]. The 13,000-MW protein, which might be contaminated by the adjacent band (prosomatostatin), may be an intermediate in the conversion process. Immunoprecipitation of the intact 18,000-MW peptides by the C-terminus-specific antibody was not unexpected, inasmuch as this antiserum will react with C-extended forms in conditions of antibody excess, presumably due to the presence of small amounts of non-discriminating antibodies (unpublished results).

To clarify the nature of the 18,000-MW component the labelled 18,000-MW protein was subjected to tryptic cleavage and two-dimensional analysis. The presence of the labelled peptides of glucagon in the tryptic digest would confirm the identification of this protein as proglucagon. Analysis of the C-terminal tryptic fragment(s) before and after treatment with carboxypeptidase B would allow the detection of an additional C-terminal basic amino acid, indicating the presence of an extension at this site. The 10,000-MW fragment which, as shown in Fig. 2, was found to be unreactive with the glucagon antisera, was included in this peptide analysis. The relevant peptide maps are presented in Fig. 3. It is evident from these maps that the 18,000-MW protein contained the N-terminal tryptic peptide (labelled with ^{3}H-phenylalanine, Fig. 3*c*, left panel) as well as the group of four peptides related to the C-terminal tryptic fragment of glucagon. This latter group of peptides, however, migrated to the positions of the respective ninhydrin-stained peptides of the glucagon carrier only if the tryptic digestion products were treated with carboxypeptidase B (Fig. 3*b*, left panel). Trypsin-treatment alone did not result in the formation of these ^{35}S-methionine-(Fig. 3*a*) or ^{3}H-phenylalanine-(Fig. 3*c*) labelled peptides of the glucagon-C-terminus, thus supporting the assumption that the C-terminus of the glucagon-moiety in this prohormone is extended by an additional sequence.

In addition, release of the N-terminal tryptic peptide of glucagon during digestion of the 18,000-MW protein with trypsin (Fig. 3*c*, left panel) shows that the glucagon sequence in this precursor is linked to its N-terminal extension by at least one basic residue.

Comparison of the maps of the 18,000-MW protein with those of the 10,000-MW protein (Fig. 3, left versus right panels, respectively) shows that these two proteins have many tryptic peptides in common, but that digests of the 10,000-MW fragment lack the corresponding glucagon-related peptides. These results agree with the immunoprecipitation data of Fig. 2, that is, the glucagon-related sequence was removed during the conversion of proglucagon to the 10,000-MW fragment.

Conversion of proglucagon

These results suggest that the breakdown of the 18,000-MW proglucagon to its 10,000-MW fragment should be accompanied either by the generation of a glucagon-containing fragment or by the formation of labelled glucagon itself. For a

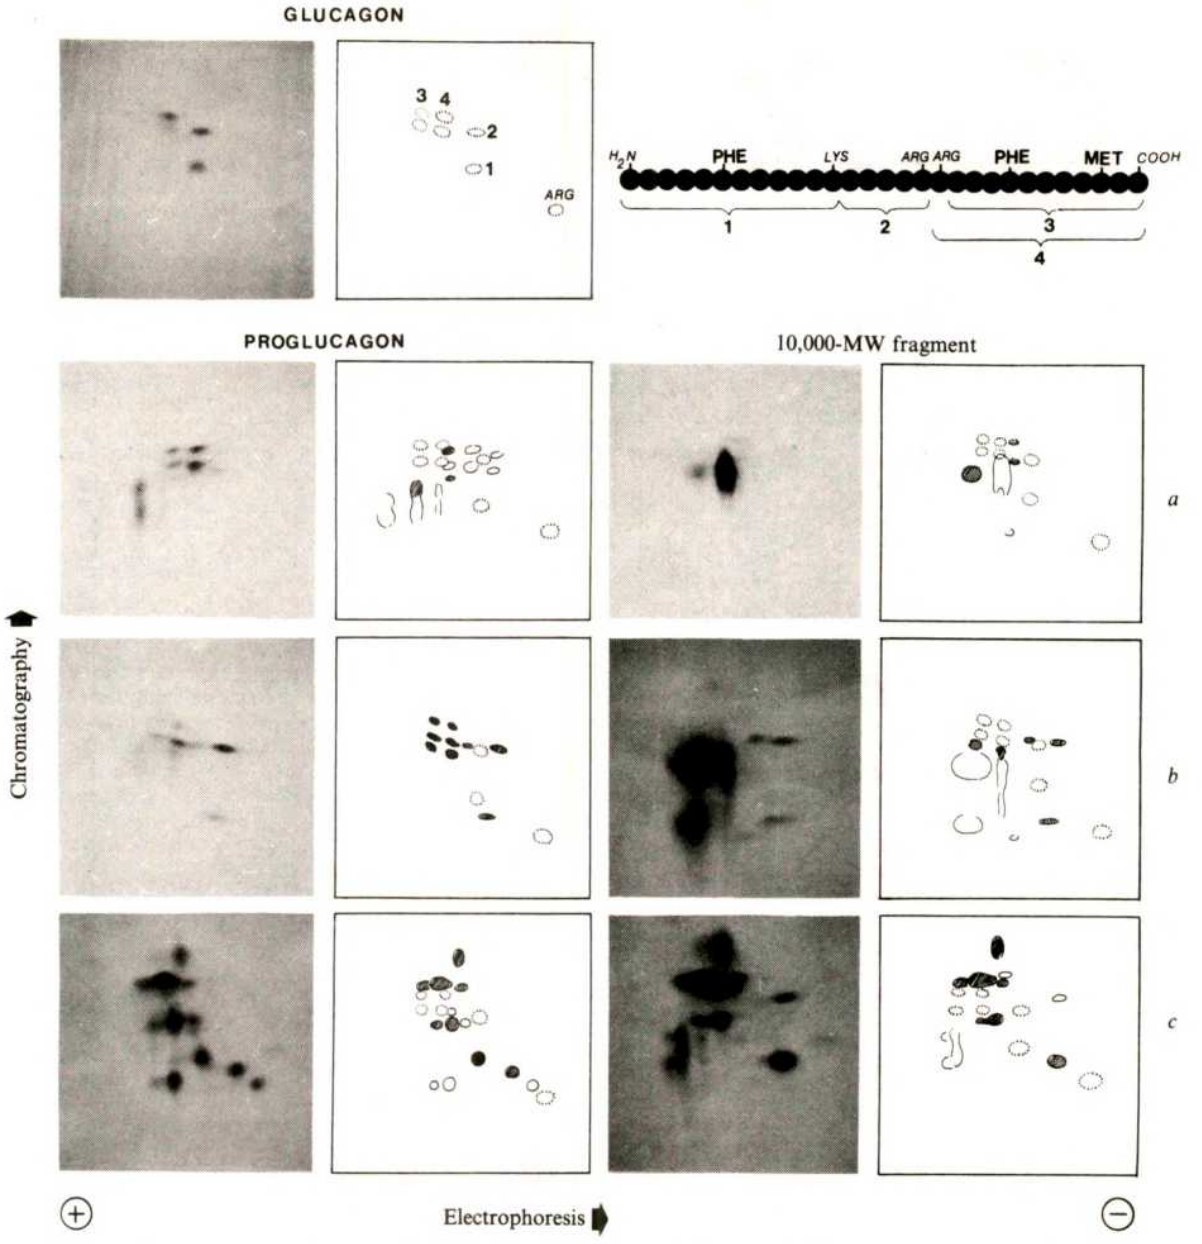

Fig. 3 Tryptic peptide analysis of proglucagon and its 10,000-MW fragment. 18,000 and 10,000-MW proteins, labelled for 2 h and eluted from the fluorographed electrophoresis gel, were treated with trypsin (*a* and *c*) or trypsin plus carboxypeptidase B (*b*) as described in Fig. 2 legend. The proteolytic digests were lyophilised, the tryptic peptides of 50 μg glucagon were added, and samples were electrophoresed on 20×20 cm cellulose-thin layer plates in 30% formic acid in the first and chromatographed in *n*-butanol/pyridine/acetic acid/water (60:40:12:48, v/v) in the second dimension. Plates were coated in PPO[34] and fluorographed. After exposure, plates were stained with ninhydrin reagent for detection of the peptides of the glucagon carrier. The figure shows at the upper left the pattern of the tryptic fragments of glucagon. Set *a* shows the fluorographed peptide maps of the tryptic digests of the respective ^{35}S-methionine labelled proteins, set *b* the trypsin + carboxypeptidase B digests of the same proteins, whereas under *c* the tryptic peptides of the ^{3}H-phenylalanine-labelled proteins are shown. Diagrams at the right side of the respective maps: dotted spots, ninhydrin-stained glucagon peptides (not visible on the fluorographs); hatched spots, peptides that are common to both proteins (proglucagon and 10,000-MW fragment); black spots, labelled spots on the fluorograph at the position of ninhydrin-stained tryptic glucagon fragment(s).

comparison of the kinetics of formation of proglucagon and its fragments, islets were 'pulse'- and 'pulse-chase'-labelled. The indicated bands were excised from the fluorographed gels and the radioactivity was quantitated by liquid scintillation spectrometry. Due to the similarity of the peptide patterns of proglucagon and the 10,000-MW fragment (Fig. 3) the presence of major contaminants in these bands is unlikely. Because of contaminating labelled peptides in the 3,500-MW band, labelled glucagon was quantitated after immunoprecipitation of the eluted material.

The data of the pulse-chase experiment illustrated in Fig. 4*a* show that the prohormone was converted into its slightly larger form within 10–30 min, and then began to decrease as label appeared in the 10,000-MW component. Immunoprecipitable, labelled glucagon was not detected in this experiment, however. With prolonged pulse-labelling (Fig. 4*b*) the expected saturation of incorporation of labelled amino acids into the two forms of proglucagon occurred within the first 60 min. Formation of the 10,000-MW protein began after a delay of 30–60 min and then continued almost linearly for the period up to 3 h. Labelled glucagon was detected in the eluate of the 3,500-MW band (Fig. 4*b* bottom panel), but its formation seemed to be somewhat slower than that of the 10,000-MW fragment. The 13,000-MW protein which showed some glucagon-like immunoreactivity (Fig. 2) was also included in these analyses. However, its kinetic behaviour did not clearly indicate whether this protein is a transient intermediate or a side-product of the conversion process (see discussion).

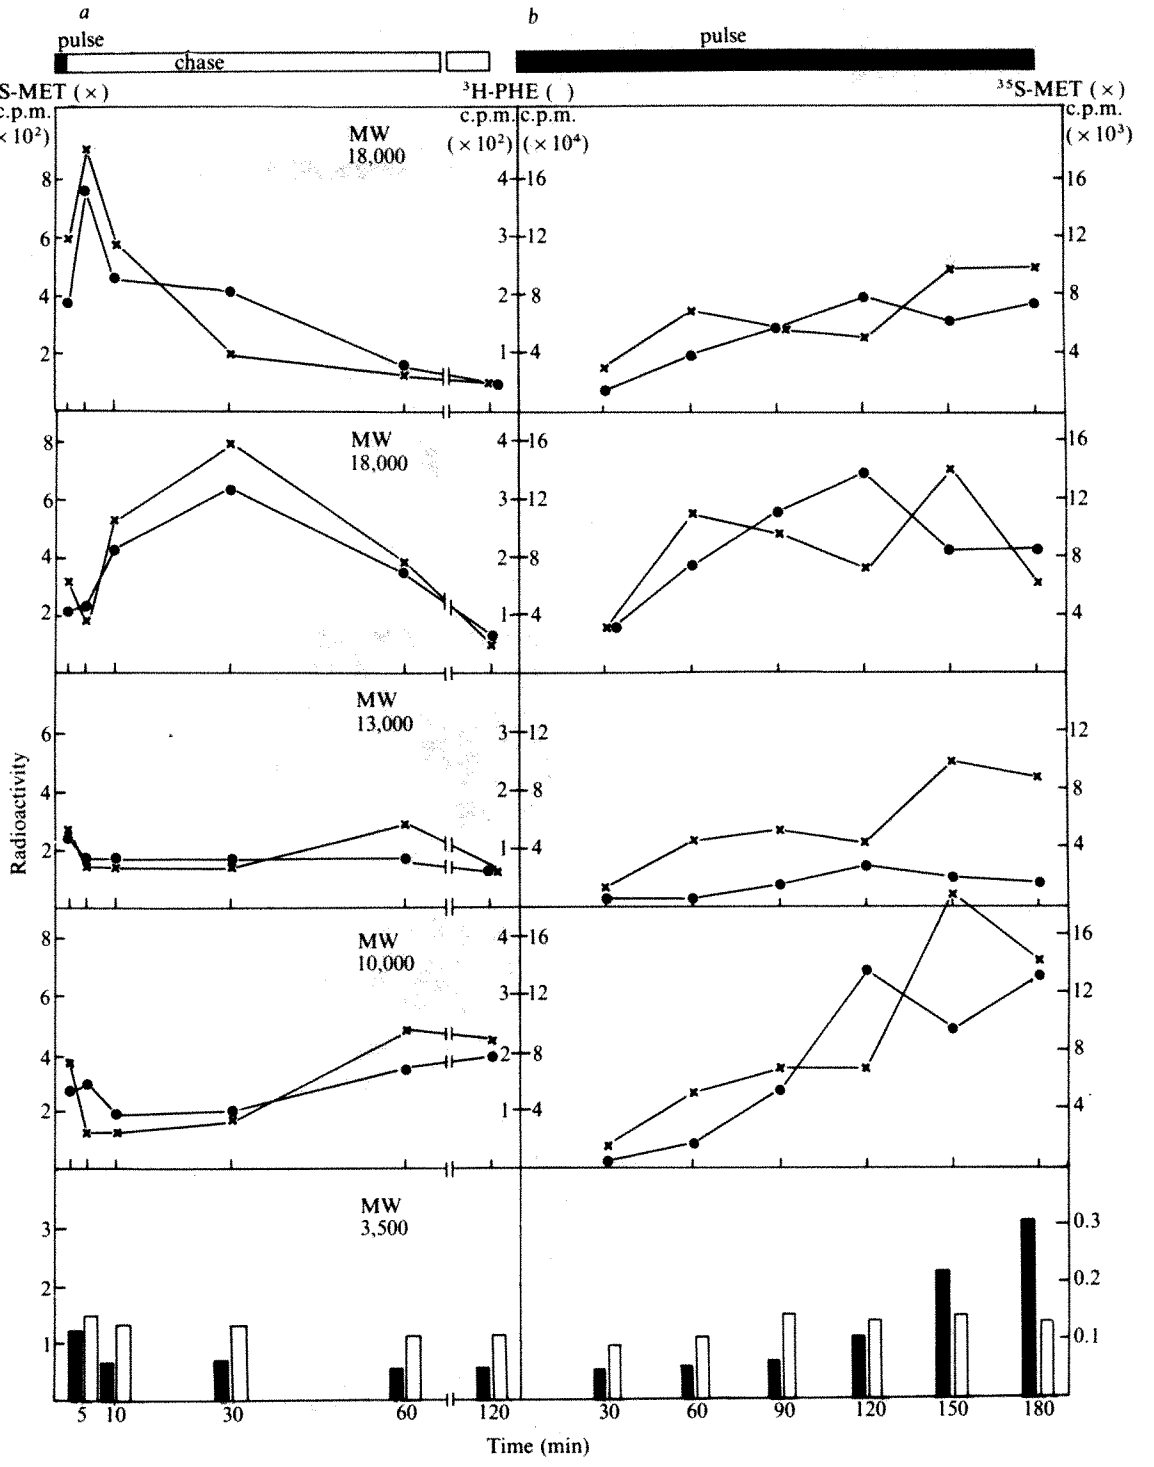

Fig. 4 Kinetics of formation and conversion of glucagon-related proteins. *a*, The pulse-chase experiments are those shown in Fig. 1*a* and *c* (see legend for details). *b*, For prolonged pulse-labelling samples of 100 islets were incubated for the indicated period and islet lysates were treated for electrophoresis as described before. The respective bands were excised from fluorographed gels, dissolved in 0.2 ml 30% H_2O_2 and counted in 10 ml Aquasol. The 3,500-MW protein was eluted from the respective band and immunoprecipitated as described in Fig. 2 legend. All data represent means of two determinations. ■, Immunoprecipitates; □, controls.

Comparison of the scales in Fig. 4 shows that the accumulation of label in the 10,000-MW fragment and in glucagon, respectively, differ by a factor of about 50. This discrepancy may be due to the presence of more than one methionine residue in the 10,000-MW protein, incomplete immunoprecipitation of glucagon or the accumulation of other glucagon-containing intermediates similar to the 4,500-MW peptide (Fig. 2) which were not included in these calculations. Furthermore, considerable losses of glucagon from the gel may have occurred during treatment for fluorography. Such losses have been found to be negligible for proteins in the range larger than 8,000–9,000 MW.

Quantitative aspects of prohormone synthesis in pancreatic islets

Pancreatic islets are composed of at least four different cell types each of which produces at least one known hormone, namely B cells (insulin), A cells (glucagon), D cells (somatostatin) and a fourth cell type which produces pancreatic polypeptide. The relative numbers of these cell types have been determined in

Table 1 Comparison of cellular composition and prohormone biosynthesis in pancreatic rat islets

Cellular composition			Prohormone synthesis			
					^{14}C-AA incorporation(c.p.m.)*	
Cell type	Hormone	% Of islet volume	Prohormone	MW	*a*	*b*
B cell	Insulin	56	Proinsulin	9,000	4,561 (66)	15,520 (87)
A cell	Glucagon	16	Proglucagon	18,000	1,766 (26)	1,566 (8)
D cell	Somatostatin	5	Prosomatostatin	12,500	200 (3)	287 (2)
PP cell	Pancreatic polypeptide	5	Pancreatic propolypeptide	—		
?	?		Unidentified prohormone	16,000	307 (5)	410 (3)

* Samples of 100 islets were preincubated for 2 h at 37 °C at 2.5 (*a*) or 25 (*b*) mM glucose. 20 μCi of a ^{14}C-labelled amino acid mixture (Amersham) was then added and incubation was continued for 20 min. Islets were washed, lysed and electrophoresed as described in the Fig. 1 legend. The respective bands were excised from the fluorographed gels and scintillation-counted (see Fig. 4 legend). Data represent means of four determinations. Relative prohormone synthesis is given in parentheses.

islets of several species, including rats[18,19]. Table 1 gives a synopsis of these data in comparison with the individual rates of biosynthesis of the prohormones identified thus far. As glucose has been reported not only to have a stimulatory effect on insulin synthesis but also an inhibitory effect on the synthesis of glucagon[20,21], prohormone synthesis was studied after preincubation of islets for 2 h at low (2.5 mM) and high (25 mM) glucose concentrations. To compensate for differences in amino acid composition, incorporation was measured with a mixture of ^{14}C-labelled amino acids. Although this experiment is based on some assumptions, the biosynthetic data compiled in Table 1 (right panel) correlate remarkably well with the proportion of the various cell types in rat islets (Table 1, left panel). Whereas proinsulin-synthesis was stimulated fourfold by preincubation at high glucose concentrations the formation of the other prohormones remained almost unaltered in agreement with our own previous findings (Fig. 2, ref. 11).

Discussion

On the basis of its kinetics of formation and processing, immunological analysis and tryptic peptide mapping, the 18,000-MW protein of rat pancreatic islets must be regarded as proglucagon. Final proof of this conclusion may come from the identification of the primary translation product of the respective mRNA as preproglucagon, the putative presecretory form which, if typical, should have a molecular weight of about 21,000. Preliminary evidence for such a translation production has been obtained by translation of RNA extracted from a human pancreatic endocrine tumour[35]. Although preproinsulin was detectable after pulse labelling of intact islets (Fig. 1, ref. 11), a similarly short-lived protein of the presumed size of preproglucagon was not detectable in the experiments reported here. The post translational modification of the 18,000-MW protein which results in an increase in its molecular size has not yet been identified. Glycosylation does not seem to be involved as judged from the very low incorporation of various labelled sugars, the lack of binding to various lectins, and the lack of any inhibition of its biosynthesis by tunicamcycin, a known inhibitor of protein glycosylation[22].

With regard to the position of the glucagon sequence within the prohormone, we can conclude that the hormonal sequence is not located at the C-terminus of the precursor. The arrangement

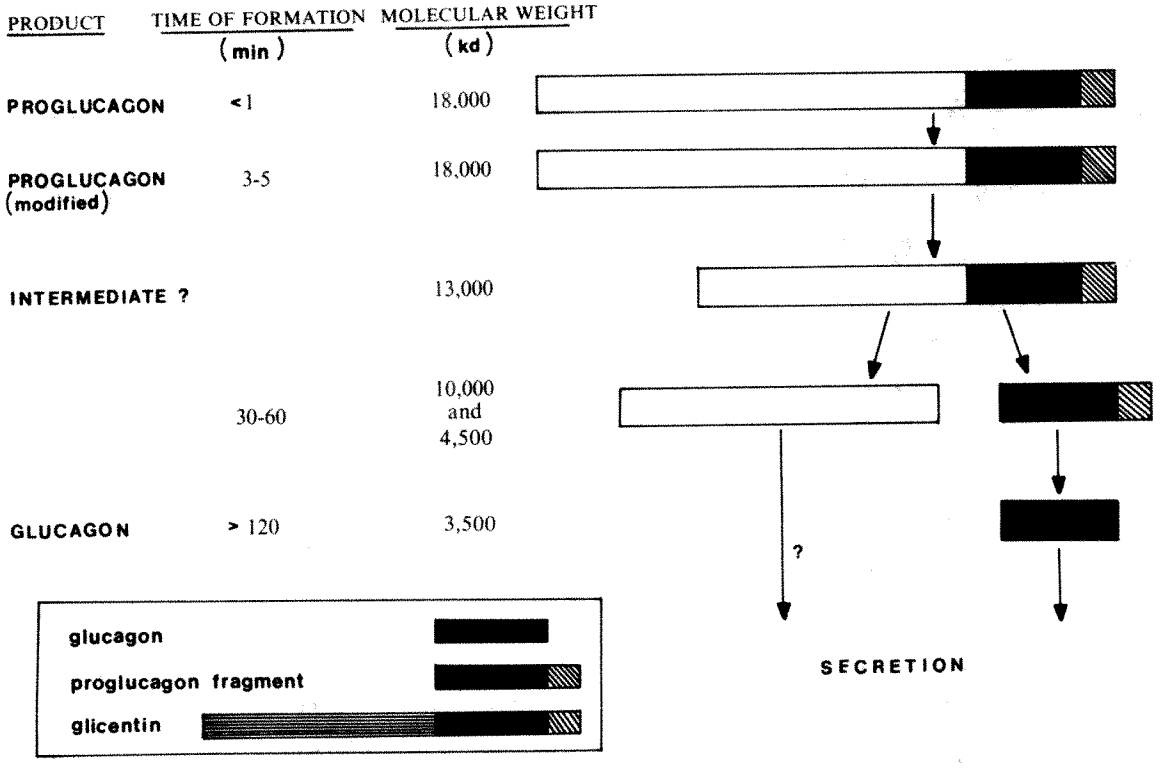

Fig. 5 Proposed scheme for the conversion of proglucagon to glucagon in pancreatic rat islets.

proposed in the scheme shown in Fig. 5 was chosen by analogy to the position of glucagon in glicentin[9], which has been demonstrated by immunohistochemistry to be present also in the rat pancreatic A cell[23]. Immunoprecipitation of the proteins listed in Fig. 2 with antiserum R-64, which is directed towards the non-glucagon portion of porcine glicentin[24], however, did not provide evidence for such immunoreactivity in proglucagon or any of its conversion products. This lack of reactivity may most simply be interpreted to indicate that larger forms of glicentin are poorly reactive with this antiserum or that some damage to the antigenic site has occurred during electrophoresis and elution of the peptides. Alternatively, it is possible that multiple genes for proglucagon-like peptides occur in the rat as is known to be the case with the insulin gene[12], and that glicentin is a minor component of the pancreatic alpha cell[10].

The sequential conversion of proglucagon can only be inferred to correspond to the scheme shown in Fig. 5. Our data support the conclusion that, in addition to glucagon, the 10,000-MW fragment is an end product of proglucagon conversion and might therefore represent a so far unidentified hormonal entity. It is not yet known whether this fragment is secreted along with glucagon. The 13,000 and 4,500-MW may represent intermediates in the conversion process, but they could also represent side-products of this process. Similar explanations may apply to several larger forms detected in glucagon-producing tumours[25], or in plasma in normal and various clinical conditions[7,25]. In any case, such intermediates or side products may have escaped detection during the 2-h period used in our biosynthetic experiments, whereas the short-lived prohormone might be overlooked during immunochemical studies on tissue extracts.

This prohormone, about five times the size of glucagon, might well contain additional hormonal sequences. Immunohistochemical techniques have suggested that additional hormones, including gastric inhibitory polypeptide[26,27], cholecystokinin[28] and even β-endorphin[29], may be present in pancreatic A cells. Our identification of a distinct protein as the prohormone of glucagon represents the first step in its further characterisation, which will ultimately answer the question of the possible presence of additional hormonal sequences, the question of the nature of the post translational modification as well as that on the mode of prohormone conversion.

The heavy chain of human histocompatibility antigen HLA-B7 contains an immunoglobulin-like region

Harry T. Orr, Doron Lancet, Richard J. Robb, José A. Lopez de Castro & Jack L. Strominger

Harvard University, The Biological Laboratories, Cambridge, Massachusetts 02138

The 88-residue fragment (ac-2) containing the second disulphide loop from HLA-B7 heavy chain is shown to have statistically significant homology with Ig constant domains, including both matches at invariant positions and conservative substitutions of structurally important residues. Thus, both the light chain (β_2m) and a segment of the heavy chain of HLA antigens may be structurally and evolutionarily related to immunoglobulins.

AMONG the products encoded by the major histocompatibility complex (MHC)[1–3] are the highly polymorphic antigens coded for by the H-2K and H-2D loci in the mouse and the HLA-A, HLA-B and HLA-C loci in man. Besides being target antigens during graft rejection, these proteins are important in the recognition of both virally infected[4,5] and chemically modified[6,7] syngeneic cells by cytotoxic T lymphocytes. These membrane antigens consist of a glycosylated heavy chain of MW 44,000 and a light chain of MW 12,000[8–11]. The larger chain is variant and is thought to be coded for by the MHC. The smaller chain is invariant and has been identified as β_2-microglobulin (β_2-m)

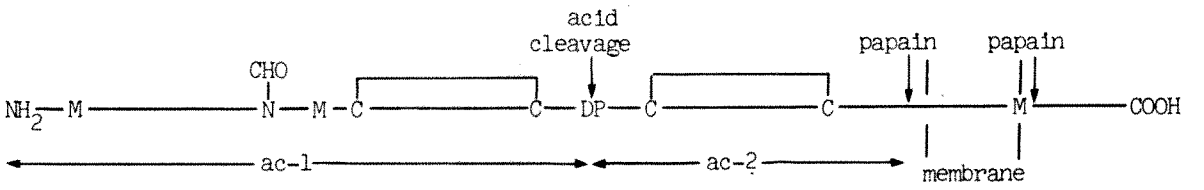

Fig. 1 Localisation of the ac-2 fragment within the HLA-B7 heavy chain. Papain-solubilised HLA-B7 heavy chain (MW 34,000) was purified from the human lymphoblastoid cell line JY as described elsewhere[21]. The ac-2 fragment was obtained by partial acid hydrolysis in 70% formic acid at 37 °C (ref. 19) followed by gel filtration. ac, acid cleavage fragment; CHO, carbohydrate moiety; M, Met; N, Asn; C, Cys; D, Asp; P, Pro.

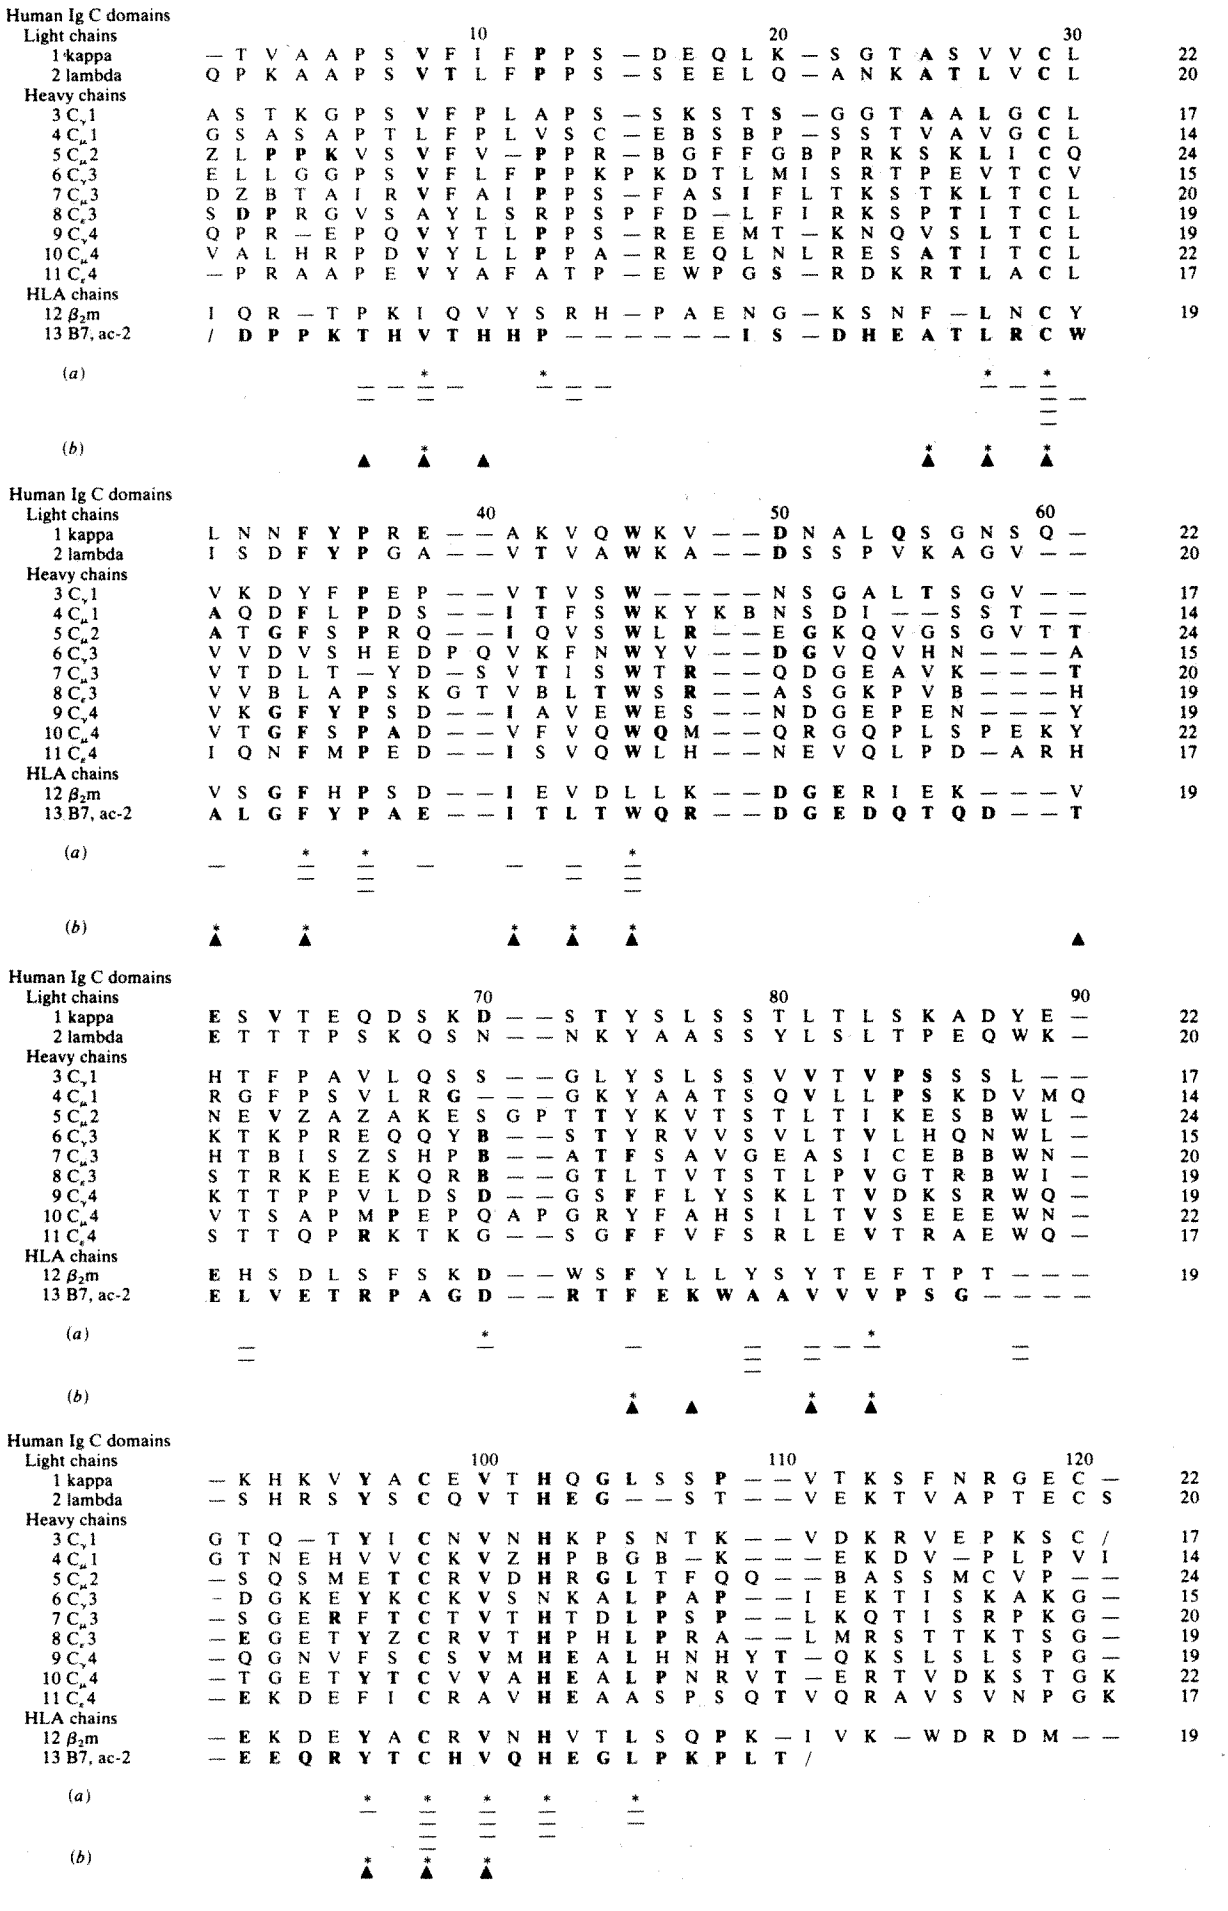
which is not coded for by the MHC. An interesting feature of β_2-m is its primary structural homology with immunoglobulin (Ig) constant domains[12,13]. As the constituent chains of many multi-subunit proteins are structurally homologous (for example, haemoglobins, immunoglobulins and many multi-subunit enzymes), it was tempting to speculate that the heavy chain of HLA-A and -B would contain segments resembling β_2m and therefore Ig-like domains. Such homology would also further support the notion of common evolutionary origins for the immunoglobulin and histocompatibility systems[14–16]. Early reports of HLA-A and -B similarity to Ig were based on indirect evidence such as overall subunit structure[17,18], susceptibility to limited papainolysis[18] and the arrangement[19] and size[20] of the intrachain disulphide loops. When preliminary data on the primary structure of the HLA-A and -B heavy chain became available, several authors reported sequence homologies with β_2m and various Ig domains[19,21–24]. However, all of these preliminary reports were based on short segments of the HLA-A and -B heavy chain.

In this article, the complete amino acid sequence of the 88-residue fragment (ac-2) containing the second disulphide loop of the HLA-B7 heavy chain is shown to display statistically significant homologies to Ig constant domains and β_2m. This homology is discussed in terms of its possible relation to structure and evolution.

Comparison of the ac-2 fragment of HLA-B7 and Ig constant domains

The ac-2 fragment comprises the COOH-terminal region of papain-solubilised HLA-B7 heavy chain (see Fig. 1). Sequence determination of papain-solubilised HLA-B7 heavy chain, including ac-2, is described in detail elsewhere[25,26]. The sequence of the ac-2 fragment was aligned with human Ig constant domains and β_2m[27–32] (Fig. 2; see legend for detailed procedure). These latter proteins are members of a single superfamily[32].



The significance of the sequence homology between ac-2 and Ig constant domains becomes more apparent by considering the positions involved: many of those are highly conserved among different Ig-like domains. The two cysteines (29 and 98) appear in all sequences of Fig. 2 and actually in all Ig domains, including the variable ones. Trp 45 is also very prominent, appearing in all Ig constant and variable domains. In the three-dimensional structure they are known to occupy a position at the centre of the domain, near the internal disulphide bridge, and probably have a role in chain folding (ref. 33 and refs cited therein). Notably, β_2m does not have this tryptophan, which is replaced by Leu 45. Val 100 and His 102 appear in all but one, Pro 36 appears in all but two and Val 8 appears in all but three sequences in Fig. 2. Of seven residues marked as particularly conserved (that is, they

The difference matrix[27] derived from the alignment of Fig. 2 is shown in the section below the diagonal line. Numbers represent per cent non-identity between pairs of sequences (including matches between a gap and any residue). All values except those involving ac-2 are reproduced from ref. 32. The numbers for ac-2 are calculated as upper limits, assuming that no identities occur beyond position 110. The numbers above the diagonal line are obtained by averaging the values of corresponding domains from different Ig chain classes. The numbers in the lowest row are averages of difference values between a particular sequence and all others. Values for a sequence with itself are excluded from all calculations.

appear in at least 80% of the Ig constant domains shown in Fig. 2), six also appear in ac-2 (Cys 29, Pro 36, Trp 45, Cys 98, Val 100 and His 102). In all, there are 30 positions in the Ig constant domain at which one residue appears in at least 50% of the sequences, the ac-2 fragment matches 14 of these residues. All of these residues are marked in Fig. 2.

Another interesting feature of the homology between ac-2 and Ig domains is revealed when the homologous residues are related to the observations of Beale and Feinstein[33] concerning the role of side chains in domain folding. These authors aligned residues occupying analogous positions in the crystallographic structures[34–36]. The resulting alignment for Ig domains and β_2m resembles very much that of Fig. 2, suggesting that sequence homology data for a new member may contain information on its tertiary structure. From their comparison several highly conserved features of Ig domain sequences and relationships to domain folding were identified. Of particular interest is that several of these features can be found in the primary structure of the ac-2 fragment of HLA-B7. Thus a dominant feature of Ig constant domains is that at some positions, substitutions are restricted within a group of hydrophobic amino acids (Phe, Ala, Tyr, Pro, Met, Val, Leu and Ile). The side chains of some of these residues are found to fill the internal space within the domain. Of 19 such residues in Ig domains, 15 are found in ac-2 (see Fig. 2). In Ig, some of these conserved residues form three hydrophobic clusters[33] which may be important in the nucleation of Ig chain folding. Most of the residues participating in the formation of such clusters appear in ac-2. These include all three residues in the first cluster (Val 8, Ala 31 and Val 100), three out of four in the second (Phe 34, Ile 41 and His 102) and two out of three in the third (Leu 27 and Val 81). Beale and Feinstein[33] further noted that many of these conserved positions correspond to the stretches of alternating hydrophobic residues characteristic of the β-sheet structure in Ig domains. Four such stretches seem to appear in ac-2, at positions 25–34, 41–45, 75–83 and 96–100. These features are illustrated in Fig. 3, depicting the human C_λ folding in relation to the ac-2-Ig homology. Of the five residues conserved in the C_λ domain (Fig. 3) and not found in ac-2, two, Trp 88 and Pro 313, are located in the loop portion of C_λ. Gaps have been inserted in the ac-2 sequence around these positions (Fig. 2). Therefore, these loops, if present in ac-2, may be shorter than the corresponding segments in Ig. In the light of the above, the ac-2 fragment of HLA-B7 has the potential of folding in a manner similar to that in Ig domains. Such a suggestion is in agreement with the high percentage of β-pleated sheet in the HLA-B7 antigen as seen by circular dichroism[37].

The matrix of differences[44] derived from the alignments in Fig. 2 is shown in Table 1. From these data it may be seen that ac-2 displays the same pattern of differences in its relation to all Ig sequences as does any other sequence in Fig. 2. Thus, ac-2 is not related to any particular Ig domain. The ac-2 fragment and β_2m are slightly more different from Ig domains than the latter are among themselves. Also, ac-2 and β_2m are marginally more similar to each other than they are to Ig domains. As it is not clear whether such differences are significant, it may only be concluded that the Ig–HLA and β_2m–ac-2 divergences occurred around the time of the C_H–C_L divergence and C_H domain duplication[32].

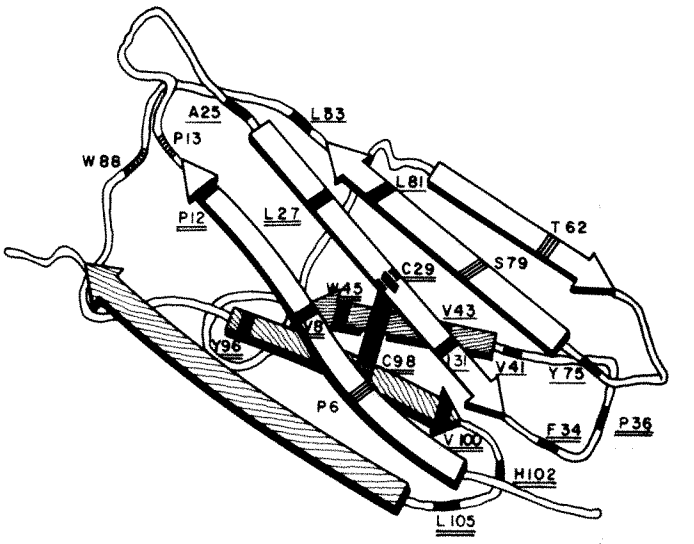

Fig. 3 The folding scheme of a constant Ig domain, as obtained by X-ray crystallographic studies of the Mcg λ human light chain dimer[36]. Arrows denote the location and direction of strands in the β-pleated sheet structure (open, the four-stranded sheet; hatched, the three-stranded sheet). The dark bar between positions 29 and 98 represents the intradomain disulphide bond. Numbering is according to Fig. 2. Single letter coded[44] residues are those appearing in the Mcg light chain sequence, except L105 which appears in most Ig constant domains and ac-2 but is deleted in Mcg. Solid bars denote residues that are invariable in all or most Ig constant domains[32] and appear in the second disulphide region of HLA-B7 (doubly underlined) or restricted to a group of hydrophobic residues in all of the above (underlined). Residues which are highly conserved in Ig constant domains[32], but different in the second disulphide region of HLA-B7, are indicated by the hatched bars. Residues identified by the single letter code[44] are from the Mcg sequence.

To establish the statistical significance of the homology between ac-2 and Ig constant domains, the Z factors (as defined in ref. 28) for some pairs of sequences in Fig. 2 were calculated (Table 2). Such a procedure was used to classify proteins into superfamilies representing a minimal level of relationship between sequences[31]. Values $Z > 6$ suffice to indicate that any two sequences belong to the same superfamily, while $Z > 3$ is sufficient when some functional relationship is known to exist between two proteins[31]. The Z values obtained for the ac-2 fragment with β_2m and seven Ig constant domains are greater than 6 (Table 2). Thus, ac-2 is a new member of the previously established superfamily of Ig constant domains and β_2m[28]. The Z values of ac-2 with a variable Ig domain are as low as those found in comparisons of Ig constant with variable domains (Table 2 and ref. 28).

Fig. 2 The alignment of the ac-2 fragment of HLA-B7 with the human-derived sequences of the superfamily of Ig constant domains and related proteins. Ig sequences from other species were not included since interspecies differences are smaller than those between different classes or homology regions[32]. A computer program AL04 (equivalent to ALIGN, ref. 30) was used, equipped with a core memory saving modification that enabled us to run it on a Data-General Nova 1200 minicomputer. AL04 is based on the algorithm of Needleman and Wunsch[45] which affords the systematic introduction of gaps in both sequences so as to maximise the homology score. As a criterion for the 'goodness of fit' of each matched pair of residues, a scoring matrix[27] was used, whose elements are related to the tendency of those residues to replace each other in many homologous proteins, as well as to their respective abundances and mutabilities. The actual matrix was an updated version for an evolutionary distance of 256 accepted point mutations per 100 residues[46]. In the alignments presented, gap formation was controlled by a penalty of 2 for each break and a bias factor of 2 added to all matrix elements (compare ref. 30). As in all cases gaps appeared only in ac-2, it was possible to reproduce here both the sequences and the numbering system of alignment 27 of ref. 32. The ac-2 sequence was added based on representative alignments following the majority where differences occurred. Boldface letters signify residues at which a particular sequence is identical to ac-2 (ac-2 residues are all boldface irrespective of identities). The number of identities scored by each sequence is given in the extreme right column. Names of sequences designate the Ig heavy chain class and the homology region (for the γ chain, those are 1, 3 and 4). Conserved residues in the Ig sequences, including β_2m, are indicated in *a* by (−), occur in 6–7/12; (=), occur in 8–9/12; (≡), occur in 10–11/12 and (≣), occur in 12/12 sequences; *b*, (▲), indicates positions of hydrophobic residues (Phe, Ala, Tyr, Pro, Met, Val, Leu, Ile or Cys) whose side chains are found to fill the internal space in a folded Ig domain[33]; (*) indicates that an identical (*a*) or homologous (*b*) residue occurs in ac-2. Residues are indicated using the single letter code[44].

Table 2 *Z* factors

$C_\varepsilon 4$	6.4	—	—	—
V_κ	0.6	1.1	1.9	1.2

The statistical alignment scores for ac-2 and several Ig domains. The value of the statistical score, Z, is calculated according to ref. 28. In short, alignment scores were calculated as described in Table 1 legend for the pairs of sequences in question. Then, using the same alignment procedure and gap-controlling parameters, alignment scores were calculated also for one of the sequences with 50 randomisations of the other. $Z = (S - \mu)/\sigma$ where S is the score for the actual protein and μ and σ are the mean and standard deviation for the distribution of scores for randomised sequences. Z is a measure of how likely is a value S to arise by chance; for example, Z equal to 3 and 6 correspond to probabilities of 10^{-3} and 10^{-9} respectively, for this to occur. For comparison some Z values are given for pairs of Ig domains. (—), not determined. V_κ is human AG variable Ig sequence reproduced from ref. 32.

Discussion

The ac-2 fragment of the heavy chain of HLA-B7 is approximately the same size as an immunoglobulin constant domain and, like the latter, contains a disulphide loop of 55 residues. The data presented here establish unequivocally that the heavy chain of HLA-B7 contains an Ig-like region. The features which relate the ac-2 sequence to that of Ig constant domains are summarised as follows: (1) The number of amino acid residues between the two cysteines is very similar to that found in Ig constant domains. (2) They are identical at the three invariant residues—the two cysteines and a tryptophan. (3) They have a high degree of homology at conserved hydrophobic residues. In Ig, some of these participate in the formation of clusters of hydrophobic side chains which are thought to be important in chain folding. (4) More homologous residues are found near the two cysteines of ac-2, as is the case when two different Ig constant domains are compared. And (5), short stretches of alternating hydrophobic residues occur and correspond to segments of β-pleated sheets in Ig. The latter points suggest that there may also be three-dimensional similarities between ac-2 and Ig constant domains. (6) Statistical analysis of the homologies between the ac-2 fragment of the HLA-B7 and Ig constant domains clearly show them to be members of the same superfamily, as defined previously[28]. Such an assessment is the first quantitative indication that the HLA-B7 heavy chain is related to Ig.

One interesting conclusion which can be drawn from the sequence data is that there is an evolutionary relationship between the second disulphide loop region of HLA-B7 heavy chain and Ig constant domains. The occurrence of an Ig-like region in an MHC product suggests that the humoral and cellular arms of the immune system share a common ancestral development. Since cellular immunity phylogenetically predates humoral immunity[38], it would be extremely interesting to determine if primitive cellular responses involve HLA-A and -B-like proteins and eventually explore the structural nature of such proteins. Such studies should lead to a better understanding of the ancestral relationships between the two arms of the immune response. The sequence homology data presented here suggest that the HLA-Ig divergence as well as that of ac-2 and β_2m occurred around the time of Ig C_L and C_H divergence.

The presence of an Ig-like region in the heavy chain of HLA-B7 may have implications concerning the organisation of the genetic material encoding this polypeptide. In the mouse, a two gene–one polypeptide arrangement has been suggested for the H-2K and H-2D antigens. Both limited sequence data[39] and the sharing of a public specificity by each of the private specificities of a given haplotype[40] have been taken to indicate a two gene–one polypeptide arrangement for histocompatibility antigens. Considering the current state of knowledge of the organisation of Ig genes[41,42], the Ig-like region also adds credence to the possiblity that a similar two gene–one polypeptide arrangement may exist for HLA-A and HLA-B heavy chains. The final elucidation of such questions must await additional amino acid sequence data of several specificities from multiple species and studies at the DNA level.

Using a tentative sequence of ac-2[43], A. Munro and A. Feinstein, independently (personal communication) noted that this region of HLA-B7 has structural similarities to an Ig constant domain.

Amino acid sequencing was performed utilising the facilities of the Protein Chemistry Laboratory at Harvard University. We thank M. L. Coe and T. Kostyk for technical assistance. A compact group of four QSOs with two appearing physically associated

C. Hazard*, H. C. Arp† & D. C. Morton‡

The objective prism plates from the UK Schmidt telescope taken under good seeing conditions can reach to about magnitude +20 and provide ideal material for studies of the distribution over the sky. We have carried out a detailed search of one of these plates centred on RA 11 h 40 min, dec. 11°00′ N in a preliminary investigation of QSO clustering on scales up to several arc min. Most of the 200 or so QSO candidates noted during this search are emission line objects and definite QSOs but several show no obvious emission features and were selected solely on the basis of their noticeably blue continuum spectra. Subsequent high-resolution spectroscopic observations show that while some of these blue continuum objects are low redshift QSOs a significant fraction are white dwarfs and blue compact galaxies. Allowing for these misidentifications we estimate that a total of 200 QSOs (~six QSOs per square degree) is a conservative upper estimate for the number of genuine QSOs to be found on this plate using our particular selection criteria. With a surface density of about six QSOs per square degree, pairings of QSOs at separations of several arc min are relatively common on a single plate and an individual pair is significant at the 1% level only at a separation of $\lesssim$10 arc. To be considered significant in its own right, a single association at separations of the order of 1 arc min requires a grouping of at least three objects. We report here the most striking association we noted satisfying these conditions, a compact group of four QSOs within a diameter of about 4 arc min. A physical association between two of the QSOs is suggested.

The field of this group of QSOs (denoted a, b, c and d) is shown in Fig. 1. The fifth object (e) is the radio QSO 1146+111 which has a redshift $z = 0.86$ (ref. 1); it shows no obvious emission features and from the objective prism data alone would have been considered only as a possible QSO candidate. There are no other probable QSO candidates in the area shown. Positions accurate to 1 arc min are given for all five QSOs in Table 1 together with O-magnitudes measured from the Palomar Sky Survey prints[2]. Adopting a value of 200 for the total number of QSOs in the 36 square degree plate and assuming them to be randomly distributed, the estimated probability of finding, on this one plate, four or more QSOs within a 12 square arc min area is $\lesssim 6 \times 10^{-5}$. This represents only about a 10% probability of finding such a grouping in a search of the whole sky and strongly suggests that the group is by no means a chance association. An objection to this estimate is that it is strongly influenced by the choice of a 12 square arc min area which has been chosen to fit the particular association. However, when the group was first discovered, the main reason for our believing that the association could be physically significant was the remarkable similarity of the objective prism spectra of a, b and c, all three of which show a single emission feature at roughly the same position in the spectrum, thus suggesting that they might have similar redshifts. Object d, however, which shows two clear emission lines which were identified as Ly-α and C IV at a redshift $z \approx 2$, had clearly a different redshift to other members of the group.

Spectroscopic observations on the five objects in Table 1 were carried out in January 1979 with the 200-inch telescope on Mount Palomar. The results of these observations are summarised in Table 2. Some preliminary observations at the Anglo-Australian Telescope in February on b, c and d gave results which agree with the Palomar observations but observations scheduled in April to obtain more detailed spectra were unfortunately clouded-out. The spectroscopic observations confirm the general inferences drawn from the objective prism data (although object a has clearly varied in brightness since the epoch of the Sky Survey), and strongly support the idea that objects a and c at least do not represent a chance association. Although the signal-to-noise ratios of our data are too low for an accurate comparison of their spectrum, the separation of 2.5 arc min is far too large to allow them to be interpreted as gravitational lens images, the favoured interpretation of the pair of QSOs 0957+561 A, B, which also have identical redshifts but are separated by only 6 arc s (ref. 3). The best redshift estimates

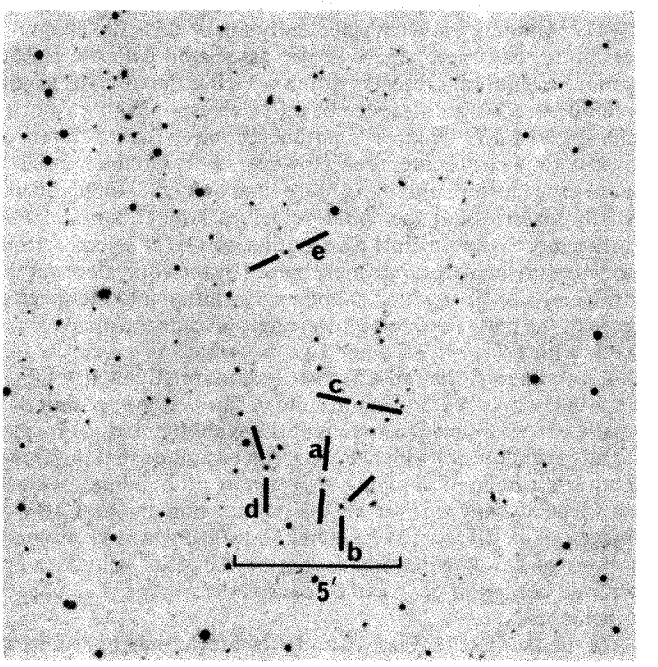

Fig. 1 An enlargement from the National Geographic Society–Palomar Sky Survey O-print of the region around the group of QSOs (a, b, c and d). Object e is the radio QSO1146+111. The 5 arc min scale shown corresponds to the angle subtended by 1 Mpc at a redshift $z = 1$. ($H_0 = 100$ km s^{-1} Mpc^{-1}, $q_0 = 1$). Reproduced courtesy Hale Observatories.

Table 1 Positions and magnitudes (epoch 1950) from the Palomar Sky Survey Prints

Object	Right ascension			Declination			O-magnitude*
	h	min	s	h	min	s	
a	11	46	09.84	11	04	38.0	18.5
b	11	46	07.58	11	03	49.4	17.9
c	11	46	04.92	11	06	57.1	18.6
d	11	46	16.96	11	05	05.8	17.6
e	11	46	13.42	11	11	39.9	17.9

* Magnitudes are accurate to ±0.3 mag.

Table 2 Spectroscopic data

Object	Magnitude* (V_{5000})	Redshift z	Emission lines observed
a	19.5	1.01 (1.010±0.001)†	C III], [C II], Mg II
b	18.0	1.10	C III], [C II], [Ne IV], Mg II
c	18.9	1.01 (1.011±0.001)†	C III], [C II], [Ne IV], Mg II
d	18.1	2.12	Ly-α, O I, [O IV], C IV, C III]
e	18.5	0.86	[C II], Mg II, He II

* Because of poor photometric conditions the magnitudes are accurate only to a few tenths of a magnitude.

† The figures in braces are the best redshift estimates for objects a and c.

for a and c give a maximum projected velocity difference of 450 km s^{-1}, while the angular separation of ~2.5 arc min corresponds to a projected physical separation of 500 kpc (H_0 = 100 km s^{-1} Mpc^{-1}, $q_0 = 1$). These are typical values for cluster galaxies and the natural inference is that a and c are both members of the same galaxy cluster. Their discovery therefore indicates that the QSO phenomenon is not confined to one highly pecular galaxy in a cluster.

The status of object b is not clear, for the probability of finding an additional two QSOs within a 5 arc min circle (~1 Mpc at $z = 1$) containing a and c is sufficiently small ($\lesssim 5 \times 10^{-4}$) that the possibility that one of these is also associated with the cluster cannot be ignored. Object b with $z = 1.10$ is the obvious candidate but a redshift difference of 0.09 corresponds to a velocity difference of 13,000 km s^{-1}, an unacceptably high differential velocity for a cluster member. However, as T. Gold has pointed out to us, a cluster containing more than one QSO might be unusually massive and the virial velocities larger than average. Furthermore, the redshift distribution of QSOs selected from objective prism plates is strongly biased by the equivalent widths of the emission lines which happen to be shifted into the spectral range of the plates and this bias strongly favours the discovery of QSOs with $1.7 \lesssim z \lesssim 3.2$ when Lyα is visible. As a result of this bias and the intrinsic redshift distribution, relatively few QSOs are found with $z \lesssim 1.7$. That in spite of this bias the redshift of b is within 10% of that of a and c is perhaps another indication that it is not a random coincidence. As it can be argued that this is just another example of applying '*a posteriori* probabilities' we will not speculate any further on this matter nor on the status of object e. The discovery of further statistically significant associations of QSOs with similar large differential velocities are required before object b can be considered other than a chance coincidence.

We thank Misses F. Hazard and F. Short for their assistance in searching the objective prism plate and for measuring the accurate optical positions.

IUE UV spectra of the clumpy irregular galaxy MKN297

P. Benvenuti*, C. Casini† & J. Heidmann‡

* ESA Villafranca Satellite Tracking Station, Madrid, Spain
† Istituto di Astronomia and Istituto di Fisica dell' Università, Milan, Italy
‡ Observatoire de Paris, 92190 Meudon, France

Clumpy irregular galaxies are made up of 5–10 bright clumps loosely scattered in a common envelope, have excess near-UV radiation and are giant compared with classic irregular galaxies[1,2]. Clumps are apparently ~100 times more massive than giant H II regions such as 30 Doradus or NGC604 (ref. 3). To get an insight into their properties we have obtained UV spectra using the IUE satellite of one of the clumpy irregular galaxies, MKN297. The UV continuum spectrum thus obtained follows a power law and is steeper (fainter at short wavelengths) than that of a classic irregular or late galaxy. The 155 nm intrinsic luminosity is 400 times larger than that of 30 Doradus. The observed absorption lines can be attributed to early O or B stars, and no emission lines are detectable. We report here that the spectra indicate that each of the clumps contain ~10^4 early stars and are supergiant H II regions in which exceptional bursts of star formation take place.

We have obtained two low dispersion spectra (0.6 nm resolution), one at short (λλ 115–195 nm) and one at long (λλ 190–320 nm) wavelengths, using exposure times of 290 and 310 min. The 10×20 arc s slit was used at PA 27°. The central clump, about half of each of the two next strongest clumps and a few other fainter clumps fell within the field of view of the slit. Without a photometric map of MKN297 it is difficult to evaluate the proportion of light which enters the slit; from Arp's photograph[4] we assume that 50% light and five clumps are present.

The main features of MKN297 (NGC6052) which have already been investigated[3,5–12] are given in Table 1.

Figure 1 shows the UV spectrum smoothed with a 5 nm band and Fig. 2 shows two unsmoothed sections. The continuum has the shape of a power law; when corrected for absorption in our Galaxy with Nandy *et al.*[13] reddening curve, the spectral index is −1.69. It is steeper than those observed for late galaxies or classical irregular galaxies, such as the Large Magellanic Cloud[14] and NGC4449 (ref. 15).

The colours, neutral hydrogen content, Hβ flux and radio continuum flux densities allows a few magnitudes to be estimated for the internal absorption in MKN297; however, these values are not enough to flatten the spectrum.

A steep UV spectrum can be accounted for by an *ad hoc* star population. The absorption lines in our spectrum indicate that

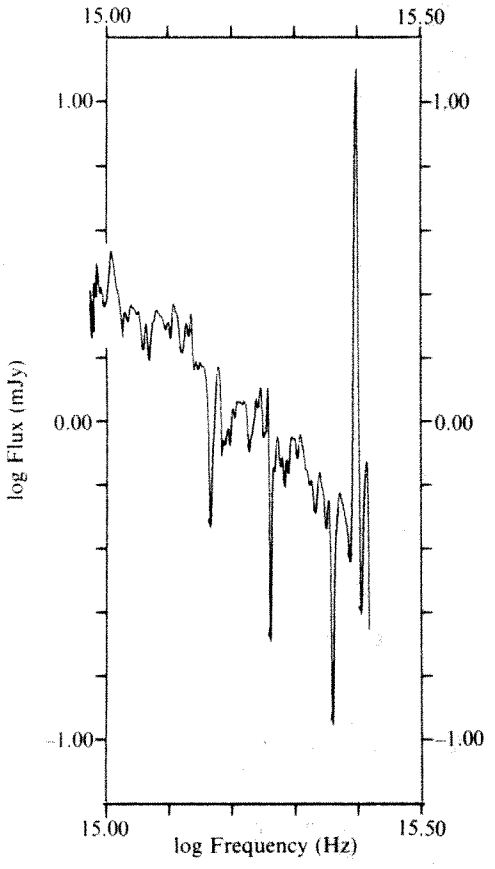

Fig. 1 Smoothed UV spectrum of MKN297. The high frequency spike is due to geocoronal Lyα and the three strong absorptions are reseau marks.

they are produced by stars earlier than AO and, though more like class V stars, they do not exclude class I. Thus, using UV spectra from the Jamar *et al.*[16] Catalogue, corrected for galactic absorption[13], we see in Fig. 3 that fits to the UV spectrum of MKN297 can be obtained by: (i) 3.0×10^4 07 V stars at the high frequency end; (2) 1.3×10^9 A5 V stars combined to the above 07 V stars for wavelengths up to 200 nm; (3) 1.5×10^5 B5 to B8 I stars for most of the UV range.

An attempt has been made to fit the spectrum with a population of 07 and AO V stars plus an internal reddening. The main conclusion is that the stellar flux cannot be reddened using the 'normal' curve of Nandy *et al.*[13] because, even at low colour excesses, it produces a detectable 2,200 Å absorption that is not present in our spectrum. This can be explained if the 2,200 Å

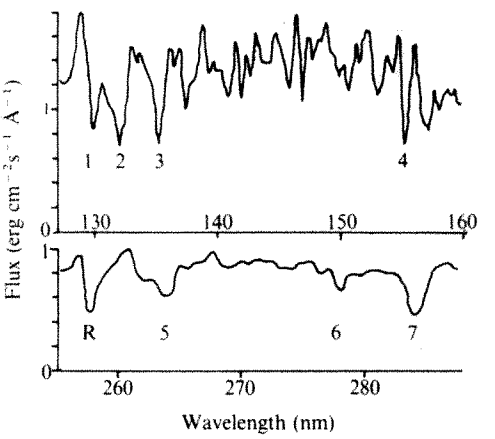

Fig. 2 Two sections of the 'net' spectrum in the short and the long wavelengths. The numbers 1–7 are those given in Table 2 for identification purpose. *R* is a reseau mark.

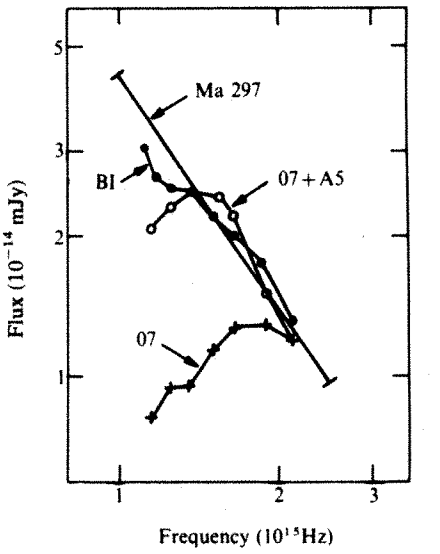

Fig. 3 The UV spectrum of MKN297, corrected for absorption in our Galaxy (straight line) compared with the different star populations given in the text.

feature were mainly due to dust scattering and if we took into account that we are observing the whole region where the scattering takes place. Allowing for this, a reasonable fit has been obtained with a mixture of 4×10^5 07 stars, 2.5×10^9 AO V stars and an internal reddening of $E^i(B-V)\sim0.5$.

Therefore, a clump apparently contains $\sim10^4$ early stars.

An interesting result is obtained by comparing the UV emission of MKN297 with that of the giant H II region 30 Doradus. Using the 155 nm map of 30 Dor obtained by Korneef[17], the de Vaucouleurs *et al.*[18] galactic absorption and the Nandy *et al.*[13] curve one gets a flux density of 30 Dor corrected for galactic absorption which, when transferred from its 50 kpc distance to that of MKN297, is 400 times less than the one we observed for MKN297. A clump is thus ~100 times more powerful than a giant H II region.

Absorption lines together with an indication of their quality are listed in Table 2. Two lines may be attributed to interstellar absorption in our galaxy: O I λλ130.1 and 135.2 and C IV λ155.0. nm. The others correspond to the redshift of MKN297.

Spectral features typical of stars from late O to AO are visible: Si IV λ140.0, C II λ133.5, C IV λ155.0, Fe II (8) λ162.0, Fe II (3) λ234.0 nm.

Table 2 Identification of absorption lines in the UV spectrum of MKN297

Measured λ(Å)	Corrected λ(Å)	Identification (main contributors)	λ_0(Å)	No. in Fig. 2	Comments
1,238	1,219	Lyα	1,216		
1,256	1,236	N V	1,241		
1,301	—	O I	1,302	1	Galactic
1,321	1,300	Si III	1,299	2	
1,352	1,331	C II	1,335	3	
1,408	1,386	Si IV:	1,398		Doubtful
1,552	—	C IV	1,549	4	Galactic
1,570	1,546	C IV; Si II:	1,549; 1,533		
1,646	1,620	Fe III; Al III; Fe II; He II	1,600÷1,640		Broad feature
1,701	1,675	Al II; Fe II	1,671; 1,675		
1,922	1,892	Fe III	1,886÷1,897		Several multiplets
1,948	1,918	Fe III:			Doubtful
2,026	1,994	Fe III:			Doubtful
2,340	2,304	?			Doubtful
2,373	2,336	Fe II; Cr II	2,340		Several multiplets
2,622	2,582	Fe II	2,578		Broad feature
2,640	2,599	Fe II	2,599	5	Broad feature
2,783	2,740	Fe II	2,739	6	
2,841	2,797	Mg II	2,799	7	
2,887	2,843	Mg I	2,852		

The Fe II and other singly ionised metal feature at λ240.0 which is a strong feature in stars later than AO V is not visible. The Mg II λ280.0 and Mg I λ284.0 nm lines are not particularly strong, suggesting also types not later than A.

In the visible, du Puy and de Veny[5] observee Ca II λ393.3 nm and some Balmer lines, which also correspond to early types.

The identifications are consistent with the presence of hot main sequence stars. The λ234.0 line favours class I–II stars, but has also been observed in class IV stars[19]. Other features corresponding to bright stars, Fe III (51) λ192.0 and the wide dip from λ180 to 215 (ref. 20) are dubious.

The presence of λ155.0 and the absence of λ240.0 are also consistent features for class I stars.

Using the criteria of Jaschek *et al.*[21], the r_1, r_2, r_3 values calculated from flux densities at λλ141.0, 155.0, 158.0, 162.0 nm after correction for absorption in our galaxy yield an integrated spectral type B5 V. A further internal absorption $E^i(B-V)=0.6$ would yield a type B2.

The r_5 ratio of flux densities at λλ240.0 and 274.0 nm of Cucchiaro *et al.*[22] for A stars leads also to a faint luminosity class.

There are no emission lines in our UV spectrum of MKN297, contrary to the visible case[5,6]. With the hypothesis that the gas in the clumps has physical conditions similar to those of H II regions, the expected intensity ratio betweeen, for example, the C III] 190.7–190.9 nm lines and the [O II] 372.7–272.9 ones is found to be too small to give a detectable signal at ~191 nm.

Accretion powers the brightest stars

G. T. Bath

Department of Astrophysics, University of Oxford, South Parks Road, Oxford, UK

The brightest known stars in external galaxies are the Hubble–Sandage variables. These are normally assumed to be hot, massive, single stars evolving either towards or off the main-sequence. An alternative model is developed here involving binary mass transfer and accretion on to main-sequence stars. In this case the Hubble–Sandage variables are a third, and presumably final, class of binary in which accretion generates the bulk of the radiation observed. The other two classes are binaries containing an accreting white dwarf (cataclysmic variables)[1,2] and an accreting neutron star or black hole (binary X-ray sources)[3,4]. Accretion disk models developed in these two cases can be scaled directly to treat the main-sequence case. One of the most complex objects in our own Galaxy is the η Carina nebula, rivalling in this respect the Orion Nebula and the Crab. I suggest below that η Can itself is an accreting main sequence star whose explosive outburst in the nineteenth century was caused by runaway mass accretion.

The Hubble–Sandage variables form a class of luminous, blue, irregular variable stars. In the original Hubble–Sandage study[5] five variables in M31 and M33 were investigated to determine their group properties for use as distance indicators. The spectroscopic properties of these variables have been extensively studied[6,7], and the optical variability of eight group members has been discussed elsewhere[8].

The main class characteristics are high luminosity, blue colour indices and irregular variability on time scales ~1 yr with amplitude ≲2 mag. The maximum visual magnitudes are between −8 and −11 (visual luminosities $\sim 10^{39}$ erg s^{-1}). Gravities are low[6]. The spectra exhibit strong UV continua, no Balmer discontinuity and emission lines of H and He I, with generally weaker Fe II and [Fe II]. In this respect they closely resemble cataclysmic variables, particularly dwarf novae at quiescence. Dwarf novae show broad H and He I together with a strong UV continuum extending in some cases down to 1,250 Å (refs 9, 10). Weak Fe II in emission is also observed[9]. The Balmer jump is either not observed, or, more rarely, is present weakly in emission[9,11]. The principal difference is the increased breadth of the lines in dwarf novae, which are occasionally double. In contrast to the spectral similarities the luminosities of cataclysmic variables could hardly differ more. Rather than being the brightest stellar objects they are fainter than the Sun with luminosities $\sim 10^{32}$–10^{33} erg s^{-1}.

The general spectral similarity and the extreme disparity in luminosity suggest that similar physical processes occur in each class, but on differing scales. In quiescent novae the spectrum is generated by infall of gas from a companion onto a white dwarf mediated by an accretion disk. The Hubble–Sandage variables would result from similar physical conditions being generated but scaled to larger radii so that a much higher luminosity is generated. The occasional nova-like outbursts in Hubble–Sandage variables supports this identification.

I assume the Hubble–Sandage variables contain an accreting main-sequence star in a mass-transferring binary with a separation $\gtrsim 10^{12}$ cm. This separation is needed to accommodate a Roche lobe-filling companion such that an accretion disk may be formed. With a main-sequence star the major changes affecting accretion result from the much reduced gravitational potential at the stellar surface, and the possibility of central masses exceeding $\sim 2M_\odot$. Recent work[12–14] shows that with high accretion rates the main-sequence star will expand, often dramatically. Such expansion would require higher accretion rates to generate disk conditions similar to those derived below for normal main-sequence stars.

For an accretion rate $\dot{m}$ g s^{-1} the gravitational luminosity, $L = GM\dot{m}/R$. The characteristic source temperature is roughly the black-body temperature, $T = (L/4\pi\sigma R^2)^{1/4}$. For a main-sequence star to be at the same temperature as an accreting white dwarf and hence have the possibility of exhibiting similar general spectral features, the accretion rate must be increased by a factor $\dot{m}_{MS}/\dot{m}_{WD} = (R_{MS}/R_{WD})^3$ $(M_{WD}/M_{MS}) \sim 10^5$–$10^7$ (for masses $1 < M_{MS}/M_\odot < 100$) and the ratio of luminosities is then $L_{MS}/L_{WD} = (R_{MS}/R_{WD})^2 \sim 10^4$–$10^6$. Thus an accreting main-sequence star with disk temperatures similar to those of quiescent cataclysmic variables will have a disk luminosity $\sim 10^{36}$–10^{39} erg s^{-1}.

I now examine this model using steady disk models (the consequences of time dependence are unimportant). Assuming the disk is optically thick, which is valid so long as $T > 10^4$ K, then[4]

$$T(R) = \left(\frac{3GM\dot{m}}{8\pi\sigma R_{MS}^3}\right)^{1/4}\left(\frac{R}{R_{MS}}\right)^{-3/4}\left(1-\left(\frac{R}{R_{MS}}\right)^{-1/2}\right)^{1/4}$$

The maximum disk temperature occurs at a radius 40% larger than R_{MS} and is given by

0028/0836/79/460274—03$01.00

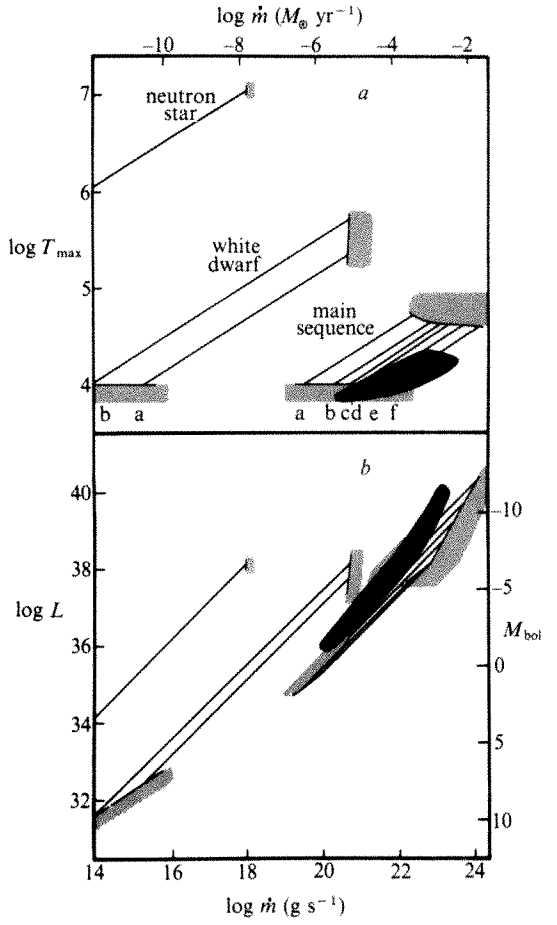

Fig. 1 Variation of maximum disk temperature (*a*) and disk luminosity (*b*) with accretion rate. Accretion tracks are shown for 0.5(a), 1(b), 3(c), 9(d), 30(e) and 121(f) solar mass main-sequence accretors. The region in which the accretion luminosity is less than the nuclear luminosity is indicated by heavy shading. At the upper boundary the disk luminosity is equal to the Eddington limit and the disk disrupts. At the lower boundary disk temperatures are less than $\sim 10^4$ K and the disk becomes optically thin. Tracks for white dwarfs of 0.4(a) and 1(b) $M_\odot$ and a neutron star of 1 $M_\odot$ are also shown.

$$T_{max} = 0.488\left(\frac{3GM\dot{m}}{8\pi\sigma R_{MS}^3}\right)^{1/4}$$

$$= 8.3\times 10^3 \dot{m}_{20}^{1/4}\left(\frac{M}{M_\odot}\right)^{1/4}\left(\frac{R_{MS}}{R_\odot}\right)^{-3/4}$$

where $\dot{m}_{20} = \dot{m}/(10^{20}\,\mathrm{g\,s^{-1}})$. Disk temperatures are hotter than 10^4 K for accretion rates $>10^{20}\,\mathrm{g\,s^{-1}}$.

Figure 1*a* shows the variation of T_{max} with $\dot{m}$ for main-sequence stars with masses in the range 0.5–121$M_\odot$. (Radii are from refs 15–17.) For comparison disk temperatures are also shown for white dwarf and neutron star accretion.

Cut-offs exist at both low and high temperatures. With low accretion rates and temperatures $<10^4$ K the rapid fall in opacity associated with hydrogen recombination leads to the possibility that the disk is optically thin. In these conditions radiation will be emitted in emission lines, with no strong continuum. In the case of massive early-type accretors a second cut-off exists at low temperatures. For $M > 9M_\odot$ the nuclear luminosity can be greater than the accretion luminosity for temperatures $>10^4$ K.

At high temperatures disk solutions break down when the luminosity becomes supercritical[4] and radiation pressure disrupts the disk. This occurs when $L > L_{ed} = 4\pi GMc/K$. This upper boundary is shown in Fig. 1*a* for an electron scattering opacity K, and a hydrogen abundance $X = 0.7$. The associated luminosity changes are shown in Fig. 1*b*.

It is evident that accreting main-sequence stars give a satisfactory model of Hubble–Sandage variables. With accretion rates 10^{20}–$10^{24}\,\mathrm{g\,s^{-1}}$ disk temperatures are the same (1–4 × 10^4 K) as quiescent dwarf novae. Luminosities, on the other hand, are $\sim 10^{38}\,\mathrm{erg\,s^{-1}}$. To achieve the highest luminosities ($>10^{39}\,\mathrm{erg\,s^{-1}}$) massive main-sequence stars ($>9M_\odot$) are required, with accretion rates $\sim 10^{23}\,\mathrm{g\,s^{-1}}$. Massive main-sequence accretors will form the brightest Hubble–Sandage variables.

Are other physical properties, besides temperature, such as optical thickness and density, similar for both main-sequence and white dwarf accretion? The optical depth, τ, at temperatures $\sim 3\times 10^4$ K is given by Sunyaev and Shakura's regime c[4], where

$$\tau = 7.5\times 10^2 \alpha^{-4/5}\dot{m}_{20}^{1/5}\left(1-\left(\frac{3R_g}{R}\right)^{1/2}\right)^{1/5}$$

Here α is the disk viscosity parameter, and R_g the Schwarzschild radius. As $\alpha < 1$, and $R_g \ll R$, $\tau > 7.5\times 10^2 \dot{m}_{20}^{1/5}$. With $\alpha = 1$ main-sequence accretors have $\tau \sim 10^3$ and quiescent cataclysmic variables have $\tau \sim 10^2$. Both are optically thick and will have a similar appearance.

The surface density, Σ, of the disk is given by[4],

$$\Sigma = 9.8\times 10^{-6}\alpha^{-4/5}\dot{m}_{20}^{7/10}\left(\frac{M}{M_\odot}\right)^{1/2}$$

$$\times\left(\frac{3R_g}{R_*}\right)^{3/4}\left(1-\left(\frac{3R_g}{R}\right)^{1/2}\right)^{7/10}\mathrm{g\,cm^{-2}}$$

Thus

$$\Sigma > 2.9\times 10^{-11}\dot{m}_{20}^{7/10}R^{-3/4}\left(\frac{M}{M_\odot}\right)^{1/4}\mathrm{g\,cm^{-2}}$$

For the case $\alpha = 1$ main-sequence stars typically have $\Sigma \sim 10^{3\text{–}4}\,\mathrm{g\,cm^{-2}}$ and white dwarfs $\Sigma \sim 10^2\,\mathrm{g\,cm^{-2}}$. Thus density differences may affect the spectrum and could account for the stronger Fe II lines in some Hubble–Sandage variables.

The broadening and doubling of the lines in cataclysmic variables are due to rotational Doppler shifts of material moving in the disk with Keplerian velocities. The maximum velocity at the stellar surface is $V = (GM/R)^{1/2}$, corresponding to an orbital period $P = 2\pi(R^3/GM)^{1/2}$. For main-sequence stars in the mass range $0.5\,M_\odot < M < 120\,M_\odot$, periods are in the range $1 < P < 14$ h and velocities $400 < V < 1{,}200\,\mathrm{km\,s^{-1}}$. For cataclysmic variables, $10 < P < 60$ s and $2{,}000 < V < 5{,}000\,\mathrm{km\,s^{-1}}$. Hence main-sequence line-broadening is 3–10 times less than that occurring in cataclysmic variables and is compatible with the observed difference in emission linewidth. Note that the maximum broadening will occur in the most massive, and most luminous objects. Doubling of lines would support the disk model.

The Balmer jump is absent due to the spectrum being composed of contributions from different radii in the disk, as in cataclysmic variables. The spectrum should obey the $F_\nu \propto \nu^{1/3}$ law[23] observed in dwarf novae[10]. In the two colour diagram both classes lie in roughly the same region, $U-B \sim -1.0$, $B-V \sim 0.0$, close to the black-body line.

The required accretion rates of 10^{20}–$10^{24}\,\mathrm{g\,s^{-1}}$ (10^{-6}–$10^{-2}\,M_\odot\,\mathrm{yr^{-1}}$) can be achieved (in principle) by Roche lobe-filling companions, particularly if these are giants. Variability is due to fluctuations in the mass transfer rate, possibly due to instabilities driven by ionisation zone destabilisation within the companion's envelope.

At accretion rates above the critical luminosity, auto-regulation of the accretion flow sets in and the disk is disrupted in the inner region[4]. This leads to a fraction of the accreting gas being ejected in the form of an outflowing wind. The low gravitational potential at the surface of a main-sequence star means that this wind is likely to be optically thick. It will have the same general properties as the optically thick winds observed in explosions of classical novae[18]—increases in the mass ejection rate will generate expansion of the photospheric radius, a decrease in both effective temperature and the bolometric correction but an

increase in the visual luminosity, with little change in the bolometric luminosity. Outflow velocities will be lower than in classical novae: roughly the same order as the escape velocity from the stellar surface.

Consequently there will be two types of spectroscopic and colour change produced by variations in the accretion rate. In the subcritical regime, increased accretion rates produce increasing disk temperatures along with increasing luminosity—both visual and bolometric. In the supercritical regime the disk is surrounded by an outflowing optically thick wind and the bolometric luminosity is held close to the Eddington value, L_{ed}. Increases in the wind mass-loss rate due to further increased accretion now produce decreasing temperatures along with increasing visual luminosity. The emission line spectrum of the disk will be replaced by an absorption line spectrum formed in the outflowing envelope—similar to the F or A type spectrum observed in classical novae at outburst maximum.

Is there any evidence for this supercritical state? The photographic magnitude of M33 Var A fell by 3.5 mag (ref. 5) in the visual in 1950–52, rose by 1.0 mag in 1952, before finally falling off sharply. Hubble and Sandage note that the changes in colour index indicate that the bolometric luminosity changed by only 1.4 mag. The visual luminosity fell by ~60 while the bolometric luminosity fell by ~4. This agrees with the expected changes due to a variable optically thick wind at Eddington luminosities.

η Carina is a close galactic relative to the Hubble–Sandage variables. It has broad spectral lines, with relatively strong Fe II and [Fe II][6]. Davidson[19] deduced a temperature of 3×10^4 K for the underlying star. Between 1836 and 1856 η Carina underwent a major outburst, followed by a subsidiary outburst in 1889. The early F absorption spectrum of 1893 was slowly replaced by the characteristic emission spectrum. The absolute magnitude at outburst was ~-14 (ref. 20), several magnitudes brighter than normal classical novae. At present, a cool surrounding dust cloud[21] heated by the underlying stellar source produces the bulk of the emission. The bolometric luminosity is still ~-14, but most of the emission is re-radiated IR from the dust shell. This high and constant luminosity, the spectral changes, the broader than average emission lines, and the nova-like explosion indicate that η Carina could contain a massive, main-sequence, accreting component in a binary which underwent a burst of supercritical accretion. Polarisation observations[20] of the nebula suggest that the dust is concentrated in an annulus of size 10^4 AU, and this has been interpreted as evidence of binary structure. This is the first observational indication of possible binary structure in this type of object. A search for binary eclipses in Hubble–Sandage variables with periods in the range weeks to years would test the binary model.

The bright galactic source MWC349 is a similar object[7]. Thompson *et al.*[22] interpret optical and IR observations as a proto-planetary disk seen face-on. In terms of the structure of the luminous source their model closely resembles that described here. The main difference is their interpretation as a preplanetary disk rather than an interacting binary.

If the brightest known optical stars are powered by infall of material on to a main-sequence star, the importance of accretion as an astrophysical energy source would be established beyond its present applications to X-ray binaries, novae and active galactic nuclei and quasars[23]. Such binaries should exist, and they would be classified as Hubble–Sandage variables when observed in external galaxies.

I thank J. Barrow and A. Edwards for helpful comments.

Streaming of interstellar grains in the Solar System

B. Å. S. Gustafson*† & N. Y. Misconi*

* Space Astronomy Laboratory, State University of New York at Albany, Albany, New York 12203
† Lund Observatory, University of Lund, Sweden

Deep-space probes offer excellent opportunities to study interstellar grains streaming into the Solar System. Direct detection of such particles would considerably add to our knowledge in many areas of cosmic dust research and could also provide information on the characteristics of both the interstellar medium and the interacting solar wind. Here we present the results of a theoretical study of the interaction between interstellar grains and the solar wind, including the effects of solar cycle variations in the interplanetary magnetic field. The latter is shown to influence significantly regions of concentration and depletion of interstellar grains within the Solar System.

Observations of the neutral gas in the solar vicinity suggest that the Solar System is moving relative to the local interstellar matter in a direction $\simeq7°$ north of the solar equatorial plane (ecliptic longitude and latitude: $\lambda\simeq250°$, $\beta\simeq7°$)[1], and at a speed of $\simeq20$ km s^{-1} (ref. 2). Bertaux and Blamont[3] computed number densities of interstellar grains in the solar cavity taking into account only gravitation and radiation pressure. Of the types of grains used in their model and based on their calculation of β (radiation pressure to gravitational attraction) only 0.02-μm radius silicate grains were able to penetrate deeply inside the Solar System. They estimated the number density of these dust grains to be strongly peaked on a line extending from the Sun backwards in the downstream direction. This number density was found to be higher by a factor of ~100 than direct observations of dust grains by Alvarez[4]. In an attempt to clarify this difference, Levy and Jokipii[5] made an order of magnitude estimate of the Lorentz force exerted by the solar wind magnetic field on a charged grain. They showed that if the 0.02-μm radius silicate grains of Bertaux and Blamont carry a net charge of 5 V, then the Lorentz force strongly dominates, thereby destroying the gravitational focusing and suggesting that these grains are largely excluded from the Solar System.

Studies of interstellar grains suggest two populations of particles[6]: (1) elongated core–mantle particles of characteristic radius $\simeq0.12$ μm, with a $\simeq0.07$ μm radius core of silicate type material, and a rather complex mantle of molecular mixtures of mainly oxygen, carbon and nitrogen; and (2) $\simeq0.01$ μm thick silicate and/or graphite type grains. Bertaux and Blamont did not consider any of these populations. In the following calculations (see also, ref. 13) we show that although population (1) particles have $\beta>1$, they still penetrate deep inside the Solar System.

The magnitude of the radiation pressure is given by $P_{pr}=(S/c)Q_{pr}$, where S is the flux, c is the speed of light, and Q_{pr} is the radiation pressure efficiency: $Q_{pr}=Q_{abs}+Q_{sca}\ (1-\langle\cos\theta\rangle)$, where Q_{abs} and Q_{sca} are the efficiency factors for absorption and scattering, respectively, and $\langle\cos\theta\rangle$ is the asymmetry factor over

0028/0836/79/460276—03$01.00

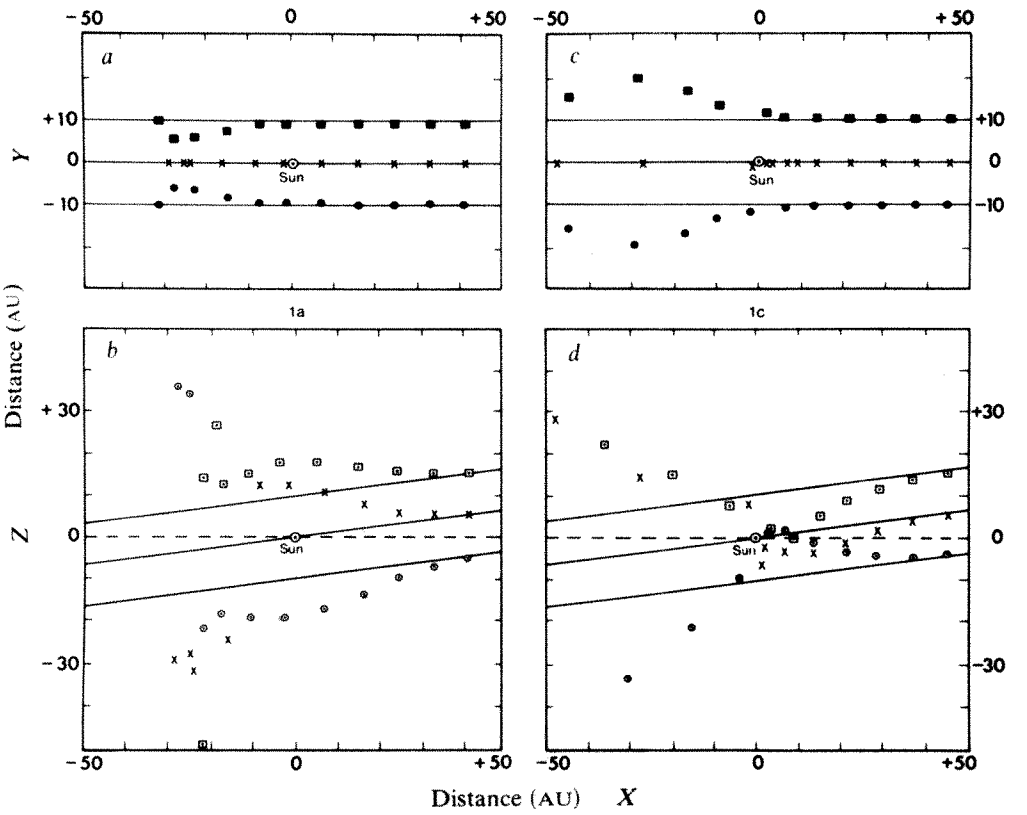

Fig. 1 Instantaneous positions of the 0.12 μm core–mantle particles initially moving in the direction $\lambda = 70°$, $\beta = 7°$ along the solid lines. The particles are entering the Solar System at $X = +50$ AU with 2 yr interval. Three streams (■, ×, ●) introduced at $Z = +6$ AU are projected onto the solar equatorial (X–Y) plane at the beginning (a) and in the middle (c) of a solar magnetic cycle. In b and d the three streams (⊡, ×, ⊙) introduced at $y = 0$ are similarly projected onto a plane (X–Z) perpendicular to the solar equatorial plane (dotted line).

the scattering angle θ. Scattering dominates over absorption for these dielectric particles in the scattering-efficient resonance region, and Q_{pr} was estimated using Mie theory for homogeneous spheres of equal volume and averaged core–mantle index of refraction. For a spherical silicate core coated by a concentric smooth spherical ice mantle representing particles of population (1) the computed Q_{pr} value using this approximation was found to be 0.4 ($\beta = 1.3$). As the grains that penetrate (population (1)) spend 30 yr or less in the Solar System, all radiation forces other than radiation pressure are negligible. Both solar-induced photoelectron emission and the accretion of solar wind ions will tend to charge these grains positively, whereas electron accretion produces negative charge. The equilibrium charge state is given by the relation

$$\sigma_e(V_0)f_e = \sigma_i(V_0)f_i + y\sigma_{ph}f_{ph} \quad (1)$$

where the σs are the cross-sections of the grains for UV photons, ions and electrons, the fs are the corresponding fluxes, y is the photoelectron yield, and V_0 is the electrical potential of the grains. σ and y have been estimated for numerous silicates, and these lead to charges ranging from 5 to 12 V (refs 7, 8). The photoemission properties are not usually decreased by surface impurities or adsorbed layers[7], or by amorphous structure[8]. However, for ice the work function is near the Lyman edge, and therefore photoemission is less efficient. We will adopt here +7 V for bare particles, and +1.2 V for the core–mantle grains. As the charged grains interact with the solar wind described by Svalgaard *et al.*[9], they will be subject to a Lorentz force given by

$$F_L = \frac{q}{c}[(V_g \times B) - (V_{sw} \times B)] \quad (2)$$

where q is the grain's charge, V_g and V_{sw} are the speeds of the grain and of the solar wind, respectively, c is the speed of light and B is the magnetic field strength.

The magnetic field is torn in an archimedian spiral by the solar rotation. Thus

$$B_r = \frac{B_0}{r^2} \quad \text{and} \quad B_\Phi = \frac{-B_0\omega b^2(r-b)\sin\theta}{V_{sw}r^2} \quad (3)$$

where B_0 is the magnetic field strength at some reference distance ($b = 5$–10 solar radii), ω is the solar angular velocity, r is the heliocentric distance, Φ is the azimuth angle, and θ is the heliocentric colatitude angle. The second (electrical) part of equation (2) which acts along θ will dominate as the grains enter the Solar System at low and medium heliocentric latitudes. This force, acting on a grain of given charge, is independent of the speed of a radially streaming solar wind as can be seen by substituting equation (3) in equation (2); high velocity plasma streams will not alter our results considerably.

The positive and negative magnetic fields are separated by a sinusoidal warped neutral sheet[10,11], the amplitude of which we assume to decay exponentially with increasing heliocentric distance. The speed of the solar wind as a function of θ was assumed to be of the form

$$V_{sw} = a + b\,|\cos\theta| \quad (4)$$

where a is the mean solar wind velocity at the equator (400 km s^{-1}) and b is 300 km s^{-1}.

The grains also encounter other less important forces such as Coulomb drag due to the nearby passing solar wind electrons, which is given by

$$F_C = \frac{\pi s^2 N_e e^2 V_0^2}{m_e W^2} \ln\left(\frac{W^2 m_e P}{e V_0 s}\right) \quad (5)$$

where s and V_0 are the radius and charge of the grain, respectively, N_e, e, and m_e are the electron number density, charge and mass, respectively, and W is the velocity of the grains relative to the electrons. P is the impact parameter, which is assumed to be $\approx N_e^{1/3}$, following a poissonian distribution for the nearest neighbour distance. Another force is ion pressure resulting from impinging solar wind ions on the grains which is given by

$$F_i = \pi s^2 \bar{M}_i V F \quad (6)$$

where F is the flux of the solar wind ions, V is their velocity and $\bar{M}_i$ is the mean ion mass $\approx 2 \times 10^{-24}$ g.

Trajectories of interstellar grains streaming into the Solar System were computed as follows: the grains are introduced at the boundary of the solar wind cavity ($X = 50$ AU) at the beginning of the 22-yr solar magnetic cycle (defined as the cycle beginning when the solar dipole field acquires a south component). The equations of motion are integrated at small intervals of time (24 h), and the position, speed and acceleration of the particles are determined.

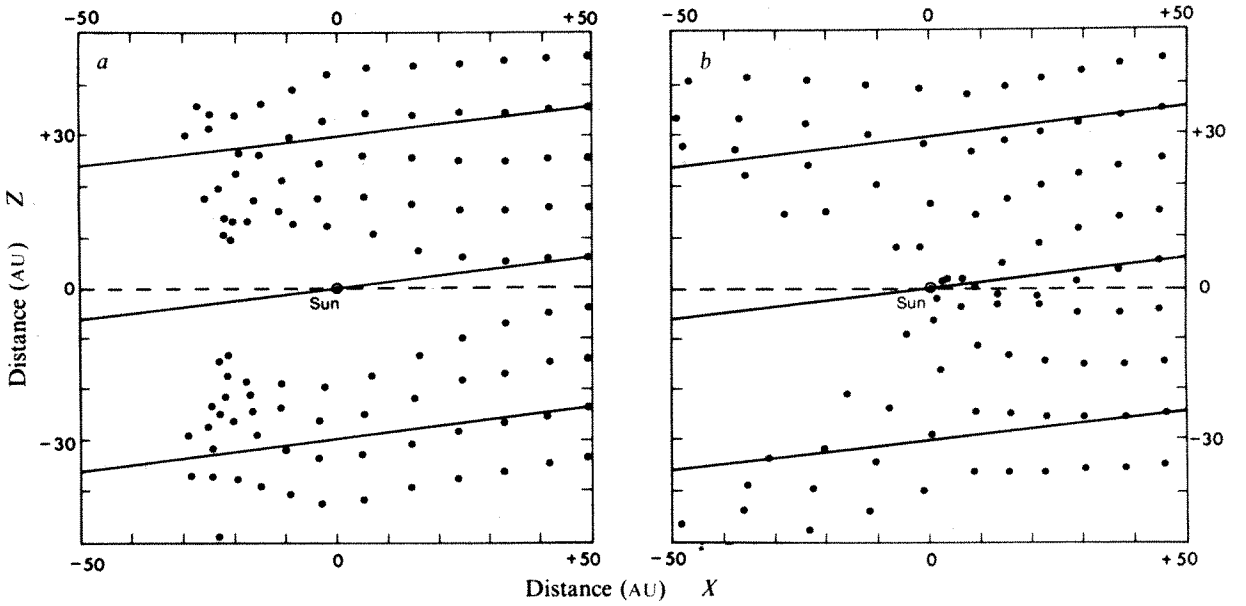

Fig. 2 Instantaneous positions of combined high latitude streams and the streams shown in Fig. 1*b* and *d*, at time zero (*a*) and time 11 yr (*b*) of a solar magnetic cycle.

The results of these computations are shown in Figs 1 and 2. Figure 1*a* and *c* shows the projection onto the solar equatorial plane (XY-plane) of the instantaneous positions of population particles arising from three streams which differ only by a separation of 10 AU in the initial value of their Y coordinate. Figure 1*b* and *d* shows the instantaneous positions in the XZ-plane of particles arising from three streams with $Y = 0$. One stream is initially directed towards the Sun and the other two lie parallel to and 10 AU on either side of that direction. The sequence of points belonging to a stream corresponds to positions of particles which differ by 2 yr from the initial time when each particle was introduced at the boundary of the solar wind cavity. Figure 1*a* and *b* shows the instantaneous positions of all the particles at a time corresponding to the beginning of the solar magnetic cycle. Figure 1*c* and *d* repeat this information for a time 11 yr into the solar magnetic cycle. The contrast between *a*, *b* and *c*, *d* clearly demonstrates the decisive influence of the solar magnetic cycle on the distribution of the grains. The streams are diverted towards the X-axis in Fig. 1*a* and away from that axis in Fig. 1*c*. Figure 1*b* shows that when the solar dipole field axis points north, the grains are diverted from the solar equatorial plane, mainly due to the action of the electrical part of the Lorentz force. The grains are concentrated towards this plane when the solar dipole field points south (Fig. 1*d*). Some 3 to 4 AU ahead of the Sun the streams cross the equatorial plane, creating an enhancement in the number density. The grains behind the Sun experienced the oppositely directed magnetic field of the first half of the solar magnetic cycle as they entered the solar wind cavity, thus creating a depletion zone in the wake of the Sun.

Our computations are almost insensitive to whether the reversal of the direction of the interplanetary magnetic field is instantaneous or whether it is as gradual as a sine function. These results are based on a simple dipole field where higher order multipole or asymmetrical magnetic fields are ignored.

In Fig. 2*a* and *b* additional streams, projected in the XZ plane, are introduced higher in latitude than the streams in Fig. 1*b* and *d*. Figure 2*a* shows a concentration of particles developing along a line $X \approx -20$ AU, $Z \approx \pm 10$–20 AU (peaked around $\phi \simeq 180°$). There is also a depletion zone of radius ≈ 20 AU surrounding the Sun. The deviation from the XZ-plane is $\leqslant \pm$ 0.1 AU. The value of Q_{pr} used in the calculation is 0.4, which might be increased by surface roughness; however, this value decreases for elongated particles. The overall effect of increasing the radiation pressure efficiency Q_{pr} of the grains from 0.4 to as much as 1.0 ($\beta = 3.25$) is to move the concentration in Fig. 2*b* ≈ 3 AU along the positive X-axis. On the other hand, a decrease in the value of Q_{pr} has a negligible effect. The smaller bare grains that enter at low and medium heliocentric latitudes are essentially trapped around the solar wind magnetic field lines, and they are swept out near the solar wind cavity.

We have extended the study of the dynamics of interstellar grains to particles having radii of 0.12 and 0.005 μm streaming into the Solar System and included the effects of the solar dipole field's change of direction during the solar magnetic cycle. Additional forces on the particles such as Coulomb drag and solar wind ion pressure are less important than the Lorentz force. Particle trajectory computations show that an enhancement of the order of 50 or more in the number density of interstellar core-mantle particles may occur some 3–4 AU ahead of the Sun and close to the solar equatorial plane during yr 8–17 of the solar magnetic cycle. During the rest of the cycle, concentrations develop some 20 AU away from the Sun, while a depletion zone of ≈ 20 AU in radius surrounds the Sun.

As particle configuration varies strongly with the solar magnetic cycle, its effect must be taken into account in any treatment of this problem. Note that even grains with $\beta > 1$ will penetrate deep inside the Solar System during part of the solar magnetic cycle.

Subsequent computations may predict more precisely the directions and times to search for an interstellar component of the zodiacal cloud. Note that during the Solar Polar Mission (mid and late 1980s), concentrations of interstellar grains are expected (Figs 1*d*, 2*b*) which will offer a unique opportunity to detect the presence of interstellar grains in the Solar System[12].

We thank Drs J. M. Greenberg, J. R. Jokipii, E. H. Levy, K. F. Ratcliff and J. L. Weinberg for helpful comments, and Dr R. T. Wang for helpful discussions relating to radiation pressure efficiencies. This research was partially supported by the Planetary Atmospheres program of the NASA under grant NSG 7093.

Deposition rate and seasonal variations in precipitation of cosmogenic ^{10}Be

G. M. Raisbeck & F. Yiou

Institut des Sciences Nucléaires, 38026 Grenoble, France

The measurement of ^{10}Be using nuclear accelerators promises to widen the applications of this cosmogenic isotope considerably[1-3]. A parameter of fundamental importance in such applications is the production rate of this nuclide in the atmosphere. This production rate has previously been estimated by two methods: (1) by measuring the concentration of ^{10}Be in marine sediments having known accumulation rates; (2) by using model calculations of cosmic ray interaction rates, combined with estimated cross-sections for production of ^{10}Be. These two methods have led to an estimated global average ^{10}Be production rate of 0.015–0.018 atoms cm^{-2} s^{-1} (refs 4, 5 and F. Guichard, unpublished work). The increased sensitivity available with the accelerator technique now makes it feasible to measure directly ^{10}Be deposition rates at the Earth's surface. We report here the results of such a measurement, which lead to an estimated global average production rate more than double the previous estimates. We also give some initial results on the seasonal variation of ^{10}Be concentration in precipitation, and comment on the possibility that such variations might permit the determination of ancient accumulation rates of polar ice.

The ^{10}Be for our measurements was collected in a child's plastic swimming pool (area 2.5 m^2) exposed on the roof of the Laboratoire René Bernas (~49° N) between 3 April 1978 and 6 April 1979. Initially 10 mg of ^{9}Be and several litres of water were added to the swimming pool. At the end of the exposure period the swimming pool contained ~700 l. A known fraction (10 l) of this volume was recovered and analysed for ^{9}Be by flameless atomic absorption spectrometry. This allowed us to determine the fraction of the initial ^{9}Be (and thus deposited ^{10}Be) which was recovered. This value agreed very well with the fractional volume of water recovered, showing that essentially all the Be had remained in solution. (This somewhat surprising result can probably be explained by the *p*H of the precipitation, which was ~5.5 at the time of recovery). As well as determining the yearly average by a single measurement, the above method of collection includes any contribution from 'dry' deposition.

Additional ^{9}Be (4mg) was added to the 10-l sample which was then passed through a Chelex ion exchange column on which the Be was retained. The Be was then eluted in 1.5M HCl, and purified by a series of solvent extractions[6]. The Be was finally transformed into a sintered BeO disk by a process described elsewhere[1].

The measurements on the cyclotron were carried out as described elsewhere[2]. An important improvement, however, was that samples and standards could now be mounted on a rotating source holder, which permitted us to change samples remotely in a matter of seconds, without modifying any of the accelerator parameters. Details of this system will be given elsewhere.

From the measured $^{10}Be/^{9}Be$ ratio, the known amount of ^{9}Be added and the known fraction of Be extracted from the swimming pool, we can directly calculate the total number of ^{10}Be atoms and the average rate of deposition during the year. The result is 0.055 ± 0.008 atoms cm^{-2} s^{-1}. The error comes essentially from the uncertainty on the measured $^{10}Be/^{9}Be$ ratio, and on the measured fraction of ^{9}Be recovered from the swimming pool.

To estimate an average global deposition rate, we first adjust the above value to the yearly average rainfall for latitude ~50° N. This correction is based on the assumption that the deposition of ^{10}Be at a given latitude will be approximately proportional to the quantity of precipitation[7]. As the average rainfall for 50° N is estimated[8] to be 75 cm compared with a value of 66.7 cm at Orsay during our measurement period, the adjusted average deposition rate at 50° N is 0.062 atoms cm^{-2} s^{-1}. We next apply a factor for the variation of deposition as a function of latitude as given in Fig. 22 of ref. 7. The final result gives a global average value of 0.042 atoms cm^{-2} s^{-1}.

It is difficult to evaluate the uncertainty in the two correction factors which transformed our basic data into an average global rate. However, we believe that our average global rate is the best estimate of the ^{10}Be production rate currently available, and that it is significantly larger than the estimates referred to earlier. It would be interesting to consider the possible sources of error in the earlier estimates. Note that in the case of estimates based on marine sediments[4,5], relatively few samples were involved, and these tended to be biased towards slow accumulation rate areas (to maximise the concentration of ^{10}Be, thus giving adequate activities for the classical counting technique). It is uncertain whether such sediments can be considered representative of the entire ocean floor. In fact, Tanaka and Inoue[9] have measured in several sediment cores ^{10}Be deposition rates comparable to those deduced above. In a rapidly (1.13 cm per 10^3 yr) accumulating sediment at 45° N, we have measured a ^{10}Be deposition rate of 0.10 atoms cm^{-2} s^{-1} (ref. 10). Thus, when a larger and more representative series of sediment results is available, it may well be consistent with our above estimate. Of course, one must also remember that sediment results refer to an integrated production rate over a considerable (and variable) period of time in history, when all the parameters influencing the production (geomagnetic field, solar modulation, primary cosmic ray intensity) may not have been identical to the present.

With regard to estimates based on cosmic ray interaction rates (ref. 4 and F. Guichard, unpublished work) there is a basic problem in choosing appropriate cross-sections. The most important particles in cosmogenic nuclide production in the atmosphere are neutrons. As very few high-energy neutron induced cross-sections are available, values based on proton-induced reactions are usually substituted. As we have pointed out[11], in the particular case of ^{10}Be formed from ^{16}O and ^{14}N, it is quite possible that the neutron induced reactions have larger cross-sections than those induced by protons. We therefore would not be surprised if calculations based on proton cross-sections were underestimated.

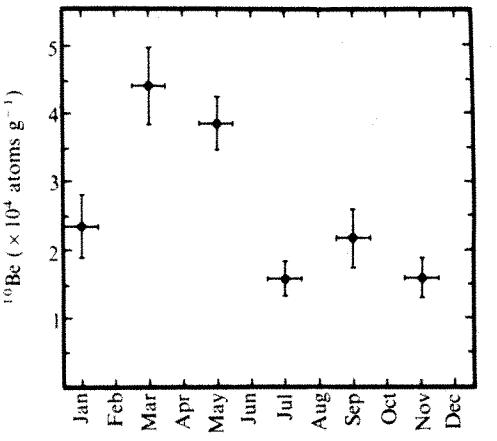

Fig. 1 ^{10}Be concentration in monthly precipitation samples collected in France during 1966.

© 1979 Macmillan Journals Ltd.

In addition to the above determination of the average ^{10}Be deposition rate, we have begun a series of measurements on monthly precipitation samples collected over a 10-yr interval by the Commissariat à l'Energie Atomique (France). Our studies are designed to look for seasonal variations, and eventually, effects due to varying solar modulation. The samples, (30–150 l) were collected at Paris, Orsay, Verdun and Bordeaux using plastic funnels having an area of 0.57 m^2. The precipitation was acidified and reduced to a volume of 15 ml by evaporation. After γ-ray analysis, the samples from the four locations were combined and stored in plastic bottles. We added 4 mg of ^{9}Be to each of these combined samples, which were treated by the solvent extraction process, made into pellets, and measured on the cyclotron as described above.

The results for six of these samples, collected in 1966, are shown in Fig. 1. There is a sharp increase in the ^{10}Be deposition rate during the spring. This is not unexpected, as it corresponds to the period in the year when there is a major transfer of stratospheric air (where ~70% of the ^{10}Be is formed[7]) into the troposphere[12]. It is interesting to consider the possibility that such a seasonal variation might provide a technique for determining accumulation rates in polar ice cores. Our present sensitivity with the cyclotron (~10^7 atoms) has the potential for measuring monthly time resolution with currently available ice cores, and we are preparing a series of samples to test this possibility. However, note that the variations are expected to be smaller in polar regions because the predicted stratospheric component is much less at high latitudes[7].

Finally, while we do not yet have a full year's data for 1966, we can compare the average ^{10}Be concentration in precipitation for the six months analysed (2.33×10^4 atoms g^{-1}) with that for the 1978–79 period (calculated from measured ^{10}Be deposition and the known precipitation rate during that period to be 2.49×10^4 atoms g^{-1}). The agreement is sufficiently good to give us confidence that this is indeed a fairly typical value for France. For a more precise global average deposition rate, similar measurements are needed at several different latitudes.

We thank J. Lestringuez for technical assistance and J. Hémon for the precipitation samples collected by the Laboratoire de Métrologie sur l'environnement, C.E.A. (France).

Unified yes, renormalised maybe

S. A. Bludman

Department of Physics, University of Pennsylvania, Philadelphia, Pennsylvania 19104

Several recent reports[1–3] have suggested that recent neutrino and polarised electron scattering experiments are not particular tests of the 'standard theory' of weak interactions, but only establish the strength and form of the weak neutral current

$$J_\lambda^w = J_\lambda^3 - sin^2\theta_w J_\lambda^{em} \qquad (1)$$

appearing in the effective weak lagrangian

$$\mathscr{L}^{eff} = \frac{4G}{\sqrt{2}}[J_\lambda^w J_\lambda^w + J_\lambda^+ J_\lambda^- + J_\lambda^- J_\lambda^+] \qquad (2)$$

along with the classical charged-current ($J^\pm$) interactions. Whether or not weak vector mesons exist, the current experiments confirm the existence of an effective lagrangian (2) containing a weak neutral current (1) with the one parameter $\sin^2\theta_w$. This letter shows that this already establishes some unification of electron and weak interactions, so that the question is no longer "Is unification really true?"[3], but rather "Is the theory $SU_2\times U_1$ symmetric and renormalisable?" It also shows that, although weak charged currents must show structure[1] below 160 GeV, the weak neutral currents can be structureless, that is $m_z = \infty$ is compatible with the observed current (1).

The first gauge theory of chiral weak interactions[5] had $\sin^2\theta_w = 0$ so that $\mathscr{L}^{eff} = (4G/\sqrt{2})\mathbf{J}\cdot\mathbf{J}$ was SU_2(w) symmetric. This theory ignored electromagnetism and predicted for the first time weak neutral currents of the same strength and form as the weak charged currents. (While this theory was a local gauge theory involving a triplet of vector mesons w$^\pm$ and w^0, the global SU_2(w) suffices for present purposes.) Glashow[4] coupled in electromagnetism, extending the theory to $SU_2\times U_1$, and first proposed the form (1). The history of neutral currents and the local gauge theory of weak interactions after ref. 5 is documented in refs 6, 7. The suppression of strageness-changing neutral currents[8] and the proof of renormalisability[9–11] were most important. Bludman's and Glashow's ideals were early emphasised by Gell-Mann[12] and formed the basis for his algebra of currents and charges. Bjorken has shown[3] that these $\sin^2\theta_w J_\lambda^{em}$ terms in the weak neutral current originate in any large electromagnetic braking of the SU_2(w) invariance such as an intrinsic neutrino form factor much larger than that induced by charged currents[13]. This symmetry-breaking term arises in any theory incorporating γ–w$_0$ mixing[2], but does not require the existence of weak vector mesons and certainly not the particular (Higgs) mechanism for symmetry breaking of the 'standard' theory.

The author was one of the first[14] and most consistent proponents of local gauge theories and to appreciate the theoretical advantages of a renormalisable theory of weak interactions. Renormalisability makes it possible to consider higher order weak processes like the $K_L - K_S$ mass difference and radiative corrections to β- and μ-decay. Certainly the suggestion[15,16] of such a renormalisable theory, together with the development of neutrino accelerator facilities, helped stimulate the discovery in 1973 of the predicted[5] neutral currents. Nevertheless, the present experiments confirm only the strength and form of the proposed neutral currents[4,5]; experiments searching for W$^\mp$, Z^0 and Higgs mesons are needed to test the standard theory[15,16] of weak interactions. At present, spontaneous symmetry-breaking by Higgs mesons apparently introduces as many problems as it solves, and a future dynamical theory may not involve the present theory of the Higgs mechanism at all.

Indeed, Bjorken shows[1] that the charged-current scattering amplitude must be of the form

$$G(q^2) = G(1 + \frac{q^2}{\mu_w^2} + \ldots)$$

with μ_w^{-2} a charged radius bounded from below or μ_w^2 a mean mass bounded from above by

$$\mu_w \leq \frac{e}{(4G\sqrt{2})^{1/2}} \frac{(1-Z_3)^{1/2}}{\sin^2\theta_w} = (37.4\ \text{GeV}) \frac{\sin\theta_1}{\sin^2\theta_w} \qquad (3)$$

Here $\sin^2\theta_w$ is defined by the neutrino charged-radius spectral function and Z_3 is the charge renormalisation induced by intermediate states ('weak quanta') dominating the weak forces. Since $0 \leq Z_3 \leq 1$, we write $Z_3 \equiv \cos^2\theta_1$. With $\sin^2\theta_w \approx 0.23 \pm 0.02$, equation (3) shows that charge current weak inter-

0028/0836/79/460280—02$01.00

© 1979 Macmillan Journals Ltd.

actions must show structure somewhere below 160 GeV, whether or not intermediate vector mesons exist. If $W^{\pm}$ mesons exist, equation (3) becomes an upper limit on their mass, $\mu_w = (160\ \text{GeV})\sin\theta_1 \leq 160$ GeV. We now show that there is a lower limit (equation (6)) on m_z, the mass of the Z^0. Following Hung and Sakuri[2], consider a phenomenological $\gamma - w_0$ mixing

$$\mathscr{L}^{\text{mix}} = -\frac{\lambda}{4}(\tilde{F}_{\mu\nu}w^0{}_{\mu\nu} + w^0_{\mu\nu}\tilde{F}_{\mu\nu}), \tag{4}$$

which may be a manifestation of a large intrinsic neutrino charge form factor or may originate in quark or lepton vacuum polarisation loops. $\tilde{F}_{\mu\nu}$ is the original unmixed massless photon field. Since the interaction (equation (4)) is electromagnetically gauge invariant, the photon remains massless after mixing, but the W^0 mass is raised to

$$m_z^2 = \frac{m_w^2}{1-\lambda^2}$$

As this requires $\lambda^2 \leq 1$ we can write $\lambda^2 \equiv \sin^2\theta_2$. After mixing, the $\gamma - W_0$ part of the effective lagrangian is

$$\mathscr{L}^{\text{eff}} = \frac{1}{2}\left\{e^2 J^{em}_\lambda \frac{1}{q^2} J^{em}_\lambda + \frac{g^2}{m_w^2} J^w_\lambda \frac{m_z^2}{q^2+m_z^2} J^w_\lambda\right\} \tag{15}$$

where J^w_λ is given by equation (1) with

$$\sin^2\theta_w \equiv \frac{e}{g}\lambda \equiv \frac{e}{g}\sin\theta_2$$

Like Bjorken's, this effective lagrangian depends on two parameters, $\sin^2\theta_w$ and $\sin\theta_1$ or $\sin\theta_2$. (The original $SU_2(w)$ theory predicting neutral currents of universal coupling strength G is recovered if $e/g = 0$ or $\lambda = 0$.)

In terms of θ_2,

$$m_z = \frac{m_w}{\cos\theta_2} \tag{6}$$

$$m_w = \frac{g}{(4G\sqrt{2})^{1/2}} = (37.4\ \text{GeV})\frac{g}{e} = (160\ \text{GeV})\sin\theta_2 \tag{7}$$

While $W^{\pm}$ vector mesons, or at least Bjorken's 'virtual quanta', must exist below 160 GeV, Z^0 could be infinite in mass. In such a case, there would be only two charged vector mesons of mass $m_w = 160$ GeV, and the neutral electro-weak interactions would retain their low energy form at all energies: electromagnetic and weak neutral interactions would be simply of infinite and zero range respectively.

The present generation of experiments establishes the existence of the neutral current (1) with $\sin^2\theta_w \approx 0.23 \pm 0.02$ and $m_w > 30$ GeV. Since this makes $g/e > 0.8$ or the mixing parameter $\lambda \equiv \sin\theta_2 > 0.2$, these experiments demonstrate large electromagnetic breaking[4] of the original[5] $SU_2(w)$ symmetry, or a particle mixing theory that is unified on the tree level of approximation. (The magnitude observed for $\sin^2\theta_w$ may suggest the importance of higher order effects, which would require a renormaliseable theory for their calculation.)

At $q^2 \ll m_z^2$ the effective lagrangian (5) reproduces the ordinary electromagnetic interactions plus the observed weak currents of universal strength $g^2/m_w^2 = 4G\sqrt{2}$. At $q^2 \gg m_z^{22}$

$$\mathscr{L}^{\text{eff}} \approx \frac{1}{2\cos^2\theta_2}\left\{e^2 J^Y J^Y + (e^2+g^2-2eg\sin\theta_2)J^3J^3 + 2e(e-g\sin\theta_2)J^3_\lambda J^Y_\lambda\right\} \tag{8}$$

Hung and Sakurai[2] show the special choice of mixing parameter

$$\lambda = e/g \tag{9}$$

or $\sin\theta_2 = \sin\theta_w$ makes the $\gamma - w_0$ theory asymptotically $SU_2 \times U_1$ symmetric and tree unitary[17–20]. It gives the $w^{\pm}$ vector mesons gyromagnetic ratio $g = 2^2$ and predicts

$$m_w = \frac{37.4\ \text{GeV}}{\sin\theta_w} = 80\ \text{GeV} \tag{10}$$

$$m_z = \frac{m_w}{\cos\theta_w} = 90\ \text{GeV} \tag{11}$$

Whether equations (9)–(11) turn out to be satisfied or not, present experiments establish unification in the tree level of approximation. Neither the two-parameter theory we are proposing nor the standard $SU_2 \times U_1$ theory is yet unified in the sense of containing one coupling constant in a simple group structure. The condition (9), which Hung and Sakurai called the 'unification condition', might therefore more properly be called the 'renormaliseability condition': it guarantees good high-energy behaviour.

The mass relations (10), (11) are those derived in the 'standard theory' from a local $SU_2 \times U_1$ renormaliseable theory with symmetry spontaneously broken by the simplest Higgs mechanism. Future experiments may indeed demonstrate the existence of $W^{\pm}$ and Z^0 mesons of masses (10), (11) and even possibly Higgs scalar mesons. Until then, however, we can only say that present experiments prove the existence of weak neutral currents of the strength originally predicted[5], with strong electromagnetic breaking[4] of the original $SU_2(w)$ symmetry and leave open the possibility $m_w = 160$ GeV, $m_z = \infty$.

I thank S. Gasiorowicz, M. Gell-Mann for stimulating discussions and others at the Aspen Center of Physics where I have enjoyed many summers. This work was supported in part by the US Department of Energy under contract Ey-76-Cl-02-3071.

Electrocatalytic oxygen evolution on reactively sputtered electrochromic iridium oxide films

G. Beni, L. M. Schiavone, J. L. Shay, W. C. Dautremont-Smith & B. S. Schneider

Bell Laboratories, Holmdel and Murray Hill, New Jersey 07733

Oxygen evolution reactions[1] are critical to the development of efficient energy conversion and energy storage devices. For example, power losses at the oxygen electrodes of commercial water electrolysers[2] and H_2–O_2 fuel cells limit their efficiencies to values well below those expected theoretically. The power loss of these devices is ≥15% even at low current densities, and much higher in practical operating conditions. We report here the preparation and the oxygen evolution reaction (OER) electrocatalytic properties of iridium oxide films deposited by reactively sputtering iridium in a humidified oxygen discharge. We find that these sputtered iridium oxide films (SIROFs) have catalytic properties far superior to the best known catalysts for oxygen evolution in acidic aqueous electrolytes at room temperature.

© 1979 Macmillan Journals Ltd.

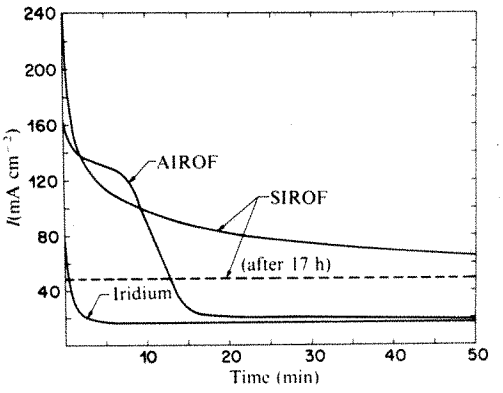

Fig. 1 Oxygen evolution reaction (OER) currents at 1.85 V against RHE as a function of time for anodic iridium oxide films (AIROF), sputtered iridium oxide films (SIROF), and for pure iridium in 0.5 M H_2SO_4 at 25 °C. Despite their high initial current, AIROFs dissolve in the acidic solution so that after ~20 min their OER current is about the same as for bare iridium. In contrast, SIROFs are stable. The dashed line shows the current of SIROFs in the steady state.

Few studies have been aimed at establishing the factors affecting electrocatalysis of O_2, so that we lack the information necessary for a theoretical approach to the search for better O_2 electrocatalysts. Semi-empirically, it has become accepted[1] that a good OER catalyst must have a relatively high electronic conductivity and a high affinity for adsorbed OH^- intermediates. The electrode must not corrode; hence much electrocatalysis research has been restricted to the noble metals and their alloys. A number of recent studies[3-6], however, have pointed out that the link among different electrodes known to be good electrocatalysts for OER (for example, Ir, Ru, Ni) seems to be a relatively thick oxide film which is present on their surfaces. This thick oxide film is clearly different from the more common thin oxide film found on the surface of many metals. In fact these thin films are known to inhibit the rate of many chemical reactions, including the OER. This is why much research ostensibly aimed at solving the problem of electrocatalysis focuses on surfaces devoid of oxides, that is, 'clean' surfaces. In contrast, for 'real' catalysts, thick oxide films (≥1,000 Å) bring about an improved OER.

Experiments show that these thick oxide films display unusual electrochromic effects. Most remarkable is the electrochromism[7-10] of anodic iridium oxide films (AIROFs). Colour-switching times are comparable to those of liquid crystals. AIROF electrochromism takes place at ~1 V (RHE) in 0.5 M H_2SO_4, and is thus a precursor of the OER which occurs at ~1.5 V (RHE). Although the relationship between electrochromism and OER catalysis is not yet completely understood, it is possible that a higher electronic conductivity and increased OH^- content in the coloured state favours the OER. In fact, AIROFs show[3-6,11] good electrocatalytic activity for the OER. A comparison[5] with the performance of the bare iridium electrode indicated that currents obtained for AIROFs on Ir were larger than currents obtained at the same potential on bare Ir.

Although AIROFs have higher OER rates than Ir, they dissolve at significant rates at low voltages (1.4–1.6 V against RHE), and very rapidly at voltages above 1.6 (RHE) in acidic solutions, rendering them of no use as practical catalysts. This initially high catalytic activity and subsequent degradation of AIROFs is illustrated in Fig. 1. After ~20 min the AIROF is totally dissolved and the exposed surface is bare iridium. Thus, in AIROFs, there seems to be a competition between catalytic activity and stability. The high catalytic activity and instability of AIROFs is consistent with the existence of metastable states of intermediate oxidation.

In an attempt to stabilise these metastable states in iridium oxide we reactively sputtered iridium in a humidified oxygen discharge. In the sputter deposition of a thin film, highly energetic species in the vapour phase impinge onto a cold substrate. the rapid quenching of the deposited material tends to stabilise structures that would normally be unstable at room temperature.

SIROFs were deposited on a variety of substrates using an iridium target in a Cooke model C-70-6-4B rf sputtering system. The substrates were washed in a detergent bath, rinsed in distilled water, ultrasonically cleaned in isopropyl alcohol, and vapour-degreased with isopropyl alcohol. They were then placed on a water-cooled J-arm substrate table in the sputtering chamber, which was subsequently evacuated to a pressure of $\sim 2 \times 10^{-7}$ torr. Oxygen at a pressure of 17 p.s.i. saturated with water at room temperature, was admitted into the chamber to a pressure of ~30-μmHg. After a few minutes, the plasma was ignited and the pressure was reduced to ~8 μmHg. Deposition times were ~1 h, typically at an r.f. power of 75 W to a 2″-diameter iridium target corresponding to a target d.c. bias of ~700 V. The metal substrate did not affect the SIROF composition; for example, in the case of tantalum substrates, Auger measurements showed no evidence for any Ta at or near the SIROF surface.

We show elsewhere[12] that the SIROFs have many of the desirable electrochromic properties of AIROFs, including the fast electrochromic response times. The voltammograms for SIROFs are similar to those for AIROFs but differ in detail. In particular, the electrochromic peak for the SIROF occurs at ~0.80 V (RHE) rather than at ~0.95 V (RHE). Both voltammograms are highly symmetric, resulting in excellent stability when operated in the electrochromic range of potentials. We show here that SIROFs (in contrast to AIROFs) are also stable when operated as catalysts in the OER region of potentials, and exhibit a much higher catalytic activity for the OER than bare iridium. Long-term stability tests have not been conducted yet. However, as no degradation has been obtained after ~20 h of operation, SIROFs are at least 2 orders of magnitude more stable than AIROFs.

Figure 1 shows the current of OER for SIROF, AIROF and Ir at 1.85 V (RHE). All currents decay with time until they reach a steady state value (after a few minutes for iridium and after a few hours for SIROF). As noted, AIROFs dissolve rapidly (~20 min). The dashed line shows the steady-state current for SIROFs recorded after ~17 h. The steady-state current is ~3 times as large as the current for iridium, hitherto the best catalyst for OER in acidic solutions.

Tafel plots for OER on SIROFs can be obtained from the steady-state currents recorded after ~17 h at various potentials with no prepolarisation (Fig. 2). Tafel plots for AIROFs have been reported[5]. These plots, however, are practically meaningless as a measure of the AIROF activity because: (1) the currents were arbitrarily recorded 10 min after the initial application of

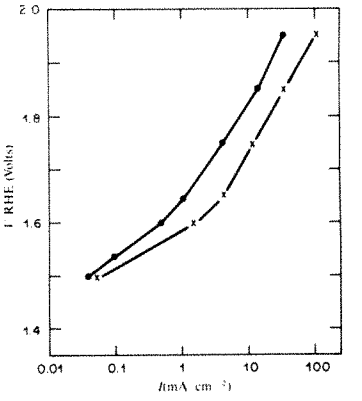

Fig. 2 Tafel slopes for Ir (●) and for SIROFs (×) in 0.5 M H_2SO_4. The data are obtained from currents recorded in the steady state (after ~17 h) with no prepolarisation. Temperature, 25 °C.

the potential to the AIROF electrode; and (2) AIROFs corrode so that the currents recorded are not OER currents but include dissolution currents. At high voltages the slope is essentially equal to that of Ir and other precious metals[13]. An independent measure of the catalytic activity of the material can be obtained by plotting the initial current, after subtracting out the capacitive component. Although the details of this analysis will be reported elsewhere (G.B., L.M.S., J.L.S. and W.C.D-S., in preparation), both steady state and transient measurements clearly indicate the superior catalytic activity of SIROFs.

In general, oxygen evolved on a metal electrode reacts with the metal itself to form an oxide. Thus, the potential at which oxygen is free to leave the electrode is determined by the potential of the metal/metal-oxide couple, or if there is more than one oxide, by the potential of the lower-metal-oxide/higher-metal-oxide couple. Empirically, it has been found[1] that the lower these potentials, the higher the catalytic activity.

Our results confirm this trend. In fact, for AIROFs and SIROFs, the lower-metal-oxide/higher-metal-oxide potential coincides with the electrochromic peak of the voltammogram. As this peak occurs at ~0.80 V (RHE) in SIROFs and at ~0.95 V (RHE) in AIROFs, the higher catalytic activity of the SIROF is consistent with the lower potential of its intermediate oxidation states. Moreover, it is likely that the reactive sputtering procedure 'freezes in' these metastable states of intermediate oxidation, resulting in high stability. Thus, in SIROFs, unlike in AIROFs, no trade-off exists between catalytic activity and stability.

We have shown that stable and efficient electrocatalysts for the oxygen electrode can be fabricated by reactively sputtering iridium in a humidified ambient atmosphere and depositing the sputtered films on substrates of non-precious metals such as tantalum. Also the catalytic activity of the SIROFs is better than that of pure iridium, and this material is stable against dissolution in acidic solutions. As this comparison is based on geometric areas, the 'intrinsic' catalytic activity of SIROFs is still unknown. Measurements of the real SIROF area are in progress. Preliminary results (G.B., L.M.S., J.L.S. and W.C.D-S., in preparation) in alkaline solutions show that steady-state OER currents for SIROFs far exceed the values obtained with the preferred catalysts for alkaline electrolysers[14–18]. For example, whereas $NiCo_2O_4$, at 1.69 V against RHE has an OER current[19] of '50 mA cm^{-2} at room temperature, SIROFs have OER currents in excess of 1 A cm^{-2} after 17 h of operation (G.B., L.M.S., J.L.S. and W.C.D-S., in preparation). Thus, although obviously not optimised, SIROFs seem to be very promising OER catalysts.

We thank A. M. Glass and D. H. Olson for the use of their sputtering apparatus, E. Hu and P. Grabbe for the Auger measurements, and A. Heller, C. E. Rice and R. J. H. Voorhoeve for useful comments.

Hydrogen evolution from water using solid carbon and light energy

Tomoji Kawai & Tadayoshi Sakata

Institute for Molecular Science, Myodaiji, Okazaki 444, Japan

Using solar energy to decompose water and produce hydrogen for use in hydrogen energy systems has attracted much attention. Some semiconductors (such as TiO_2 and $SrTiO_3$) can decompose water to produce hydrogen and oxygen using the energy[1] of light and the decomposition of water using powdered semiconductors has been reported[2,3]. One problem with powdered semiconductors is that when H_2O decomposes into H_2 and O_2 in one cell an explosive gas is produced. Furthermore, although Schrauzer and Guth reported[2] that traces of H_2 and O_2 were detected after the decomposition of water gas on TiO_2, the reverse reaction will increase simultaneously as product is evolved. Hydrogen evolution stopped after a few hours. Hence the hydrogen or oxygen produced should be converted to more stable gaseous chemical species. The use of solid carbon is an interesting problem in relation to coal gasification and we have now examined the photocatalytic decomposition of water on TiO_2 using solid carbon. We found that reactions (1) and (2)

$$2H_2O(g) + C(s) \xrightarrow[TiO_2,\ RuO_2]{h\nu,\ RT\sim 80\,^\circ C} 2H_2(g) + CO_2(g) \qquad (1)$$

$$\Delta G^\circ = +63\,kJ\,mol^{-1}$$

$$H_2O(g) + C(s) \xrightarrow[TiO_2,\ (RuO_2)]{h\nu,\ RT\sim 80\,^\circ C} H_2(g) + CO(g) \qquad (2)$$

$$\Delta G^\circ = +92\,kJ\,mol^{-1}$$

$$\xrightarrow{heat,\ 1{,}000\,^\circ C} \text{Thermal water gas reaction}$$

occur producing hydrogen gas from water vapour and solid carbon when mixed powders of TiO_2, RuO_2 and active carbon exposed to water vapour at room temperature ~80 °C are illuminated. The free energies are increased by 63 and 92 kJ mol^{-1} respectively, utilising light energy.

In our experiments 30 mg of TiO_2 (Katayama Kagaku), 10 mg of RuO_2 (Rare Metallic Co.) and 3 mg of active carbon (Katayama Kagaku) were mixed and rubbed in an agate mortar, and spread inside a Pyrex glass bulb (20 cm^2 sample area). The cell and its side arm containing liquid water were then evacuated and illuminated for 5 h in water vapour by a 500 W high-pressure mercury lamp. Any light having a wavelength longer than 320 nm can pass through a Pyrex glass bulb. The gas evolved was trapped at −197 and −78 °C, and was analysed by a mass spectrometer. The gas which was not trapped at liquid N_2 temperature was mainly hydrogen (0.2 torr in 350 ml vessel) and a small amount of carbon monoxide. The gas which was not trapped at −78 °C was mainly carbon dioxide ($H_2 : CO_2 = 1$–1.5) (Fig. 1). When D_2O was used instead of H_2O, D_2 was detected, proving that the evolved hydrogen had been produced from the decomposition of water. Tests were carried out on the systems, TiO_2–H_2O to examine the effect of impurities, and SiO_2–C–H_2O to confirm that without the TiO_2 photocatalyst no appreciable H_2, CO or CO_2 evolved.

Direct reaction of carbon (cokes) with water using heat energy is known as the water gas reaction (2) which takes place at temperatures above 1,000 °C. In our photocatalytic system, however, the reaction with water proceeds at lower temperatures, using carbon as the raw material to decompose water and produce hydrogen. This indicates that oxygen (atom or molecule) produced on the surface of the photocatalyst (TiO_2–RuO_2) has a strong oxidising effect on the carbon.

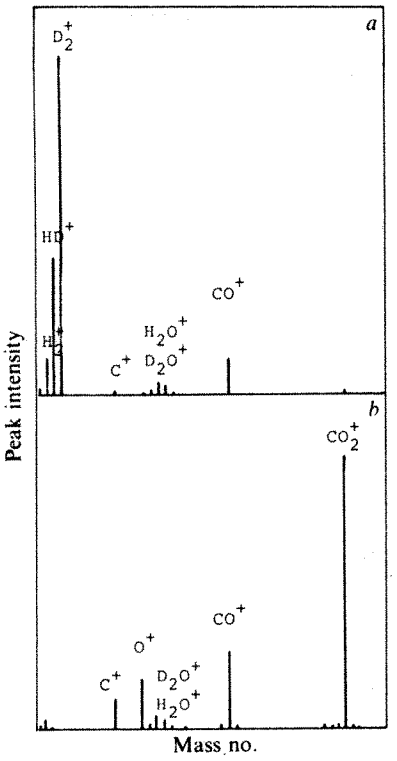

Fig. 1 Mass spectra of the photoproduced gases on TiO_2–RuO_2–C–D_2O (90%). *a*, Fraction not trapped at −197 °C: D_2, H_2 and small amount of CO; *b*, fraction not trapped at −78 °C: mainly CO_2. The C^+, O^+ and CO^+ in *b* are fragments of CO_2^+. H_2O^+ and D_2O^+ are due to background gas and incompleteness of the trapping of water. Pressure of the mass chamber during measurements are 2×10^{-7} torr. 'No hydrogen evolution' means that no D_2 signal was noted when the sample gas was introduced into the mass spectrometer after the photolysis using D_2O. The amount of evolved H_2 and CO depended on how well the catalyst powders were rubbed in an agate mortar. Therefore, the average values obtained after five experiments were considered here.

As TiO_2 powder is regarded as a microcell for the photoredox reaction, water will be oxidised to form oxygen which reacts with carbon to form CO and CO_2, whereas at the reduction site, hydrogen will be formed. Carbon by its own oxidation acts as a reducing reagent. RuO_2 is one of the best electrode materials for oxygen evolution with the lowest overpotential[4]. Hence it may act as the oxidation site at which carbon forms CO and CO_2. In fact, CO_2 formation was suppressed when the RuO_2 catalyst was not added to the system. Only traces of hydrogen molecule could be detected when oxidised TiO_2 photocatalyst alone was used. The addition of RuO_2 and solid carbon markedly increased the hydrogen evolution. Although absolute quantum yield of the reaction has not yet been obtained, the relative quantum efficiency of H_2 evolution in the TiO_2–RuO_2, C, H_2O system increased by at least 10^2 times that from the TiO_2–H_2O system we tested. Consequently, although the increased energy per reactions (1) and (2) is less than that of the decomposition of water into H_2 and O_2, the total energy efficiency for the incident light is much larger in our system. We have examined the effect of several kinds of metals as catalyst (Ru, Ni and Pt) with TiO_2. Although the evolved hydrogen is increased ~7–15 times in the first stage of the reaction, this would be due to the oxidation of metal itself by the oxygen produced from H_2O, assisting hydrogen evolution. Hence the system combined with metal–oxide catalyst is catalytically regenerative. This system remained catalytically active for more than 7 days illumination. When the temperature was raised from room temperature to 60–80 °C, the rate of CO and CO_2 formation increased, probably because a lot of energy is required to split the C—C bond of active carbon to form CO or CO_2. Therefore the use of solar energy as a combination of light energy and heat energy will be more useful.

In the photo-driven ammonia synthesis from N_2 and H_2O (ref. 2) and CO_2 reduction by H_2O (refs 5, 6), hydrogen produced from water was used, whereas the oxygen evolved reacted with carbon, and in our system gaseous hydrogen is produced. Note also that during the reaction, hydrocarbons were produced by reactions among photo-products or solid carbon directly.

As the Earth contains a lot of carbon in the form of coal, this method may be a possibility for coal gasification and hydrogen evolution from water, accompanied by storage of solar energy.

Phosphorylation of adenosine in aqueous solution by electric discharges

Y. Yamagata, T. Matsukawa, T. Mohri & K. Inomata*

Department of Physics and * Department of Chemistry, Faculty of Science, Kanazawa University, Marunouchi, Kanazawa 920, Japan

Dehydration reactions involving condensing reagents in aqueous solution[1] have been studied as models of chemical evolution, and one such reagent has been found to be produced in the supposed primitive Earth conditions[2]. We assumed that the dehydration condensation in aqueous solution could occur if the condensing reagents, which appear to be produced by electric discharges in the gas phase, could be carried to the aqueous solution through the recycling of water washing the wall of the vessel. We present here an experimental study of the dehydration condensation between phosphate and adenosine in aqueous solution using a new discharge apparatus (Fig. 1) which simulates prebiotic chemical evolution. The apparatus was designed so that water recycles in a vessel containing a solution at a relatively low temperature (~30 °C), achieved by showering water at 18 °C from above the vessel. This is a simulation of the recycling system of water on the Earth, depending on a large difference in temperature between the ocean surface and the sky.

Four parallel discharges simulating lightening were induced by four neon-sign transformers (Matsushita, 15 kV), each connected to a ring co-electrode at the centre of the vessel and one of four electrodes around it. The gaps between the electrodes were 3–4 cm. Nichrome wire of 1.6 mm diameter was used for the electrodes. In each of the experiments the aqueous solution and the gases were prepared in the 5-litre discharge vessel in the conditions shown in Table 1. Adenosine was purified on a DEAE-Sephadex column to eliminate impurities such as AMP and other nucleotides. The solution was kept at about 30 °C and stirred with the magnetic stirrer.

The pressure in the vessel changed considerably during the discharge. Figure 2 shows this in runs 1 and 7. The patterns of change were similar in runs 1 to 6, and that of run 8 was to that of run 7 for up to 1 week, thereafter decreasing gradually to 16 cm Hg. The initial increases of the pressure in runs 1–6 are probably due to the decomposition of ammonium bicarbonate. Gas chromatography of the gas component in run 5 [Shimazu Model GC-6APTF; column: active carbon 3 mm × 3 m; column temperature 40–200 °C; carrier gas He, 40 ml min^{-1}] showed that about 90% of its nitrogen appeared as molecular nitrogen, and 30–40% of its carbon as carbon monoxide and dioxide. In runs 7 and 8 the pressure decreased suddenly at the start of

0028/0836/79/460284—03$01.00

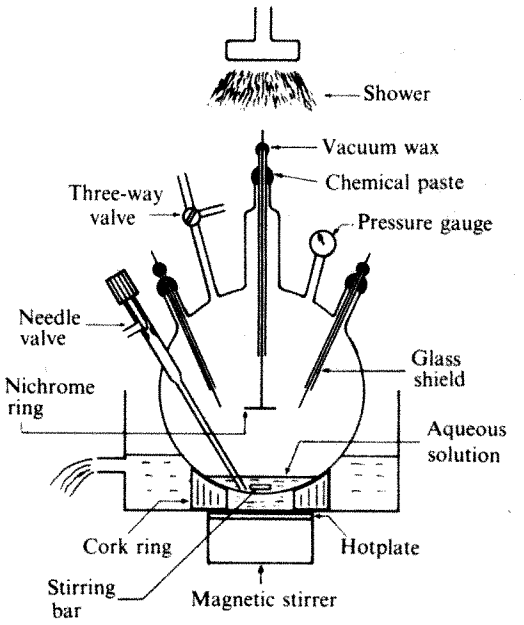

Fig. 1 Five-litre electric discharge apparatus.

discharge, mainly due to consumption of hydrogen. Gas chromatography after a week of discharge showed that the remaining hydrogen constituted only a few per cent of initial level in both cases, but the remainders of the nitrogen and carbon compounds (CO_2+CO) were 87% and 74% (18%+56%) for run 7, respectively, and 85% and 67% (50%+17%) for run 8 (although these results contain errors of several per cent).

After the discharge had taken place for a week, the solution was applied to a DEAE-Sephadex column (1.5×37 cm) and a gradient elution was carried out with 500 ml each of 0.02 M and 0.5 M NH_4HCO_3 (rechromatography was not necessary in runs 7 and 8, because AMP fractions contained only a small quantity of impurities). The fractions expected to contain AMPs were collected, evaporated, and rechromatographed on a Sephadex G-15 column (2.64×65 cm) by elution with 0.1 M NH_4HCO_3 (rechromatography was not necessary in runs 7 and 8, because AMP fractions contained only a small quantity of impurities). The fractions of the main peaks corresponding to AMPs were collected and evaporated to remove NH_4HCO_3, and the residue was subjected to preparative TLC (silica gel) with a solvent system, ethanol ammonia/water, 4:1:1. The extracts from UV-absorbing bands corresponding to 5′-AMP and 2′(3′)-AMP were confirmed to be the expected products on cellulose TLC (solvent system, saturated ammonium sulphate/1M ammonium acetate/isopropyl alcohol, 80:18:2) in which the 2′(3′)-AMP component was separated into two nearly equal UV-absorbing spots corresponding to 2′- and 3′-AMP[3]. Identifications were confirmed by the degradation of the products to adenosine with an application of alkaline phosphatase[4]. Total yields of AMPs are given in Table 1 together with the ratios of the yields of 5′- and 2′(3′)-AMP. The yields are relatively high, considering that the yield of phosporylation is, at most, a few per cent even in the experiments in which a large amount of the condensing agents was used[5], and the very low yields (0.002–0.02%) of the dicyanamide formation in the CH_4–NH_3–H_2O mixture irradiated by electrons[2].

Table 1 Starting conditions and results of analyses after 1 week of electrical discharge

Starting condition	Run no. 1	2	3	4	5	6	7	8
Aqueous solution (100 ml)								
Adenosine (M)	0.03	0.03	0.03	0.03	0.03	0.03	0.02	0.02
$(NH_4)_2HPO_4$(M)	0.2	0.2	0.2	0.2	0.2	0.2	—	—
KH_2PO_4(M)	—	—	—	—	—	—	0.2	0.2
NH_4HCO_3(M)	1.0	1.0	1.0	1.0	1.0	1.0	—	—
Gas component								
CO_2(cm Hg)	11	21	31	11	11	11	14	14
H_2(cm Hg)	—	—	—	5	—	—	21	14
O_2(cm Hg)	—	—	—	—	5	10	—	—
N_2(cm Hg)	—	—	—	—	—	—	7	7
*p*H	7.70	7.70	7.70	7.70	7.70	7.70	4.80	4.80
*p*H(final)	7.30	7.52	7.30	7.45	7.40	7.40	7.30	7.21
Total-AMP yield (%)*	0.016	0.038	0.029	0.013	0.020	0.010	0.019	0.21
5′-AMP / 2′(3′)-AMP	1.2	1.3	1.3	1.4	1.3	1.1	1.5	1.6

* Total yield values (% adenosine converted to AMPs) contain relative errors of ~±10%.

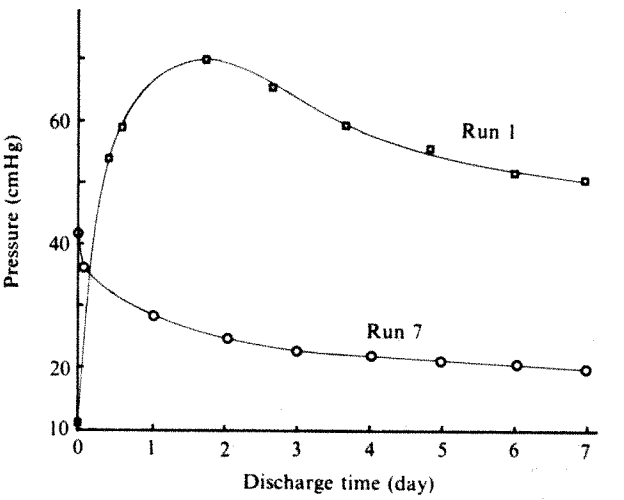

Fig. 2 Pressure change during discharge.

Formation of pyrophosphate was also confirmed in run 8 by detecting phosphate[6] in the fractions corresponding to pyrophosphate after they were boiled for 8 h or treated with pyrophosphatase[7]. The yield of pyrophosphate was estimated to be about 0.01% of the starting phosphate.

A striking result was the finding that the yield of run 8 was one order of magnitude higher than that of run 7. The control experiment in which no electric discharges were applied was also carried out in the same conditions as run 8. Fifty ml of the solution was pumped out after 2 weeks of the incubation. Apart from adenosine, no UV absorbing substances were detected. This indicates that the yield of AMP would be <0.001% which is the limit of the detection. Discharges in run 8 were continued over 1 week to study the dependence of the yield on the

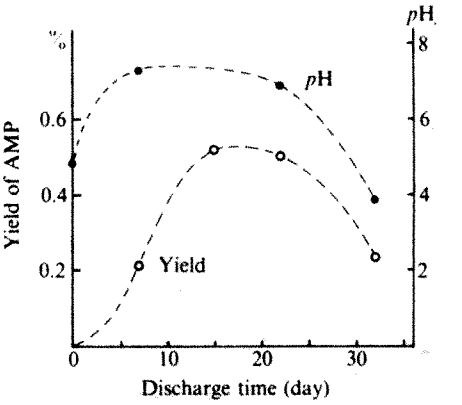

Fig. 3 Dependence of total yield of AMP, and of the *p*H of the solution, on the discharge time in run 8.

discharge time. The findings are shown in Fig. 3, together with measurements of *p*H. The initial increase of *p*H may be due to the formation of ammonia, and the decrease at the latter half to the formation of nitric acid (detected by the method using ferrous sulphate and concentrated sulphuric acid). The remaining solution was pumped out at the end of the run, and the vessel was washed with 10 ml of water. The *p*H of the washing was 0.05. The decrease of the yield at the end is probably due to the rather oxidative composition of the remaining gas, in which nitric acid and other oxidants would have been formed by the discharges. TLC and ion exchange chromatography showed many unknown substances, suggesting that adenosine decomposition took place.

As the results of these runs were dependent on the starting conditions, it seems possible that in certain conditions dehydration condensation could proceed linearly with discharge time. Studies to find such conditions are under way.

Acetylene was first polymerised to a linear polymer in 1958[1], but the resulting grey powdery material, insoluble, infusible, and devoid of any interesting electrical properties, remained a scientific curiosity until Ito *et al.*[2] showed that it was possible to polymerise acetylene into a continuous film on the wall of a reactor. This polyacetylene film, $(CH)_x$, a large band gap semiconductor, can be transformed into a highly conducting material with $\sigma_{RT} \sim 1{,}000\ (\Omega\ cm)^{-1}$ (refs 3–12) upon doping with either electron donors or acceptors[13,14]. Although fibrous electron micrographs (EM) of unaligned[2] and partially aligned (stretch elongated) samples having enhanced conductivities have been reported[3], it has been suggested that the observed morphology might be misleading, possibly resulting from a post-polymerisation handling of the film, or even an artefact such as the result of ultrasonication. The aim of this work is to determine the true nascent morphology of polyacetylene. We have polymerised acetylene directly on electron microscope gold grids and examined the polymer with scanning and transmission modes. The ultrathin specimen is entirely fibrous with diameters of ~5–40 nm, with 20-nm fibrils the most abundant. Some films show surface fractures revealing partially or completely aligned fibrils bridging the gaps. Some globular features were also observed suggesting local fusion. Thick films of polyacetylene also have fibrous morphology throughout. The observed structure is consistent with surface area measurements. Therefore, acetylene polymerises directly into fibrils, possibly due to the rigidity of the polymer backbone which is comprised of conjugated double bonds.

Acetylene was polymerised directly onto EM grids (3-mm disks of 300-mesh gold screen). This was accomplished by indium soldering of the grid on to a fine gold wire and hanging it in the reactor above the catalyst solution. The catalyst solution [7 mM $Ti(OBu)_4$, 28 mM $Al(C_2H_5)_3$] was introduced onto the grid as a thin liquid film by shaking. Acetylene gas (total pressure ranging from 10 to 760 torr of acetylene) was admitted for less than 1 min and pumped off immediately. The thickness of the polymer film may be controlled by varying the catalyst concentration, acetylene pressure and the time and temperature of the reaction. The ultrathin $(CH)_x$ specimen thus prepared was washed to remove catalyst residues by repeated pentane distillation. A JEOL 100 CX Temscan electron microscope was used in this work. The four modes of observation were transmission (TEM), electron diffraction (ED), scanning (SEM) and scanning transmission (STEM). The polymerised film was observed by the first two modes; gold-coated films were examined with the other two modes. Gold coating was applied either by sputtering or evaporation with its thickness carefully controlled and kept in the 3–7-nm range.

Figure 1*a* is a STEM image at low magnification (10^4) showing fibrous webs throughout the specimen. At higher magnification of 5×10^4, Fig. 1*b*, *c* shows STEM images of the identical portion of the sample in which voids appear black (and white), respectively, demonstrating that the film is only a few fibrils in thickness. At 10^5 magnification (Fig. 1*d*) individual fibrils were clearly discernible having diameters ranging from ~5 to 40 nm with 20-nm diameter fibrils being the most abundant. BET measurements (nitrogen gas) gave a surface area of $60\ m^2\ g^{-1}$ which corresponds well with the observed fibre morphology.

Interestingly, polymerisations at higher acetylene pressure (760 torr) yield extremely smooth film on the grid even when observed at the highest magnifications. These films, however,

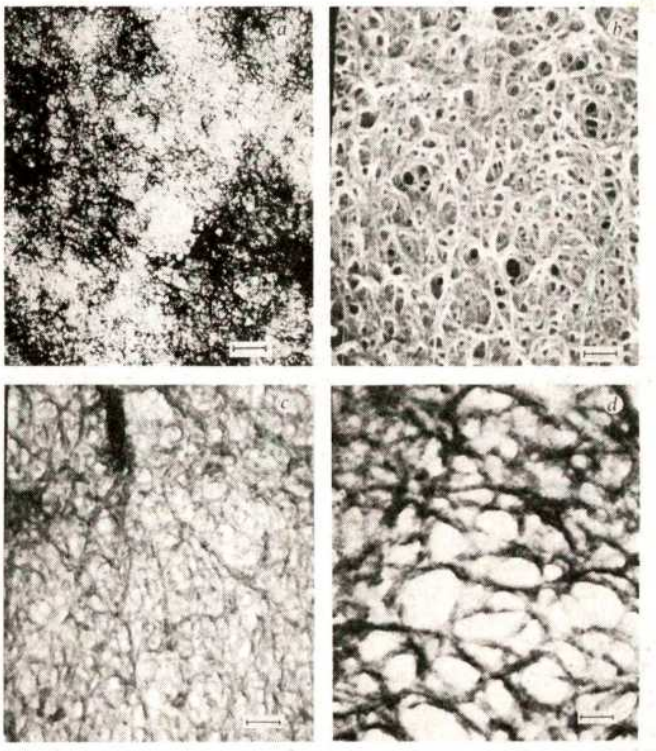

Fig. 1 *a*, Electron micrographs of ultrathin $(CH)_x$ films polymerised directly onto a gold grid at 55 torr of acetylene for 30 s, dried and coated with a 3-nm later of palladium gold by evaporation, ×10,000 in the STEM mode. *b*, Same sample as in *a* at ×50,000 SEM for matched areas. *c*, As for *b* but in STEM mode. *d*, Same sample as in *a* showing 100,000 STEM. Scale bars: *a*, 1 μm; *b*, *c*, 0.2 μm; *d*, 0.1 μm.

possess fractures (Fig. 2*a*) in which are found partially aligned fibrils (Fig. 2*b*). Occasional regions contain highly aligned 10-nm diameter fibrils (Fig. 2*c*). These fractures are probably formed during the washing procedure and are due either to the displacement of one diluent (toluene) with another (pentane) or to the thermal contraction occurring when the film was cycled between 78 K and room temperature. One explanation for the smooth film surface is that it consists of layers of $(CH)_x$ polymerised in a substantially aligned state.

There are also globular structures, as shown, with increasing magnification, in Fig. 3. Examination of Fig. 3*a* shows that the globular growth appears to have been separated from a portion of the film as a result of melting contraction. Such local heating is entirely possible as the polymerisation is highly exothermic.

That the above morphology extends to thick continuous films formed by depositing a thin layer of catalyst solution on the wall of a cylindrical reaction vessel and subsequently exposing this layer to an atmosphere of acetylene, with polymerisation extending for several minutes, may be readily demonstrated. Such film has a highly reflecting metal-like surface on the side adjacent to the glass wall of the reactor (Fig. 4*a*) and a duller surface on the opposite side (Fig. 4*b*). The latter has the typical random fibrous morphology discussed above. The shiny side apparently has an identical morphology except that the fibrils are flattened and merged or fused into larger entities. Fusion is a distinct possibility even though one might expect heat transfer to be more efficient at the reactor wall. However, polymerisation is likely to occur very rapidly there because of a high catalyst concentration and lower monomer diffusion limitation.

Continuous $(CH)_x$ film has a gross density of only ~0.4 g cm^{-3} whereas its flotation density is 1.16–1.18. Therefore, the film is highly porous with voids constituting two-thirds of the total volume. When the fibrils are not aligned, the gross morphology of $(CH)_x$ film is somewhat analogous to the cellulose fibrils constituting a sheet of paper.

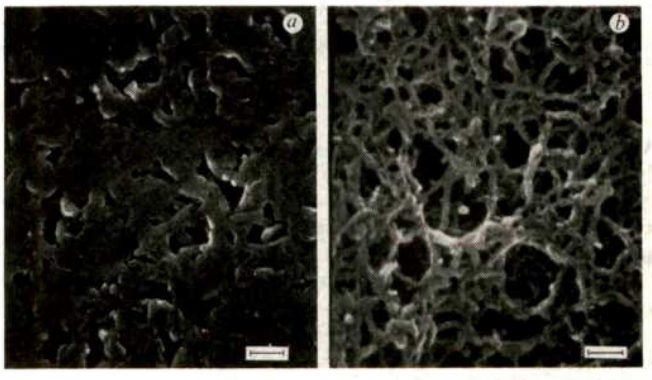

Fig. 4 SEM micrographs at ×50,000 of thick $(CH)_x$ film polymerised on the glass wall of reactor with 760 torr acetylene. *a*, Highly reflecting side of the film facing the wall; *b*, dull side of the film facing away from the wall. Scale bars, 0.2 μm.

Ethylene and propylene polymerised by Ziegler–Natta catalysts have fibrillar, spherical, globular, worm-like, needle-shaped, and helical nascent morphologies depending on the type of catalyst and experimental conditions. Polyethylene fibres of 20–30 nM were obtained with $TiCl_3/AlEt_3$ catalyst[14]. Polypropylene fibrils of 30–50 nM diameter were formed by the

same catalyst[15]. The mechanism suggested was that the polymer chains formed on adjacent active sites of the α-$TiCl_3$ surface were insolubilised together into microfibrils[16]. The present $Ti(OBu)_4/AlEt_3$ catalyst has been described as an homogeneous or an heterogeneous system depending on experimental conditions[17–19]. The fact that uniform fibrillar polyacetylene was produced suggests an heterogeneous catalysis mechanism. Work is in progress to determine the dependence of nascent polyacetylene morphology on catalyst concentrations and polymerisation conditions.

We thank Professor E. L. Thomas for advice on electron microscopy.

^{87}Rb–^{87}Sr chronology of the Binda howardite

J. L. Birck & C. J. Allegre

Laboratoire de Géochimie et Cosmochimie, Universités de Paris VI et VII, 4 Place Jussieu, 75230 Paris Cedex 05, France

Differentiated meteorites have numerous similarities with igneous rocks from the Earth and the Moon. They are of primordial importance in our understanding of magmatic processes in the early Solar System. The howardites constitute a particular class of differentiated meteorite as they are mechanical mixtures[1–7] (polymict breccia) of components from two other classes—eucrites and diogenites. The eucrites are representative of magmatic liquids and the diogenites are the corresponding cumulates[3]. This relationship is supported by oxygen isotopic data[8]. The ^{87}Rb–^{87}Sr chronology of eucrites[9,10] shows that these objects result from a very early igneous activity near the surface of their parent body (<150 Myr after formation of the Solar System). As for howardites, within the same meteorite Kapoeta, basaltic clasts have been dated by the internal Rb–Sr isochron at 4,400 Myr and around 3,500 Myr (refs 11, 12). ^{39}Ar–^{40}Ar dating of these clasts provides evidence for their initial crystallisation 4,500 Myr ago, and for their independent history until the final lithification of Kapoeta, probably as late as 2,200 Myr ago[13]. Due to this complexity their initial age of crystallisation, and in particular, their $^{87}Sr/^{86}Sr$ initial ratio is not precisely known. We report here our investigation of the Binda howardite which seems to have had a simpler history; it is the only one which is a monomict breccia. The component representing the cumulate fraction seems to be in equilibrium with that which represents the eucritic melt[3]. Therefore one might expect to date the howardites formation by dating this meteorite, assuming that they all formed in the same parent body.

Minerals were separated from the meteorites by hand-picking and heavy liquid methods. Our experimental technique is similar to that used for the Lunar 24 basalt analysis[14]. Blanks are 2 ng, 0.004 ng, 0.03 ng for K, Rb and Sr, respectively. (Blank correction was never more than a few per cent.)

The results are given in Table 1, and Fig. 1 shows the conventional Rb–Sr diagram. Although the total rock samples of Binda are between those of Juvinas and Bereba[10], concentrations in K, Rb and Sr are a factor of 2 to 5 lower than in these meteorites. The cumulate fractions are very poor in these elements[7] and from our K–Rb–Sr concentration data, they must represent at least 50% of the Binda howardite. By plotting the data in the $^{87}Rb/^{86}Sr$, $^{87}Sr/^{86}Sr$ diagram (Fig. 1) it may be seen that this object has undergone perturbation. However, all the points except one (PXH3) fall on a straight line within experimental error limits. This line corresponds to an age of 3,450 ± 340 Myr (2σ) with $\lambda = 1.42\ 10^{-11}\ yr^{-1}$ as decay constant for ^{87}Rb.

Heavy liquid can have preferential leaching effects on meteoritic and lunar minerals[15]. This can be understood if we assume that some fine particles become partially dissolved during the separation, because they are not separated from heavy liquids even when these are centrifuged. For achondrites[9,10] and some lunar samples[14] this seems to be the case for the light interstitial K–Rb rich phases, and might significantly affect the age. In the case of Binda, however, we believe that such an effect cannot produce our results. First, we have made a very rapid separation using small quantities of heavy liquids for Binda expecting that the effects increase with time. Second, short-time leaching by heavy liquids generally increases the model age of the leached fractions. Finally, both hand-picked and heavy liquid separates plot on the same straight line. We have also analysed the K, Rb and Sr contents of the liquors after the separations and (unlike ref. 15) they represent <1.3% of the total concentrations in the samples (Table 1). We conclude that the 3,450 ± 340 Myr age of Binda is not an experimental artefact and at least sets an upper limit for the age of the last remobilisation of the strontium but most probably dates this one.

The $^{87}Sr/^{86}Sr$ initial ratio calculated from whole rock assuming an age of 4,470 Myr is 0.69894 ± 0.00004. Similarly, if the hand-picked plagioclase 'Plag H' is assumed to have the same age, this indicates an $^{87}Sr/^{86}Sr$ initial ratio of 0.69894 ± 0.00004. This value is indistinguishable from that for eucrites[10–16]. The small insignificant difference might be due to a non-representative whole rock sample. A small excess of pyroxene in the latter may explain the difference. One can compare this $^{87}Sr/^{86}Sr$ initial ratio to that for the other howardite studied so far: Kapoeta[11,12]. That for Kapoeta is significantly lower in clast C which has an age of 4,440 Myr and $^{87}Sr/^{86}Sr$ initial ratio of 0.69885 ± 0.00005. The Sr initial ratio for clast A is almost as low as that for clast C. We are faced with two alternatives. First that this low initial value is real. In this case the basaltic clasts (A and C) are not related to the magmatism which created Binda and the eucrites. They may come from another part of the same parent body or Kapoeta comes from another parent body with a similar history with a different timing. In any case, Kapoeta contains exotic components like chondritic material[1], and its formation seems to involve many components[17] of various origins. The alternative interpretation is that this low initial ratio is insignificant and results from Kapoeta being a mixture of different components of various ages; a similar interpretation has been discussed for lunar samples[18]. We cannot distinguish between these possibilities at present.

As in eucrites, the ^{87}Rb–^{87}Sr mineral age for Binda is controlled by a light K-rich phase. The internal age might simply relate to this mineral. One can interpret this younger age as a secondary resetting of the ^{87}Rb–^{87}Sr clock by metamorphism or shock, 3,450 Myr ago. This result is similar to the ^{87}Rb–^{87}Sr and ^{39}Ar–^{40}Ar ages around 3,800 and 3,500 Myr of some clasts of Kapoeta[11–13]. It also agrees with the 3,600 Myr ^{39}Ar–^{40}Ar age of Malvern[19]. At the opposite, the ^{39}Ar–^{40}Ar ages of the

howardites Bununu and Yamato L are higher than 4,200 Myr (ref. 19) and 4,000 Myr (ref. 20) respectively. Similarly ^{39}Ar–^{40}Ar dating of Kapoeta also yields ages ≥4,500 Myr (ref. 13). If all howardites are genetically related, these data show that they probably crystallised 4,500 Myr ago and were later disturbed by one or several large scale secondary events 3,400–3,800 Myr ago which are probably related to impacts. As discussed by Wetherill[22], the absence of a cluster of resetting ages around 4,000 Myr is not a conclusive argument against an inner Solar System wide 'cataclysm' such as determined on the Moon[21]. However, there is a lot of evidence for large-scale impacts in Basaltic Achondrites between 3,900 and 3,500 Myr which are not so far recorded in the lunar rocks actually analysed.

We thank S. Clark for the meteorite sample and J. F. Minster and N. Shimizu for helpful discussions.

Allende meteorite—old age but normal isotopic composition of potassium

W. Stegmann & F. Begemann

Max-Planck-Institut für Chemie (Otto-Hahn-Institut), Mainz, FRG

The extensive investigation of the Allende meteorite has provided much new information on the early history of our Solar System. The findings include small but significant anomalies of the isotopic composition for several elements which are clearly not due to any of the processes hitherto known to cause such variations (see ref. 1 for review). These anomalies seem to confirm the reality of astrophysical concepts developed since the classical paper of Burbidge *et al.*[2] on the different modes of origin of the nuclei. Evidence has also been found which points to the possible presence in Allende of pre-solar condensates. Jessberger and Dominik[3] have presented data to support an earlier result[4] according to which the ^{40}Ar gas retention ages of some white inclusions from Allende exceed the canonical age of the Solar System. These gas retention ages were obtained by ^{40}Ar–^{39}Ar dating, however, and are therefore based on the assumption that the ^{39}K/^{40}K ratio in the inclusions is identical to that used in the reference standard. In view of the far-reaching implications of finding in meteorites solid matter pre-dating by roughly 500 Myr the condensation of the Solar System we have attempted to verify this assumption. This is especially important because the Allende inclusions contain elements with an anomalous isotopic composition.

We were given (by E. K. Jessberger) two portions of inclusion 18: three chips with a combined weight of 1.9 mg and another aggregate of 16 mg. Although these portions are not true aliquots of a well homogenised sample they are, nevertheless, considered representative of the sample analysed by Jessberger and Dominik.

The small sample was used for pilot experiments. One chip (780 μg) was treated in a small Teflon bomb with a mixture of 5 μl HF (40%) and 3 μl $HClO_4$ (70%) for 5 h at 190 °C. It was fumed to dryness in the Teflon bomb and taken up with 20 μl HF (10%). Part of the solution was spiked with both ^{40}K and ^{42}Ca for the determination of the concentrations of potassium and calcium by isotope dilution, the remainder was used for the potassium analysis. If there had been a residue its distribution among the spiked and the unspiked fraction may have been inhomogeneous.

Although using HF to take up the sample drastically reduced the Ca^+/K^+ ratio in the mass spectrometer, the interference on mass 40 from $^{40}Ca^+$ could not be entirely neglected. Hence, from all subsequent samples with one exception (see below) the potassium was separated by ion exchange. This resulted in very weak signals on the monitor masses 42 and 44 but, because of the high ^{40}Ca/^{42}Ca and ^{40}Ca/^{44}Ca ratios respectively, it caused a large uncertainty in the residual interference on mass 40. This was avoided by adding a ^{42}Ca spike to the potassium after it had been separated on the ion exchange column. (The resulting ^{40}Ca/^{42}Ca ratio itself was measured after termination of the potassium measurement by increasing the temperature of the sample filament until Ca dominated the mass spectrum.) The spike solution contained 10^{-3} g K of normal isotopic composition per gramme of ^{42}Ca.

The remaining two chips from the small sample (1,100 μg) were treated as before (10 μl HF + 4 μl $HClO_4$, 5 h at 180 °C, fuming to dryness, 5 μl each of HF and $HClO_4$, 10 h at 190 °C, fuming to dryness). The residue was taken up with 20 μl of 0.5 M HCl. Part of it was spiked with ^{40}K and ^{42}Ca, the rest (95%) was filtered through a Teflon filter (Millipore FH 0.5 μm) and the filtrate put on a quartz ion-exchange column (3 mm diameter, length 5 cm) filled with Dowex 50 WX 8. Potassium was eluted with 0.9 M $HClO_4$. The eluate (0.63 ml) was spiked with 12 ng of ^{42}Ca, it was evaporated to dryness and dissolved again in 5 μl HF (10%) for the mass spectrometric measurement.

The 16 mg aggregate was decomposed as described above except that larger amounts of acid were used and that the heat treatments in the Teflon bomb were 48 h and 15 h, respectively. After the last fuming to dryness the residue was taken up in 530 μl of 0.9 M $HC10_4$ and centrifuged. About 1% of the supernatant was spiked with ^{40}K and ^{42}Ca, the bulk put first through a large (4mm diameter, length 5 cm) and then a small ion exchange column. In both instances potassium was again eluted with 0.9 M $HClO_4$ and ^{42}Ca was added as before. The undissolved portion of the aggregate, the residue after centrifuging, amounted to <1% of the original 16 mg. It was brought into solution by treating it in the Teflon bomb for 16 h at 190 °C with 5 μl each of H_2SO_4 (96%) and H_3PO_4 (85%). It was analysed by mass spectrometry without any more chemistry.

Only quartz and Teflon were used throughout the experiments; all acids were Merck grade 'suprapur'. Their K-content was determined by isotopic dilution and was found to be for HF (40%) 4 p.p.b. (parts per 10^9); $HClO_4$ (70%) 50 p.p.b.; HCl (4.5 M) 1 p.p.b.; H_2SO_4 (96%) 80 p.p.b.; H_3PO_4 (85%) 140 p.p.b. and H_2O 1 p.p.b. The total blank of dummy runs with

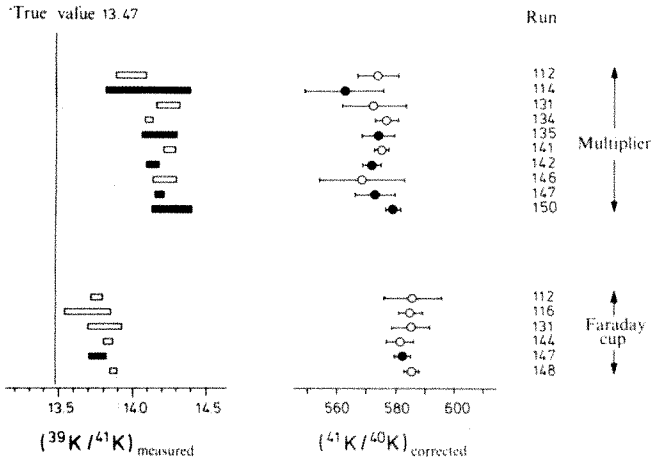

Fig. 1 Measured $^{39}K/^{41}K$ ratios and mass discrimination-corrected $^{41}K/^{40}K$ ratios of terrestrial (open symbols) and Allende (filled symbols) samples. The length of the bars for the measured $^{39}K/^{41}K$ ratios do not indicate the errors of these ratios but rather the shift with time observed during the measurement. The Faraday cup measurements are in complete agreement with the results of Burnett *et al.*[10] and Begemann and Stegmann[7] who, after normalisation to the same $^{39}K/^{41}K$ ratio of 13.47, reported values of 584.89 and 584.87, respectively.

appropriate amounts of acids was ≤2 ng K, passing the solution through the ion-exchange columns increased the value to ≤10 ng.

The mass spectrometric measurements were performed by surface ionisation using double (rhenium) filament sources. Only in the case of the 16 mg sample was the ion current high enough for a Faraday cup, together with a $10^{11}\Omega$ resistor, to be used as a detector. This necessitated a correction for the nonlinear voltage dependence of the resistor; a second order polynomial gave a fit through the experimental data to better than 3×10^{-4} for the whole range of interest (10–65 V). In all other instances a 16-stage secondary electron multiplier (1,500–1,800 V, $10^9\,\Omega$, gain $\approx 2\times10^5$) was used where no such correction was necessary. Data acquisition was by computer-controlled peak jumping using a $5\frac{1}{2}$-digit integrating voltmeter. Details will be published elsewhere[5].

The results are compiled in Table 1. The potassium contents in column 4 are uncorrected for blanks, the last column gives upper limits for the contribution of blank potassium to the total, based on 2 ng K for samples SI and SIIIR and 10 ng for SII and SIII (see above). Owing to the low ion currents in the mass spectrometer a considerable fraction of the total potassium had to be measured. Consequently, a marked shift with time of the isotope ratios was observed. This is indicated by the range of $^{39}K/^{41}K$ ratios in column 7, where the highest values are the initial ones. The $^{41}K/^{40}K$ ratios are corrected for fractionation by adopting as true value $^{39}K/^{41}K = 13.47$ (ref. 6) and assuming the mass discrimination between neighbouring isotopes to be constant. In no case was there any positive evidence for a contribution to mass 40 from $^{40}Ca^+$; the limits which can be set are indicated in column 9.

Figure 1 shows the isotope data of Table 1, together with results for normal terrestrial K as obtained on samples of similar size as the meteoritic ones. The degree of the instrumental fractionation can be seen from the off-set of the measured $^{39}K/^{41}K$ ratios from the Nier value of 13.47. Particularly obvious is the additional discrimination caused by the mass dependent gain for different isotopic species of the multiplier. It also seems that the corrected $^{41}K/^{40}K$ ratios are systematically lower for the multiplier compared with the ones with the Faraday cup as collector. Contributions on mass 40 from species other than ^{40}K can be excluded as was verified by large terrestrial samples. The reason for this discrepancy is not clear. As both the terrestrial and the meteoritic samples are affected, however, there is no potential reason apparent for any misinterpretation as long as both sets of data are considered separately.

We conclude from these data that within the experimental limits of error the isotopic composition of potassium from the Allende inclusion is indistinguishable from that of normal potassium. Neither the $^{39}K/^{41}K$ nor the $^{41}K/^{40}K$ ratio shows any evidence for an anomaly in excess of 1%. As pointed out by Jessberger and Dominik[3], for a sample 4,600 Myr old to yield an apparent ^{40}Ar–^{39}Ar age of 5,100 Myr the ^{40}K would have to be enriched by about 35%. As our upper limit to a possible anomaly falls short of this by more than an order of magnitude the old apparent age of this inclusion cannot be due to an anomalous abundance of ^{40}K.

As one of the assumptions underlying the ^{40}Ar–^{39}Ar method has been verified the old apparent ages of some of the Allende inclusions are more likely to be the true ones. Unfortunately, however, the interpretation is still ambiguous as another prerequisite for obtaining true ages is that all ^{40}Ar from the sample is indeed produced by the *in situ* decay of ^{40}K. We feel that it would be premature to exclude the possibility of the presence in meteoritic matter of extraneous 'unsupported' or 'orphan' ^{40}Ar.

We should re-emphasise that in the inclusion investigated the relative abundance of ^{41}K agrees with the normal value to within ±1%. Thus there is no evidence[7,8] to support Clayton's suggestion[9] that pre-solar grains might contain excess ^{41}K from the *in situ* decay of ^{41}Ca. This result will be particularly important if the ^{40}Ar–^{39}Ar ages should turn out to be the true ages as this would make the inclusions, or part of them, true presolar condensates.

Age and significance of alluvium in the Windrush valley, Oxfordshire

J. Hazelden & M. G. Jarvis

Soil Survey of England and Wales, Rothamsted Experimental Station, Harpenden, Hertfordshire, UK

The floodplain deposits of the upper Thames and its tributaries commonly comprise 0.5–1 m of clay alluvium overlying, with a sharp boundary, a variable thickness of sandy limestone gravel. Samples of wood (probably alder root) from the top of the gravel in a temporary exposure (SP 360084) in the floodplain of the river Windrush, south of Witney, Oxfordshire, gave a radiocarbon date of 2,660±85 yr BP (I-9337); these roots had been truncated at the gravel/clay interface. Here we consider the sequence of events and the possible causes of this change to clay deposition; we conclude that the latter resulted chiefly from a rapid increase in local forest clearance and in the amount of ploughed land, after 2,660 yr BP.

The Windrush is a tributary of the Thames; it drains the southern edge of the Cotswolds, Jurassic limestone hills north and west of Witney, and then flows southeastwards across the Oxford Clay country to the Thames at Newbridge (SP 403015).

0028/0836/79/460291—02$01.00

© 1979 Macmillan Journals Ltd.

Its valley is characteristically narrow and entrenched within the Cotswolds but widens to about 1 km where it crosses the undulating clay land south of Witney.

The solid geology of the district is fairly simple. Thin Cornbrash limestone outcrops beneath Witney and to the north, with older limestones and clays of the Great Oolite series exposed locally in small folds and faults. These strata dip gently to the south-east and are overlain by Oxford Clay south of Witney. Drift deposits are extensive, especially the limestone gravels on river terraces.

About 1 m of Flandrian clay alluvium overlies the gravel in the Windrush floodplain adjacent to the river. Locally layers of peat, up to 0.3 m thick, occur at the junction of these two deposits, especially near the margins of the floodplain. Auger bores and occasional pits have proved this sequence of deposits throughout the Windrush floodplain from Witney to the Thames.

The site we sampled showed 1.06 m of clay alluvium over about 5 m of sandy limestone gravel, in turn probably over Oxford Clay (not seen); the gravel contained scattered organic matter. The root fragments were up to 0.04 m in diameter and seemed to be in position of growth in the gravel. They were truncated, only one fragment protruding some 0.1 m above the gravel surface.

These deposits suggest the following sequence of events. At first a high energy stream deposited the sandy gravel. Then followed peat accumulation, either locally in quiet backwaters or perhaps as a widespread deposit subsequently largely removed by erosion. Elsewhere in the Windrush floodplain we have seen large, unidentified logs in this peat, up to 0.1 m diameter. In either event the top of the gravel was eroded, at least locally, as in the section we studied the roots had been broken off and no tree stumps remained. The last event in this sequence was deposition of clay alluvium. A dark layer within it, about 0.5 m above the gravel and 0.07 m thick, represents an old topsoil—a level at which deposition temporarily slowed or ceased allowing organic matter to accumulate at the ground surface.

The radiocarbon date is significant for the age of the clay alluvium. Clearly the alder fragments post-date the gravel in which they grew, but are older than the period of erosion and the subsequent deposition of clay. The beginning of accumulation of clay alluvium at this site was, therefore, after 2,660 yr BP.

Corroborative evidence for changing conditions near or after this date is available at Farmoor, on the Thames 8 km east of this site. Here the Oxfordshire Archaeological Unit excavated an Iron Age site, dated to around 200 BC, which lies above the gravel surface but is buried by clay alluvium 0.3–1 m thick; mollusc, beetle and seed remains suggested that the site became very wet around 200 BC or possibly earlier[1].

Similar radiocarbon dates to ours have also been obtained from alluvial deposits, of a slightly different nature, at Ipsley, Worcestershire[2,8] at Pilgrim Lock, Warwickshire[3,8] and at Worcester[3,8], although here the alluvium seems to have accumulated at a faster rate than in the Windrush floodplain.

Although the sequence of events on the Windrush floodplain is reasonably clear, the cause of the change from the period of erosion which truncated the alder roots to the period of deposition of the clay is not. Four possible causes are considered below: lateral movement of the stream within its valley, a rise in sea level relative to the land, a change in climate, or a response to human activities.

Floodplain conditions in the Witney district were fairly uniform; the same sequence of deposits is recorded throughout much of the valley, and thus the changes must have been in response to factors of more than local significance. The available evidence[4] suggests that sea-level changes during this latter part of the Flandrian were very small, and unlikely to have significantly affected a river this far inland. The worsening of climate (higher rainfall) at about this time, the beginning of the sub-Atlantic period[5–7] could have been a contributing factor[5] but such changes alone are an unlikely cause. Climatic changes were possibly responsible for the cessation of erosion but there is no supporting evidence for the major change which would have been necessary to bring about this change in the nature of deposition, which seems to have lasted to the present, as the alluvium is still accumulating.

Although the deposits here are somewhat different our conclusions are similar to those of Shotton[8]. We suggest that the deposition of clay alluvium here began chiefly as a result of man's activity, probably a rapid increase in land clearance and cultivation (ploughing). This would have increased soil erosion, and have meant more rapid surface run-off and increased likelihood of short-term flooding in the river valley. Run-off would have been greatest over clay (impermeable) ground, so that much of the detritus carried to the river valley would be clay-sized (<2 μm) particles. This increase in land clearance and cultivation and the consequent deposition of the clay alluvium began after 2,660 yr BP.

Oxygen 18 in estuaries

J. M. Martin

Laboratoire de Géologie, Ecole Normale Supérieure 46 rue d'Ulm, 75230 Paris Cedex 05, France

R. Letolle

Laboratoire de Géologie Dynamique, Université Pierre et Marie Curie, 4 place Jussieu, 75230 Paris Cedex 05, France

A basic approach used in estuarine chemistry is to determine the experimental distribution of one given element with chlorinity and compare it with that predicted from the simple mixing of river water with seawater. This method provides useful results but several practical problems arise—including the definition of correct end-members, the role of input of tributaries or bank flow in the saline part of the estuary, and the occurrence of several water masses of different ages along the estuary. In addition, this method is not applicable in those areas of constant density which can be of prime importance in estuarine geochemistry and dynamic understanding. To characterise these various problems it is worthwhile to use a suitable freshwater tracer such as tritium[1], D/H or the $^{18}O/^{16}O$ isotopic ratio. The oxygen isotope ratio has been used successfully to study river water mixing[2] but has been little used in estuaries. The basic principle of this method is that the isotopic composition of river water might vary with time, and that different rivers might have different isotopic composition whereas ocean water is of fairly uniform composition. We present here a study of oxygen isotope composition in various estuaries, ranging (in Pritchard's classification[3]) from the saltwedge type such as Rhône (France) and Zaire (Congo), to a partially mixed type such as Gironde, Loire and Charente (France) and Godavari (India). These estuaries cover a wide variety of hydroclimatological conditions including the temperate and tropical regimes.

Samples were collected in Niskin bottles, or with a plastic bucket for surface samples. Aliquots of 25 ml were stored in tightly closed glass bottles for ^{18}O analysis and larger volumes were kept in polyethylene bottles for chlorinity measurements.

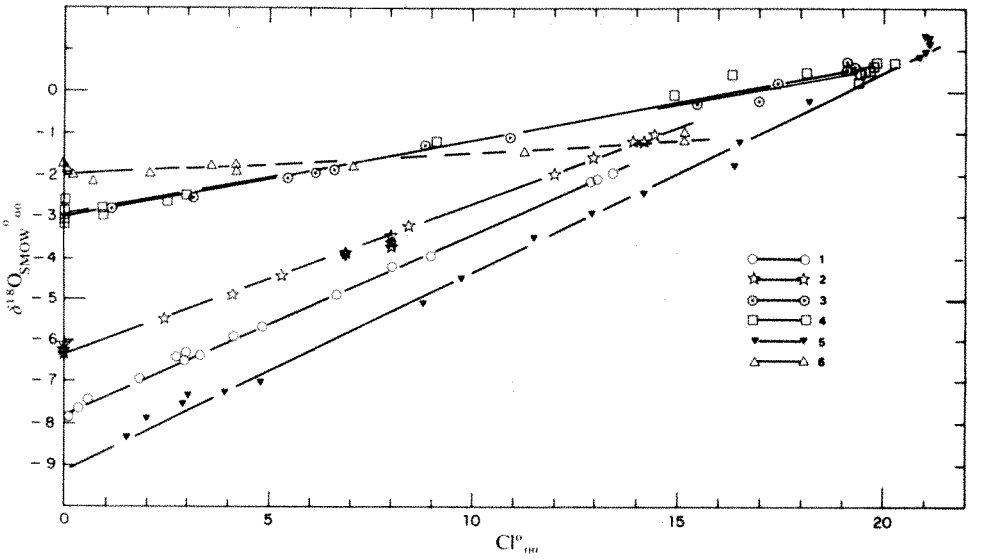

Fig. 1 ^{18}O content and chlorinity for: 1, Loire (30/04/1970); 2, Loire (23/11/1970); 3, Zaire (9–19/11/1976); 4, Zaire (7–13/05/1978); 5, Rhône (01–05/02/1978); 6, Godavari (13–17/12/1978).

The analytical procedure used in determining the $^{18}O/^{16}O$ isotopic ratio involves the equilibration of 3 ml of water with carbon dioxide gas at 25 °C and analysing a small aliquot of the gas in a mass spectrometer (VG 602 C)[4]. Oxygen isotopic ratios are expressed as per mil deviation ($\delta^{18}O$) from standard mean ocean water (SMOW), and the absolute accuracy of the method is ±0.05 δ‰.

Results of the analyses are presented in Figs 1–3 which systematically show the correlation of $\delta^{18}O$ with chlorinity. The estuarine classification based on the chlorinity structure[1] can be expanded by data on $\delta^{18}O$ distribution with chlorinity. It is possible to distinguish two categories of estuary:

(1) Estuaries with an isotopically homogeneous freshwater component (Fig. 1): in these estuaries the $\delta^{18}O$ experimental points fit fairly well the theoretical dilution curve. This most common type is observed for Zaire and Rhône estuaries which are typical salt-wedge estuaries according to chlorinity distribution. Results obtained in the Loire[5] and Godavari estuaries are given for comparison. These estuaries which are partially mixed and occasionally stratified according to chlorinity structure show a strict correlation between ^{18}O and chloride content. Thus in these four estuaries there is a perfect mixing between river and ocean water molecules. The slope of the regression curve for the Godavari estuary is much smaller, and extrapolation to the ocean water end-member—which it was not possible to sample at that time—gives values much lower than those shown on the Atlantic Ocean. However, a chlorinity end-member of 18.3‰ (ref 6) corresponds to a $\delta^{18}O$ of −1.0 using the Craig and Gordon equation[7] for the Pacific ($\delta^{18}O = 0.68S - 23.5$); the same using a similar equation developed by Duplessy[8] on the South Indian Ocean ($\delta^{18}O = 0.66S - 22.6$) would give −1.5‰. Therefore the Godavari regression line appears completely compatible with the local ocean setting.

(2) Estuaries with an isotopically heterogeneous freshwater component (Figs 2, 3): in this type of estuary $\delta^{18}O$ value of estuarine waters corresponds to the mixing of ocean waters with river water of various ages or origins: this has been observed in the Charente (1973) and Gironde (March 1978) where the rate of tidal mixing cannot smooth the small variations in river water isotope composition (Fig. 2). Moreover, in the Gironde (October 1978) and Charente (1974) (Fig. 3) well differentiated water masses can be identified. Considering first the Gironde (October 1978) waters with a chlorinity higher than 1‰ result from the mixing of ocean water with river water of $\delta^{18}O = -7$‰; below this chlorinity, the original river water has a $\delta^{18}O$ of −7.5‰. In the Charente (1974), the high chlorinity area corresponds to the mixing of ocean water with river water of $\delta^{18}O = -8.5$‰. For the domain with chlorinity below 7‰, the river end-member is characterised by $\delta^{18}O = -5.5$‰. A transitional zone exists between these two water masses. The water mass existing near the mouth which is located in the semi-enclosed basin of Marenne-Oleron results from the mixing of a 3 months old river water with $\delta^{18}O = -8.5$‰ with seawater.

Several factors may contribute towards the different isotope ratios encountered in river water. Some seasonal variations of the isotopic composition of precipitation reflect the parallel variation in the temperature of rain formation and sometimes in the relative humidity. The range of these long-term variations is

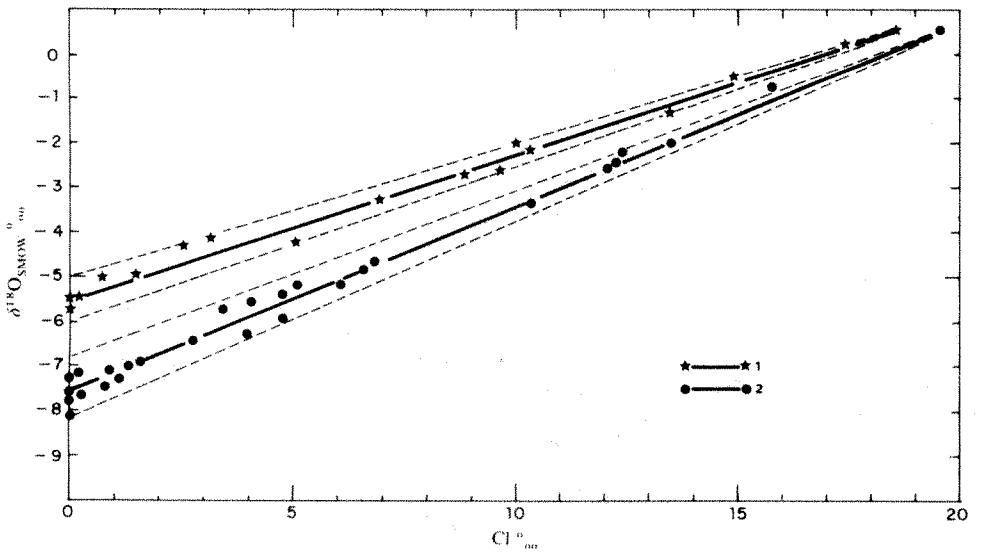

Fig. 2 ^{18}O content and chlorinity for: 1, Charente (22–26/10/1973); 2, Gironde (8–21/03/1978).

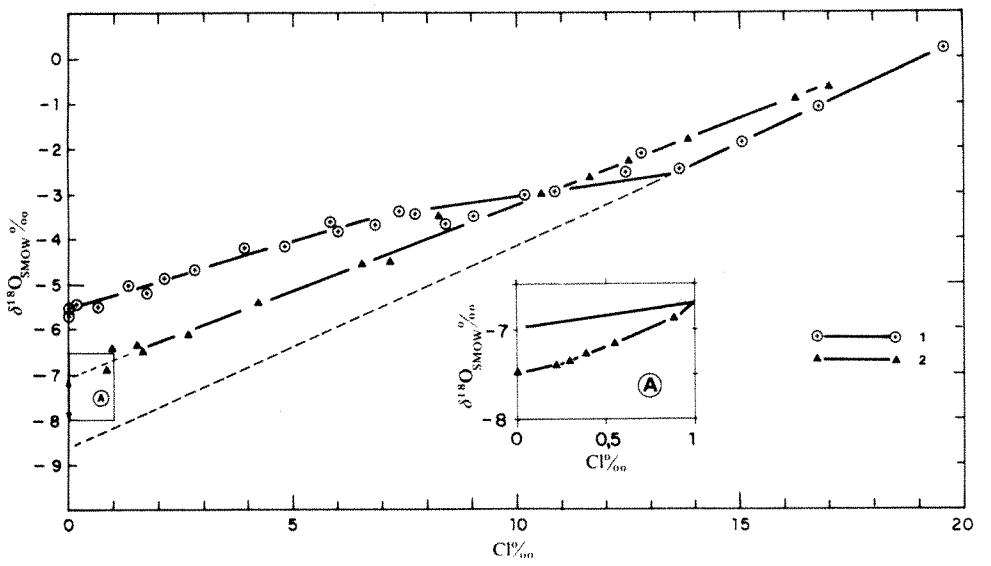

Fig. 3 ^{18}O content and chlorinity for: 1, Charente (22–24/07/1974); 2, Gironde (21–26/10/1978).

important, especially in continental areas[9]. Once they reach the drainage area, these variations can be smoothed by processes such as evaporation, mixing of rain water with ground and superficial waters, buffering through lacustrine retention, and possibly through exchange with host rocks and dissolved gases. However, these isotope ratios generally remain a good tracer for hydrological studies, summer waters being enriched in ^{18}O in comparison with winter waters. On a short-term basis, the isotopic composition of river water can also change as a result of a piston effect due to storm waters which flush out the water from soils and shallow aquifers: such variations reaching several δ‰ in ^{18}O have been observed in small alpine rivers[10].

As well as varying with time, the $\delta^{18}O$ isotopic ratio can also change, for a given watershed, with the distance from the ocean and with altitude. The effect of altitude which has long been recognised as an important factor in isotopic hydrology is basically related to changes in temperature. Together with the 'continental effect'[11] it provides an efficient tool to differentiate waters of different origins.

This first assessment of ^{18}O distribution in estuaries suggests a new approach in the study of water mixing, making it possible to differentiate between water masses along the estuary, including those in areas of constant chlorinity such as in the Gironde estuary (see above). It is then obvious that the comparison of the theoretical distribution curve with the actual distribution of one given element by using a single river water end-member can be misleading. This is shown by the dissolved Ca distribution in the Charente estuary in July 1974. At that time, a definite excess of Ca in the middle estuary was attributed to a dissolution process[12]. It is now clear from measurements of ^{18}O distribution that three water masses corresponding to river water of different chemical composition occurred along the estuary. Similarly, the PO_4^{3-} distribution, although biased by a severe pollution input, reflected the occurrence of the same water masses. In the Gironde estuary (March 1978) the river water samples which can be clearly defined through ^{18}O measurements, corresponds to a dissolved and particulate chemical composition very different from one sample to the other—for example, Zn, Cu and organic carbon, are respectively higher by factors of 1, 5 and 2 in the most downstream river sample (Cauwet *et al.* in preparation). More detailed analysis might provide a means of studying lateral mixing of different tributaries: in the Gironde estuary which receives two major rivers (Garonne and Dordogne rivers), the respective ^{18}O isotopic ratios during October 1978 survey were: ^{18}O-Garonne $= -7.75 \pm 0.27$‰ ($n = 17$) and ^{18}O-Dordogne $= -7.15 \pm 0.15$‰ ($n = 17$). In the case of Charente (1974) (Fig. 3) it was possible to estimate the estuarine water residence time.

The various freshwater components of estuaries might have different chemical compositions, so the classical comparison of actual chemical distribution of one given element with that predicted from the mixing of one single river water with seawater, can complicate geochemical interpretation. Systematic ^{18}O analyses should be of value in deciphering these problems. A limiting factor of this approach is the variation of the river isotopic signal, but in this study the variation was negligible in six of the estuaries described in this paper.

Middle Pliocene climatic change in the western Mediterranean from faunal and oxygen isotopic trends

L. D. Keigwin Jr

Graduate School of Oceanography, University of Rhode Island, Kingston, Rhode Island 02881

R. C. Thunell

Department of Geology, University of South Carolina, Columbia, South Carolina 29208

The pelagic sedimentary sequences recovered by the Deep Sea Drilling Project (DSDP) from the Mediterranean are important because of their proximity to the classical shallow-water Neogene marine-type sections in Europe and because they may help correlations between the type sections and marine sequences outside the Mediterranean basin. We have studied the middle Pliocene (2.7–3.6 Myr ago) histories of surface-water temperature and oxygen isotopic composition at DSDP Site 132 in the Tyrrhenian Sea and here we compare these with another approach to estimating palaeotemperatures[1] based on the

transfer function technique[2]. The record clearly shows a climatic cooling commencing between 3.2 and 3.0 Myr ago. An oxygen isotopic curve derived from the planktonic foraminiferan *Globigerinoides ruber* significantly correlates with a palaeotemperature record estimated from a transfer function palaeotemperature equation on planktonic foraminiferal data. Transfer functions may therefore be of value in interpreting palaeoclimatic history in sequences at least as old as the middle Pliocene.

Surface-water palaeotemperature estimates for Site 132 reveal relatively little temperature change before a cooling dated between about 3.1 and 3.2 Myr ago, followed by a slight warming over the Pliocene/Pleistocene boundary, and a cooling during the late Quaternary[1]. Previous studies of the Mediterranean late Neogene based on DSDP sites include semi-quantitative studies[3,4] and stable isotopic studies[5] of planktonic Foraminifera.

The transfer function technique has previously only been used to quantify Quaternary climatic variation[6]. The approach relates the distribution of microfossil assemblages in surface sediments of the ocean to the hydrographic conditions in overlying surface waters. Past temperatures at a given location may then be estimated based on changes in the microfossil assemblages with time. In extending this method to pre-Quaternary assemblages, the most fundamental assumption is that the fossil species lived in similar conditions to those of the present-day species. As a working hypothesis, we assume that species in evolving lineages and species which are similar in morphology to present-day species also have similar environmental preferences. Similar assumptions were made in a study of late Cenozoic palaeoceanography of the Panama Basin[7].

The middle Pliocene was chosen to isotopically test the reliability of pre-Quaternary palaeotemperature estimates using transfer functions for two reasons. First, middle Pliocene planktonic foraminiferal assemblages are significantly different from those of the Quaternary on which the transfer function is based. Thus, if our basic assumptions about morphologically similar species and evolving lineages of species are unjustified, the palaeotemperature estimates should become less accurate with increasing age. Second, the transfer function approach indicates a distinct cooling beginning about 3.2 Myr ago, a result which needed to be independently evaluated using stable isotopes.

Stable isotope stratigraphy using benthonic Foraminifera is based on correlating $\delta^{18}O$ variations which are inferred to largely reflect changes in continental ice volume[8]. During the Pliocene and early Quaternary the sill at the Gibraltar portal is thought to have been about 1 km deeper, based on ostracod assemblages[9], and a stable isotopic study of the earliest Pliocene at DSDP Site 132 (ref. 10). Therefore, the western Mediterranean basin probably exchanged deeper intermediate waters with the Atlantic Ocean during the middle Pliocene and the $\delta^{18}O$ of benthonic Foraminifera at DSDP132 should largely reflect ice volume variability.

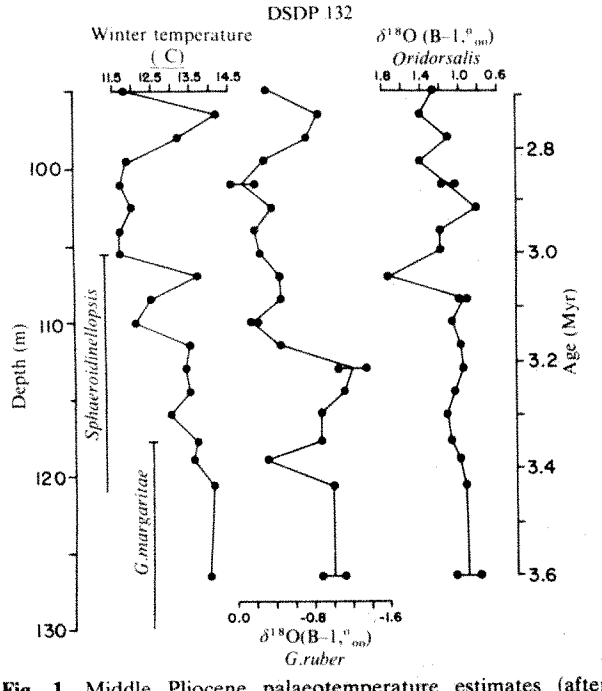

Fig. 1 Middle Pliocene palaeotemperature estimates (after Thunell[1]) and oxygen isotopic results at DSDP Site 132.

Standard procedures were used in the stable isotopic analyses of this study[11]. Results are presented with respect to the powder standard B-1 because calibration of our working standard gas to PDB is incomplete at present. Friedman (personal communication to Shackleton[12]) has found the standard B-1 to be +0.29‰ with respect to PDB $\delta^{18}O$. Numerous analyses of B-1 give reproducibility (1 s.d.) of about ±0.06 for $\delta^{18}O$. Precision is slightly less for foraminiferal samples. *Globigerinoides ruber* was chosen (from the size fraction 175–350 μm) for analysis because of its persistant abundance throughout the Pliocene at DSDP Site 132 and because it is a modern surface-dwelling species, thus providing a surface-water temperature message. The benthonic foraminiferal genus *Oridorsalis* was chosen for analysis because of its relative abundance and because in another measured Cenozoic section this genus showed no fractionation of $\delta^{18}O$ relative to *Uvigerina*[11]. Likewise, Boersma and Shackleton[12] have reported no fractionation between *Uvigerina spinulosa* and *Oridorsalis umbonatus*. Unfortunately, *Oridorsalis* was rarely abundant enough to perform replicate analyses.

The chronological framework used in this study (Fig. 1) is based on previous calibration of planktonic foraminiferal events using a palaeomagnetic stratigraphy[13–15]. The most useful events are the extinctions of *Globorotalia margaritae* at approximately 3.3 Myr ago and *Sphaeroidinellopsis* at 3.0 Myr ago.

Stable isotopic results are presented in Table 1 and Fig. 1. Simple statistics comparing temperature estimates and isotopic results for the intervals before and after evidence of climatic change are presented in Table 2. The $\delta^{18}O$ of both planktonic and benthonic Foraminifera exhibits a sharp permanent increase in the middle Pliocene. Faunal evidence[1] and stable isotopic results on *G. ruber* suggest climatic deterioration began at about 3.2 Myr whereas it is dated at about 3.1 Myr based on

Oridorsalis isotopic results (Fig. 1). Thus, evidence of pronounced cooling and ice volume increase occurs within an interval of about 0.1 Myr in the western basin of the Mediterranean.

The benthonic oxygen isotopic record between 3.1 and 3.6 Myr is highly stable and similar to other benthonic δ^{18}O records of the same age elsewhere. Thus, there is strong evidence that the Pliocene between 3.1 and 3.6 Myr ago was a time of relatively constant ice volume and bottom-water temperature[11,16,17]. The fact that these Mediterranean results are similar to those outside the Mediterranean basin supports Benson's[9] concept that deep, cold (psychrospheric) Pliocene ostracod assemblages in the Mediterranean indicate a deeper-water connection across the Gibraltar sill. At about 3.1 Myr the δ^{18}O of benthonic Foraminifera increases by about 0.8‰ and on average by 0.24‰ (significant at the 95% level) and becomes much more variable (Fig. 1, Table 2). The change at 3.1 Myr is interpreted as reflecting the first major increase in permanent Northern Hemisphere ice volume, supporting previous studies outside the Mediterranean[11,18–22]. The detail of the DSDP Site 132 isotopic record, especially the sudden inferred ice growth between about 3.0 and 3.1 Myr is very similar to the records obtained at DSDP Sites 310 (ref. 11) and 397 (ref. 22). The increased variation in the benthonic δ^{18}O signal reflects an increase in climatic variation after 3.1 Myr as polar ice caps changed in volume. Evidence from glacial tills overlain by lavas[18,19] and from deep-sea cores[20,21] suggests that this first ice growth occurred between about 3.0 and 3.2 Myr ago, and is supported by our results.

The permanent isotopic enrichment recorded by *G. ruber* occurs at 3.2 Myr, predating that exhibited by *Oridorsalis* by about 0.1 Myr (Fig. 1). After about 3.2 Myr the δ^{18}O of *G. ruber* is enriched by an average of 0.51‰ (Table 2) which we interpret to reflect a decrease in surface-water temperature in addition to the compositional effect recorded by *Oridorsalis*. The oxygen isotopic record of *G. ruber* correlates well ($r = 0.79$, significant at the 99% level) with the winter palaeotemperatures calculated by Thunell[1], using the transfer function approach. A comparison of these curves (Fig. 1) shows that the sense of climatic change is the same but the amplitude is often different. Such differences in amplitude may result from the effects of evaporation and precipitation on δ^{18}O. If we assume that the average isotopic enrichment of *Oridorsalis* after the onset of climatic cooling (0.24‰) represents only an ice volume change, and that the average enrichment of *G. ruber* (0.51‰) reflects an additional temperature effect, then the difference between the two (0.27‰) should be an estimate of the average surface-water oxygen isotopic change resulting from decreased temperatures after about 3.1 Myr ago. An isotopic change of about 0.27‰ represents about a 1 °C cooling, in good agreement with the average cooling estimated by faunal means (1.2 °C; Table 2). Such agreement must be demonstrated for larger coolings and over longer time intervals. In general we believe that the transfer function approach is valuable for determining palaeotemperatures in Pliocene sequences, when the evolution of species lineages is taken into account.

The lag of about 0.1 Myr between the enrichment in the benthonic δ^{18}O record and the cooling indicated in both the palaeotemperature and planktonic δ^{18}O records indicates that a cooling of surface waters in the Mediterranean, and possibly increased evaporation relative to precipitation, predated the build-up of permanent Northern Hemisphere ice sheets. The development of climatic cooling immediately before the initiation of Northern Hemisphere ice growth is also manifested as an intensification of abyssal circulation at approximately 3.3 Myr[23].

A comparison of the benthonic δ^{18}O record and the surface-water palaeotemperatures reveals that the initial growth of permanent ice occurred during a time of warm surface waters. A similar relationship has recently been observed by Ruddiman and McIntyre[24] in which they found periods of most rapid ice growth during the late Quaternary in the North Atlantic were associated with warm surface conditions. We speculate that warm surface waters may have provided a necessary source of moisture for the first permanent accumulations of Northern Hemisphere ice sheets.

We thank W. A. Berggren, B. H. Corliss, J. P. Kennett and T. S. Loutit for reviewing the manuscript. This work was supported by NSF grant OCE76-81489 (CENOP) and by a Woods Hole Oceanographic Institution postdoctoral fellowship to R.C.T.

Nest of juveniles provides evidence of family structure among dinosaurs

John R. Horner

Department of Geological and Geophysical Sciences, Princeton University, Princeton, New Jersey 08544

Robert Makela

Rudyard High School, Rudyard, Montana 59540

One of the greatest mysteries associated with dinosaurs is the rarity of juveniles. With the notable exception of the Djadochta and Iren Dabasu Formations of Mongolia and the Two Medicine Formation of Montana, skeletal elements of very young dinosaurs are exceedingly uncommon[1–3], leaving a gap in the understanding of dinosaur social structures[1,3,4]. The most popular explanation, based chiefly on negative evidence, is that the eggs and young were 'kept' in the uplands where they were rarely covered by sediments and as a result were destroyed by erosion[2]. The discovery of fifteen 1-m long hadrosaurian ('duck-billed') skeletons together in a nest-like structure offers the first tangible evidence of the social behaviour of at least one group of dinosaurs. They were discovered by Marion Brandvold in terrestrial sediments of the Two Medicine Formation (Upper Cretaceous) near Choteau, Teton County, Montana.

0028/0836/79/460296—03$01.00

© 1979 Macmillan Journals Ltd.

The skeletons of 11 little hadrosaurs were found jumbled together in a fine-grained green mudstone that infilled a bowl-shaped depression in a fine-grained brown mudstone (Fig. 1). The concave structure, oval in outline, was about 2 m in diameter at its weathered surface and extended about 0.75 m deep near its centre. Portions of four other individuals were scattered around the weathered surface, no more than 2 m away. Measurements of the skeletal elements, particularly the femora, indicate that all individuals were essentially the same size. The uncrushed femora vary between 120 and 130 mm long. Within the surrounding green mudstone were several minute fragments of eggshell and three terrestrial gastropods (family Polygyraeidae). Although it may have been an artefact created by differential weathering of the sediments, the concave structure was situated on the apex of a mound-shaped 'hill' approximately 3 m in diameter and about 1.5 m above the surrounding topography.

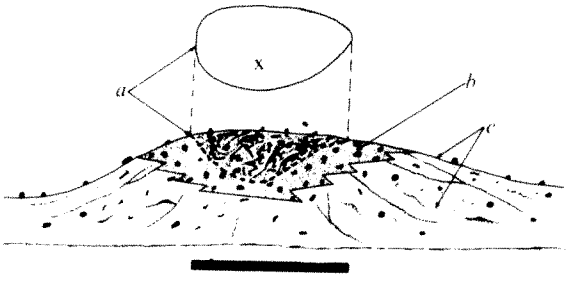

Fig. 1 Reconstruction of nest. *a*, Outline of green mudstone which contained the baby dinosaurs, eggshell and gastropods; *b*, brown mudstone that surrounded the green mudstone; *c*, weathered surface. (Scale bar, 2 m.)

The presence of several small skeletons, apparently all the same species and size, together with eggshell in an oval, concave structure, strongly suggests that the structure was a nest. The skeletons (Fig. 2) have several characteristics indicative of very young individuals. The sacral vertebrae are not fused; the neural arches are not fused to the vertebral centra; the proximal and distal ends of the limb bones are not well-formed, and the absence of the basicranial bones suggests that they were not ossified[5,6]. Nevertheless, there is evidence that the young were capable of activity outside the nest. With the exception of the basicranial elements, all the skeletal elements present in an adult hadrosaur were already ossified, including the carpals and tarsals and the ossified tendons that run along the sides of the neural spines of the posterior dorsal, sacral and caudal vertebrae. The feet are somewhat large for the size of the animal, but the limb proportions are very similar to those of adult hadrosaurs, suggesting that very little ontogenetic change occurred in the postcranium during growth. Wear on the occlusal surfaces of the dental batteries indicates that the young had been feeding for some time. Some of the individual teeth are worn more than three-quarters their length. Another group of juvenile hadrosaurs found in the same general area, although several hundred metres from the nest, indicate that these nestlings are at least twice the size of hatchlings. Among the elements (PU 22432) are three femora averaging 69 mm in length, indicating that the animals were about 450 mm long. A considerable number of large eggshell fragments was found with the specimens.

The fact that 15 baby hadrosaurs had been feeding, and had stayed together for a period of time, indicates that some form of extended parental care was administered for, if the young were confined to the nest, food must have been brought to them. If the young had ventured out to forage for food, it is unlikely that they would have returned to the nest together without parental supervision.

Extended parental care is suggested by several other age-cohort associations of young dinosaurs in the same formation and area. Gilmore[7] wrote that a mounted skeleton of the horned dinosaur *Brachyceratops montanensis* (USNM 7951) was made up of the bones of at least five individuals, all from the same deposit, all belonging to one species and all practically the same size. *Brachyceratops* is considered to be a juvenile of *Monoclonius*[8] which averages about 4.2 m long, or slightly more than twice the length of the juveniles described by Gilmore. Of a second occurrence, Gilmore[9] described a stratum full of scattered bones representing many individuals of a small hadrosaurian dinosaur. Measurements of the limb elements indicate that the individuals (USNM 16600) were about half the length of an average adult hadrosaur. The average length of the femora is 500 mm. Another group of hadrosaurs (USNM field no. Qu-3-35) collected by Gilmore consists of portions of at least three individuals each slightly less than half the length of an adult. The American Museum of Natural History has three individual hadrosaurs (AMNH 5358) which each have a femur length of about 450 mm.

All these groups of dinosaurs were collected from the Two Medicine Formation, no more than 95 km north of the nest described here. Of the more than 200 specimens from this formation now in the US National, American and Princeton Museums, more than 80% seem to pertain to individuals one twentieth to half the linear dimension of their adult counterparts. Eggshell fragments are the most common fossils in the formation and whole or partial eggs are not uncommon. The abundance of eggshell and juvenile hadrosaurs and ceratopsians in these sediments, as opposed to the scarcity of them in the adjacent Judith River (Oldman) Formation of Alberta[2,10,11] and Montana (our observations), suggests that the depositional area of the Two Medicine Formation was a nesting ground for at least these two groups of ornithischian dinosaurs.

If the juvenile dinosaurs collected by the US National and American Museums from the Two Medicine Formation represent nestlings similar to those described here, parental care may have been extended until the young were about half the linear dimension of their adult counterparts, which suggests that the parent or parents spent considerable time with the young, or that the young grew very rapidly. As with birds, a rapidly growing dinosaur would have required a very high metabolic rate (endothermy), a considerable supply of food and a very efficient means to process the food. Efficient mastication seems to have been highly specialised among the hadrosaurs and ceratopsians, both of which possessed teeth able to pulverise and grind considerable quantities of food (? plant material). This may indicate that the other ornithischian dinosaurs, such as ankylosaurs and other ornithopods which do not have complicated dental systems, either grew more slowly or had other means for efficient food processing.

Because of the immaturity of the juvenile dinosaurs and the ontogenetic changes which probably occurred in the skulls during growth, a specific identification of the 15 individuals from the nest may not be possible until more specimens of older individuals are found. Characteristics of the skulls, however, suggest that they are generically similar to a large skull (Fig. 2) found within 100 m of the nest. The large skull represents a new genus and species and, although it has some rather peculiar characteristics, is placed in the subfamily Hadrosaurinae.

Maiasaura (new genus)

Holotype: PU 22405, skull with partial right dentary and predentary.

Referred specimens: PU 22400, skeletons of 15 individuals.

Horizon: Two Medicine Formation, Upper Cretaceous (Campanian).

Locality: 12 miles west of Choteau, Teton County, Montana, on the James and John Peebles ranch.

Collectors: J. R. Horner and R. Makela, 1978, for the Museum of Natural History, Princeton University.

Nature Vol. 282 15 November 1979

Etymology: Maia from the Greek which means good mother, saura which means reptile (feminine).
Diagnosis: Wide elongate facial region. Short naris located on anterior end of snout with an extensive lateral facial region between the posterior end of the naris and the anterior end of the orbit. Short wide premaxillary bill with deflected border similar to that of lambeosaurines. Long shallow maxilla with an anterior maxillary process and anterior maxillary notch as present in hadrosaurines. Small, solid incipient crest above and between orbits, formed by the nasal and frontal bones. Nasals concave anterior to incipient crest. Quadratojugal process of the jugal long, thin and angling steeply upward to meet quadratojugal. Dentary teeth with long and narrow enamel crown. Predentary wide and very shallow with round, evenly spaced, denticulate processes around its anterior edge.

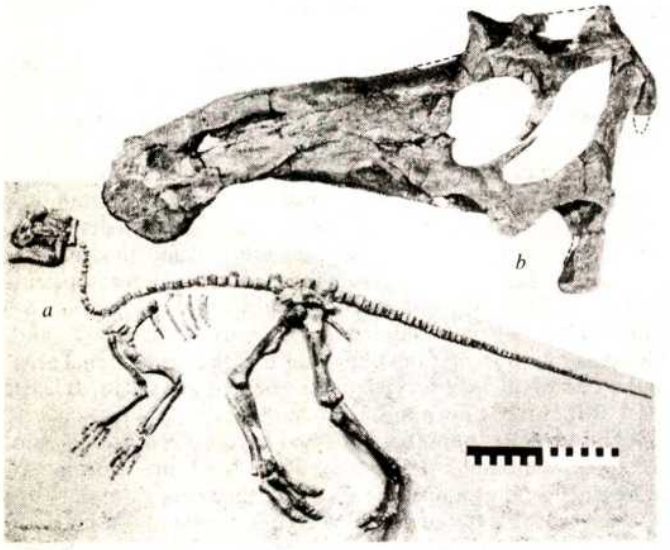

Fig. 2 *Maiasaura peeblesorum*. *a*, Incomplete reconstructed composite skeleton of individual from nest (PU 22400); *b* holotype skull (PU 22405). (Scale bar, 20 cm.)

Maiasaura peeblesorum (new species)
Specific characters same as generic characters.
Etymology: Specific name to honour the James and John Peebles families, owners of the land where the specimens were collected.
Discussion: The skulls of the referred juvenile specimens have short, wide deflected premaxillary bills, long shallow maxillae with anterior maxillary processes and notches and long, thin, steeply angling quadratojugal processes of the jugals. In all these characters they agree with the adult specimen. The juvenile skull elements are however disarticulated and in many instances crushed so that a positive identification cannot be made.

We thank M. Brandvold, D. Trexler and A. Luthin for their discoveries, the Peebles families for hospitality and D. Baird, D. Jones, P. Dodson and D. Weishampel for helpful discussions.

The Cossack skull and a dihybrid origin of the Australian Aborigines

L. Freedman

Department of Anatomy and Human Biology, University of Western Australia, Nedlands, Western Australia 6009

M. Lofgren

Department of Anthropology, Western Australian Museum, Francis Street, Perth, Western Australia 6000

Recent surveys of Australian prehistory[1–4] reveal the interest and debate surrounding the evolutionary implications of the observed range in cranial morphology of modern Australian Aborigines and their predecessors. In spite of an earlier model postulating a trihybrid origin[5,6], a theory favouring a homogeneous colonising stock had gained some acceptance[7,8]. Discoveries[9,10] of the past decade raised doubts about the validity of the homogeneity concept and suggested an alternative two-population—gracile and robust—model[11–13]. However, as all the material described was derived from a restricted area of South-East Australia, the possibility existed that the apparent dichotomy might reflect isolate variation or local adaptation[14]. We discuss here recently described human skeletal material from Cossack, Western Australia[15] which has a demonstrable affinity with the postulated South-East Australian robust group, making local adaptation/population isolate explanations unlikely. The Cossack skull supports arguments favouring an early dihybrid origin with substantial change in Australian Aboriginal cranial morphology since the Pleistocene.

Discovered 3 km ESE of Cossack, Western Australia (Fig. 1), the material comprises most of a cranium and mandible together with fragments of the shafts of several limb bones. The skull was lying at the base of an eroding coastal dune and fragments of the long bones were scattered over the lower face of the dune. Direct dating of this individual is not feasible at present. However, the region's coastal features indicate that rising post-Pleistocene sea levels first reached the contemporary coastline around 6,500 yr BP[16], thus apparently restricting the material's age to a period after that event.

Most areas of the skull are represented except for the base, the central portion of the face, and the left temporal, zygomatic and orbital regions; almost all the teeth are present. After cleaning and restoration, it was apparent that inward compression of the whole left side of the skull had occurred after death. However, the right side is relatively complete and undistorted, and some metrical observations are possible. On morphological criteria[17], the individual is clearly male and was about 40 yr old at death.

The Cossack skull (Western Australian Museum no. A22684) includes a massive dolichocephalic calvaria with a large and slightly prognathous face (Fig. 2). The most striking feature is the markedly backward-sloping forehead. The supra-orbital margins are well developed and slope back strongly from the glabella to the large zygomatic trigones. Other features include some occipital bunning, an occipital torus, a clearly marked temporal line, a large supra-mastoid crest and a prominent malar tuberosity. The mandible is correspondingly large and robustly built, and the dentition shows heavy wear. The right 1^1 is missing and the alveolus completely resorbed, suggesting the possibility of tooth evulsion for cultural purposes as practised by recent Australian Aborigines.

Metrical comparison of the Cossack skull with a series of recent male Western Australian Aborigines[18] reveals several

0028/0836/79/460298—03$01.00

© 1979 Macmillan Journals Ltd.

significant differences (Table 1). Cranial length is more than 5 standard deviations greater than the series mean. Although estimated breadth is slightly greater than the maximum Western Australian value, the cranial index of Cossack is comparable to the series lowest figure. Parietal size (bregma-lambda chord) is close to 3-standard deviations greater than the Western Australian mean. The Cossack skull's frontal curvature index is more than 5 standard deviations below the series minimum value. Cranial bone thicknesses are considerably greater than those of recent Australian Aborigines[15]. The most notable metrical mandibular comparison is of the corpus projective length, which yields a value more than 3 standard deviations greater then the series mean.

The features in which the Cossack skull differs from recent Western Australians are precisely those in which it resembles certain prehistoric South-East Australians (Table 1). Low frontal index and great length (the Cossack skull has the highest Australian values yet recorded) as well as general robusticity, highlighted by cranial vault bone thickness, are characteristic of the postulated robust group, including Talgai, Cohuna, Mossgiel and Kow Swamp. Comparison of lateral cranial contours[15] reinforces the referral of the Cossack skull to this group.

The demonstrable affinity of the Cossack skull to the robust South-East Australian group indicates that this morphology was not a regional variant but continental in distribution. This newly established range strengthens the evidence for a two-population occupation of Australia.

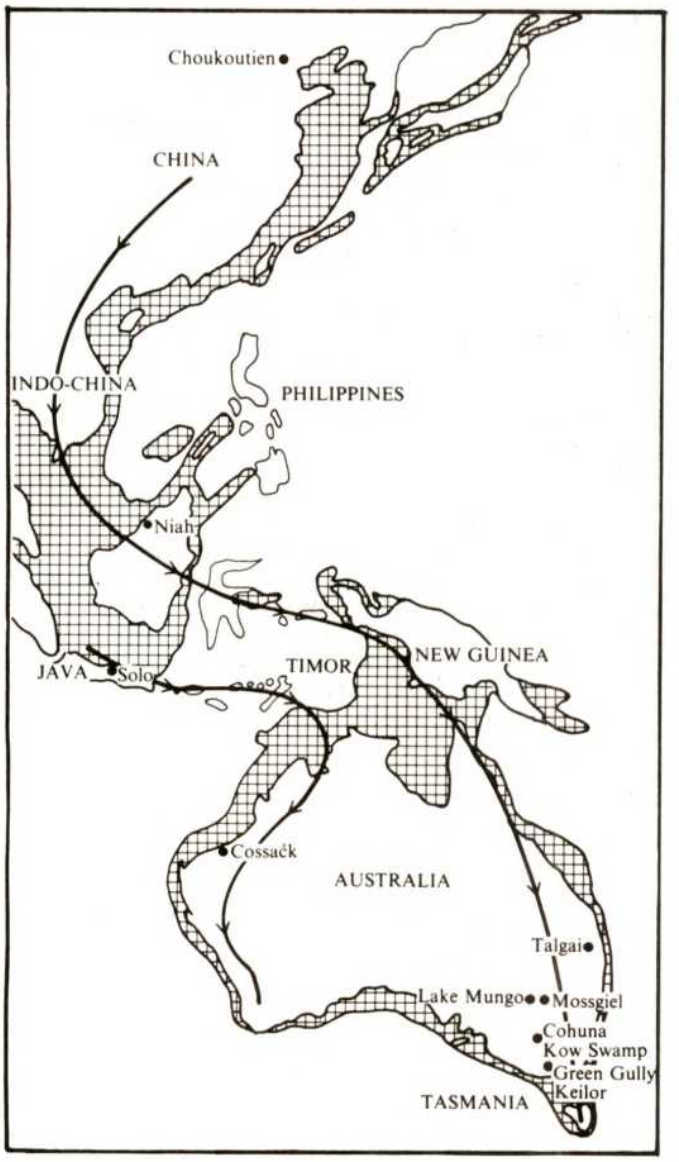

Fig. 1 Present and late Pleistocene (hatched) land areas. Fossil hominid sites and possible migration routes to Australia.

Fig. 2 Lateral view of the Cossack skull.

It is now generally accepted that human colonisation of the Australian continent first occurred at least 40,000 yr ago and probably earlier[3]. Fossil evidence in Australia of a more robust population extends from about 13,000 yr BP (Kow Swamp) to 6,000 yr BP (Mossgiel) and now possibly to even more recent times (Cossack). For the more gracile group the time span now ranges from 26,000 yr BP (Lake Mungo) to 13,000 yr BP (Keilor) to 6,000 yr BP (Green Gully)[8,11,13].

The two Asian stocks from which these populations could have been derived are: (1) a South-East Asian population, perhaps from Java and adjacent areas, and (2) a more northern population, possibly from southern China. These would be early *Homo sapiens* populations perhaps differing morphologically from each other as do the earlier Javanese and Chinese *Homo erectus* people. The more robust South-East Asian migrants, possibly morphologically related to the Solo (Ngandong) people[19], could have taken a southerly route from Java by way of Timor into northwestern Australia and then down the west coast (Fig. 1). The more gracile population from southern China may have followed a more northerly course, perhaps passing through Indo-China, Borneo and New Guinea before arriving at the northeastern part of Australia. They would then have passed down the east coast and perhaps finally across the land bridge to Tasmania (Fig. 1). The 40,000-yr-old Niah cranium[20] from Borneo and the apparently more gracile appearance of the recent Tasmanians[11] may be the best evidence of this migration. These two early colonising Australian populations may have used different adaptive strategies. Their subsequent fusion might have been triggered initially by the climatic and faunal changes of the late Pleistocene but was only completed in recent times[22].

Table 1 Selected metric comparisons

Measurement	Cossack[15]	Male West. Aust.[18] (range)	Kow Swamp[21] (range)
Max. cranial length	220	169–202	190–214
Max. cranial breadth	(145)	117–143	128–150
Bregma-lambda chord	131	104–128	115–126
Cranial index	65.9	64.64–76.33	(66.67)–72.39
Frontal curvature index	12.6	18.58–25.66	12.71–16.12
Mandibular corpus projective length	98	71–95	

Measurements are given in mm.

Rapid advances have been made in the study of the prehistory of the Australian Aborigines over the past 10 yr. Syntheses of the new material and concepts[1-4,11-13] are now bringing closer an understanding of the people who in the latter part of the Pleistocene colonised one of the last two major unoccupied land masses.

Thermal buffering in Afro-alpine plants due to nucleating agent-induced water freezing

John O. Krog*, Karl Erik Zachariassen†, Bjørn Larsen‡ & Olav Smidsrød‡

Plants in the alpine zone of Mount Kenya are exposed throughout the year to environmental temperatures varying from about −10 to +10 °C (ref. 1). In contrast to plants in Arctic and temperate regions, which are in a state of suspended growth during the cold season, these plants have to combine growth with tolerance to low environmental temperatures. It has been suggested that flowers of the Afro-alpine plant *Lobelia telekii* gain thermal protection from the long, thin bracts which hang down at the outside of the inflorescence, and which seem to lower the radiative heat loss of the plants at night[1]. We report here that vital tissues of *L. telekii* are also protected by the heat of fusion of water, which is present in the central part of the inflorescence, and that freezing of this water is ensured by the presence of nucleating agents, which induce freezing at a few degrees below zero.

The inflorescence of *L. telekii*, which may reach a height of 2 m, is cylindrical and hollow, with an inner diameter of 5–8 cm (Fig. 1*a*). The central cavity contains a slightly viscous fluid, which is apparently produced by the plant. The fluid level within the plant reaches more than 0.5 m above the ground, and several litres may be drained from each inflorescence. The temperature of the air and in the central part of a flower and that of the central fluid in the inflorescence of a *L. telekii* plant were measured during the day by means of thermocouples mounted in fixed locations. Temperatures recorded are shown in Fig. 2. After sunrise the temperature in the flower rose to several degrees above that of the air, indicating that the bracts are also important for absorbing radiant heat from the Sun[2]. The absorbed heat also gradually leads to an increase in the temperature of the central fluid. As the air temperature dropped in the afternoon, the temperature in the central fluid lagged behind. In contrast to the temperature in the air, the temperature in the flower and in the central fluid did not drop below zero during the night; the temperature in these parts of the plants levelled out at zero and stayed there until sunrise.

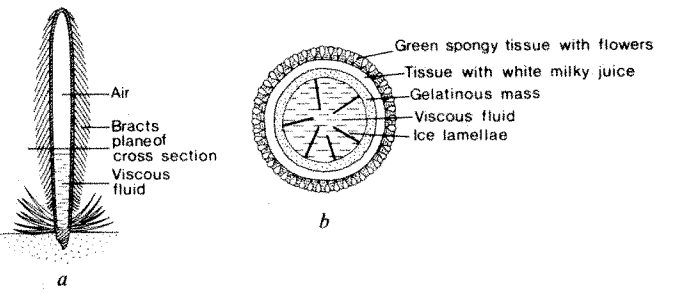

Fig. 1 Longitudinal section (*a*) and cross section (*b*) of *Lobelia telekii*.

The time lag between the drop in air temperature and the fall in temperatures measured in the plant is mainly due to the high heat capacity of the central fluid. This time lag, as well as the stabilisation of the temperature of the plant at zero, imply that the flowers are thereby protected from exposure to the low and possibly injurious air temperature.

When the inflorescence of a *L. telekii* plant was cut just above the surface level of the central fluid at sunrise, the central fluid was found to contain ice, in the form of vertical thin lamellae, which protruded radially into the central fluid from the wall of the inflorescence, as indicated in Fig. 1*b*. The amount of ice was estimated at ~2% of the fluid volume. Liberation of the heat of fusion of the frozen water leads to a stabilisation of the temperature at the melting point of the unfrozen fraction of the central fluid. Thus the formation of ice in the central fluid and the concomitant liberation of the heat of fusion form the physical basis for the stabilisation of fluid and flower temperature at about 0 °C during the night. The temperature of the partially frozen central fluid was 0.1 °C, indicating that in spite of its viscous character, the central fluid has a very low osmotic activity. This will ensure maximal thermal protection of the plant by leading to a stabilisation of the temperature of the frozen central fluid at the highest possible subzero temperature.

The freezing of the central fluid will in turn also have a thermally buffering effect on the air-filled compartment above

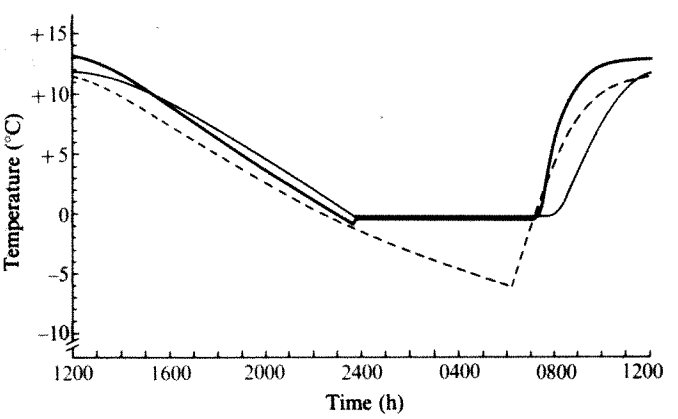

Fig. 2 Temperature variations of the air (dashed line), the central part of a flower (heavy line) and the central fluid in the inflorescence (thin line) of a *Lobelia telekii* plant.

the central fluid (Fig. 1*a*). As the air is trapped inside the inflorescence and cannot escape, it will circulate inside the upper part of the inflorescence and cause internal heating at the top of the plant. Thus, the heat of fusion liberated in the central fluid will contribute not only to the thermal protection of those parts of the plant which surround the central fluid, but also to the whole inflorescence.

Based on these observations, it seems to be of importance to the survival of the plant to induce freezing in the central fluid at the highest possible subzero temperature. Freezing at high temperatures and prevention of supercooling are known to be affected by the presence of so called nucleating agents. A search for such agents in the internal fluids from the plant was initiated, using a method described by Zachariassen and Hammel[3]. Samples of central fluid (0.25 μl) were transferred to 5-μl samples of 0.9% NaCl solution, and the supercooling point of the mixed samples was measured. The supercooling point of four parallel samples was -4.6 ± 1.3 °C (±s.d.), whereas samples of undiluted NaCl solution supercooled to −15 to −20 °C. This revealed that the central fluid of the inflorescence of *L. telekii* plants must contain nucleating agents, which will induce freezing at as high temperatures as possible.

The nucleating effect of the central fluid was still intact following heating of the fluid to +100 °C for 5 min. Investigations of the chemical composition of the central fluid revealed that the fluid contains about 15 mg ml^{-1} of carbohydrates, as determined by the phenol sulphuric acid colour method[4], using glucose as standard. The content of protein was found to be about 0.15 mg ml^{-1} by the FC analysis[5], using bovine serum albumin as a standard. This low protein value agreed with analysis for nitrogen on a Carlo Erba elemental analyser Model 1104. A fraction of the organic material was non-dialysable, indicating that the central fluid contains a high molecular weight polysaccharide as one of the components. The high heat stability of the nucleating agents, combined with the quantitative domination of carbohydrates in the fluid, might indicate that the nucleating agents are carbohydrates.

After a standard hydrolysis (1 M H_2SO_4, + 100 °C, 5 h), the monomeric sugars in a yield of about 30% were separated as glycitol hexoacetates by gas chromatography. By co-chromatography, the main glycitols were shown to be iditol, glucitol and mannitol. The carbohydrates gave a strong positive reaction in a test for keto sugars[6]. Work to identify the sugars and to elucidate the constitution of the polysaccharides is being carried out.

Melatonin, the pineal gland and human puberty

R. E. Silman. R. M. Leone & R. J. L. Hooper

M. A. Preece

Department of Growth and Development, Institute of Child Health, London EC1, UK

Animal experiments have suggested that the pineal gland produces an anti-gonadotropic hormone. The hamster, for example, undergoes reproductive collapse when kept in short-day periods, an effect which is abolished by pinealectomy[1]. Although there is little direct evidence about the endocrine role of the pineal gland in man, it has been noted that tumours of the pineal gland in young boys are associated with precocious puberty and the human pineal gland has been suggested to produce a substance that holds sexual maturation in check[2]. This observation has been extended by Kitay[3], who has shown that destructive tumours are associated with precocious puberty whereas hyperactive tumours are associated with delayed puberty. However, no studies have described any change of pineal function with normal puberty. Because two pineal indoles, melatonin[4] and methoxytryptophol[5], have been shown to be antigonadotropic when administered to animals[6–10], we have now measured them in schoolchildren. Our findings show that in young boys there is an abrupt fall in the concentration of melatonin with advancing development suggesting that it may play an important physiological role in the control of human puberty.

We studied 51 healthy boys and girls between the ages of 11½ and 14 yr; all attended a normal secondary school in Somerset, UK and blood was taken between 1100 and 1300 hr. At the time of sampling each child was assigned to one of five maturity stages[11] according to genitalia or breast development. Some of the children were studied on up to four occasions such that an overall total of 101 blood samples was taken. In addition to pineal hormones, serum luteinising hormone (LH), follicle stimulating hormone (FSH), testosterone and oestradiol were measured by radioimmunoassay. Melatonin and methoxytryptophol were assayed by gas chromatography–mass spectrometry (GCMS)[12,13] (Fig. 1). The sensitivity of the assay was assured by single ion monitoring at *m/e* 232 because this was the most abundant fragment ion in the mass spectra of melatonin and methoxytryptophol. It was also a fragment characteristic of the methoxyindole nucleus and therefore contributed to the specificity of the assay. Specificity was further enhanced by increasing the resolution to 2,000 so that the more precise mass 232.12 was monitored. Selected samples from the schoolchildren which gave high values for melatonin using the routine assay (monitored at *m/e* 232) were validated by being re-assayed at *m/e* 245 and *m/e* 304 and results were consistent with those previously obtained. The ratio of *m/e* 232 to *m/e* 245 was 1.23 ± 0.16 s.d. (synthetic melatonin 1.21 ± 0.04).

The concentration of methoxytryptophol ranged from <4 to 92 pg ml^{-1} in the boys and from <2 to 400 pg ml^{-1} in the girls and did not show a sex distribution or any change with development. The concentration of melatonin in the schoolgirls ranged from <5 to 280 pg ml^{-1} and did not change with development. In contrast, the concentration of melatonin in the boys which ranged from <10 to 2,300 pg ml^{-1} showed a marked change during adolescent development (Fig. 2). The means and 95% confidence limits were calculated from log transformed data by mixed longitudinal methods described by Tanner[14]. At genitalia stage 1 the mean value of melatonin was 218 pg ml^{-1} (95% confidence limits 509–93, $n = 13$). At stages 2, 3 and 4 the mean values of melatonin were 30 pg ml^{-1} (128–18, $n = 28$), 17 pg ml^{-1} (24–13, $n = 15$) and 18 pg ml^{-1} (32–11, $n = 11$). At stage 5 there were only two samples from the school population and to these were added the daytime values from normal adults, making a mean of 16 pg ml^{-1} (11–21, $n = 18$). The fall in concentration of melatonin from stage 1 to stage 2 was highly significant ($P < 0.001$), but no significant changes occurred thereafter.

When the concentration of melatonin was tabulated against the concentration of LH assayed in the same samples (Fig. 3), the mean value of melatonin decreased from 287 pg ml^{-1} to 24 pg ml^{-1} when the concentration of LH increased from

0028/0836/79/460301—03$01.00

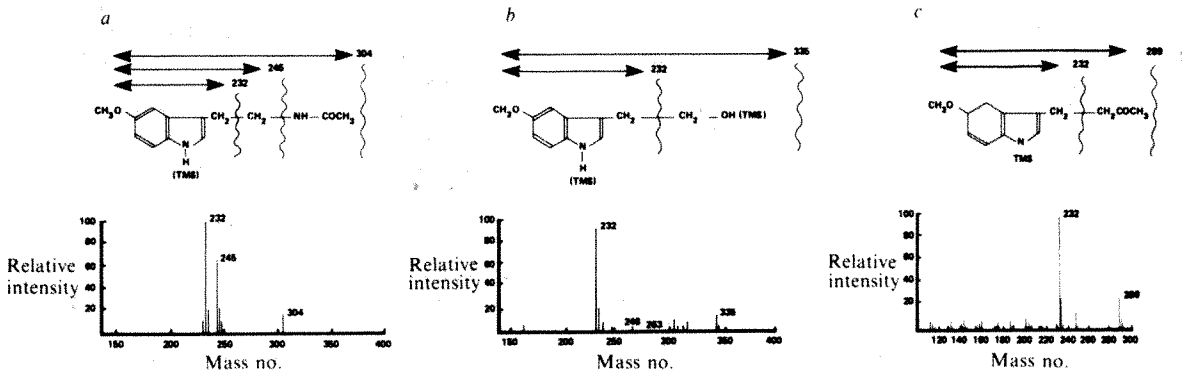

Fig. 1 Molecular structures and partial normalised mass spectra of TMS derivatised melatonin (*a*), methoxytryptophol (*b*) and the internal standard [3-(butan-3'-one)5-methoxyindole] (*c*) are illustrated. Internal standard (50 ng) was added to 1 ml of plasma or serum sample and vortex mixed with 3 ml of chloroform. The organic phase was separated and evaporated to dryness. Before assay the dried extract was reconstituted in 10 μl of silylation reagent. Portions of 5 μl were injected on to GCMS. Methoxytryptophol entered the ion source at 2 min 15 s, the internal standard at 2 min 40 s and melatonin at 4 min 40 s. The magnet and electrostatic analyser were tuned to allow only the passage of ions of mass 232 (strictly m/e 232). Each sample was quantified by determining the ratio of the peak height of endogenous melatonin or methoxytryptophol to the peak height of the internal standard and calculating the concentration from a standard curve.

undetectable values to values measurable but still below 1 IU l^{-1}. This fall in concentration of melatonin was highly significant ($P \ll 0.001$). The analysis of the fall in concentration of melatonin relative to increasing levels of FSH or testosterone showed the same pattern but the association was less striking.

We have reported a limited study and further work is required, especially in relating these findings to circadian changes. However, it is already clear that, using the same GCMS assay for melatonin as reported here, the levels of melatonin found in most samples from the prepubertal schoolboys exceed anything measured in the day or night from normal adult volunteers who have been monitored in a sleep laboratory (P. E. Mullen, unpublished observations). Also, studies on the circadian values of melatonin in pubertal boys show values which are no different from those of the mature adult[15]. However, ethical considerations have prevented investigation of prepubertal boys in the sleep laboratory where it would have been valuable to relate the circadian changes of melatonin to the first night time increases in gonadotropin secretion which herald puberty[16].

Nonetheless our results clearly show that the circulating level of melatonin drops significantly in schoolboys before the first physical signs of puberty have become apparent and before the increase in gonadotropins and testosterone which accompanies puberty. Animal experimentation had indicated that melatonin can act on the hypothalamus and pituitary to suppress the release of LH and FSH[6,7]. Melatonin may also act directly on the gonads to suppress ovarian and testicular function[8]. Thus it is possible that the drop in melatonin, which we have observed, is part of the process which initiates the physical and endocrine changes of puberty.

A major unsolved problem is whether the changes in melatonin secretion also occur in young girls. We have been unable to show any fall in the concentration of melatonin in our schoolgirl population and this may indicate that there is a sex difference in pineal endocrinology. Alternatively there may be an age

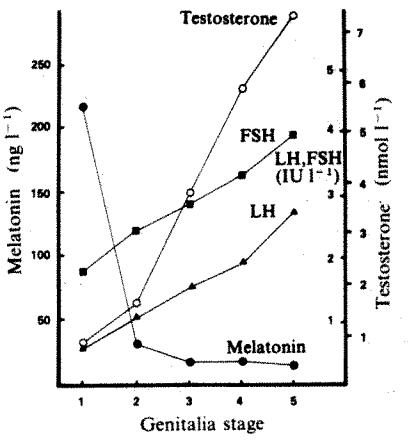

Fig. 2 Mean concentration (calculated from log transformed data) of melatonin (●), FSH (■), LH (▲), and testosterone (○) in serum samples from schoolboys. The values are grouped for each stage of puberty at which they were obtained. Stages: 1, testes, scrotum and penis the same size and proportion as in early childhood; 2, enlargement of testis and scrotum, change in texture and some reddening of scrotal skin; 3, further growth of penis, mainly in length but some increase in breadth; 4, further enlargement of penis in length and breadth and development of glans; 5, genitalia adult in size and shape.

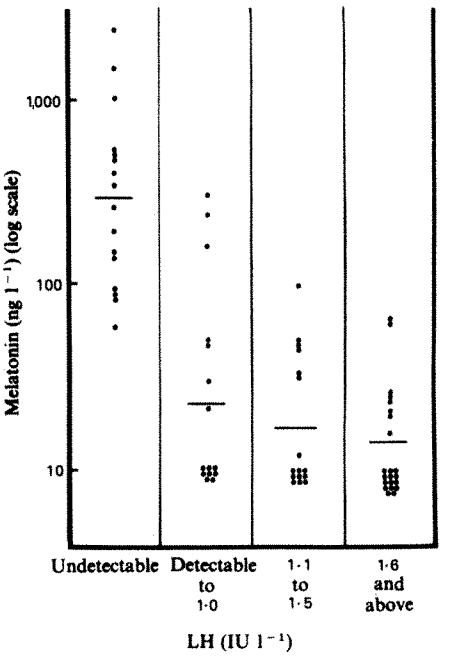

Fig. 3 The concentration of melatonin has been plotted against the concentration of LH in the same sample and the values of LH shown as four groups. *a*, LH undetectable, mean concentration of melatonin 287 pg ml^{-1} (95% confidence limits 494–167, $n = 16$); *b*, LH detectable to 1.0 IU l^{-1}, melatonin 24 pg ml^{-1} (48–12, $n = 15$); *c*, LH 1.1–1.5 IU μl^{-1}, melatonin 17 pg ml^{-1} (24–11, $n = 16$); *d*, LH 1.6 and above IU l^{-1} melatonin 14 pg ml^{-1} (21–10, $n = 22$). The mean concentration of melatonin in each group is shown by the horizontal bar. The limit of detection for the GCMS assay of melatonin was approximately 10 pg ml^{-1}.

difference insofar as the girls have matured earlier than the boys. Thus a drop in the concentration of melatonin may have occurred in the girls but at a younger age than we were able to obtain in our school sample.

Finally, it is curious that the fall in concentration of melatonin is probably evident without the need to use expensive technology. Melatonin is the most potent lightener of melanocytes[17] and has been shown to lighten mammalian hair[18] and human skin[19]. Because children are fairer skinned and lighter haired when they are young and become darker as they grow older, it is likely that the fall in concentration of melatonin is the stimulus for such colour changes, giving visible sign of the early endocrine changes of puberty.

We thank Janet Baines-Preece and Dr N. C. Cameron for assessing the stages of puberty in the schoolchildren and Dr K. Nicol and S. Brown for the assay of gonadotropins and gonadal steroids. We also thank the children and staff at Hollyrood School, Chard, Somerset, for participating in the study. This work was supported by a grant from the Wellcome Trust and is part of an interhospital, interdisciplinary project with Drs P. Mullen and Ivor Smith.

Specific distribution of metabolic alterations in cerebral cortex following apomorphine administration

James McCulloch*, Helen E. Savaki, Mailis C. McCulloch* & Louis Sokoloff

Laboratory of Cerebral Metabolism, National Institute of Mental Health, Bethesda, Maryland 20205
*University of Glasgow, UK

The topographic distribution of dopaminergic receptors in the cerebral cortex closely parallels that of the dopaminergic innervation[1-6]. In the rat, dopaminergic axons which originate in the mesencephalon are confined to a few discrete regions of the neocortex—anterior cingulate cortex, entorhinal cortex, frontal cortex (particularly anteromedial and supragenual areas) and the transitional zone between the neocortex and the pyriform cortex[1-4]. Moreover, biochemical examinations of processes generally considered to be indicative of dopaminergic neurotransmission—neuronal uptake of labelled dopamine or dopamine-activation of adenylate cyclase activity[5,6]—have confirmed a highly restricted locus of action of dopaminergic systems in the cerebral cortex. We describe here data obtained using the 2-deoxyglucose technique[7] in conjunction with conventional neuropharmacological techniques, suggesting that the influence of dopaminergic systems on cortical function extends beyond the known confines of the mesocortical dopaminergic system.

The technique using ^{14}C-labelled 2-deoxyglucose for the measurement of the rates of local cerebral glucose utilisation[7] offers a novel approach to study the pharmacology and physiology of the central nervous system (CNS). The energy requirements of cerebral tissue are derived mainly from the metabolism of glucose, and alterations in functional activity of any region of the brain are associated with changes in its energy demands[8]. The ^{14}C-labelled 2-deoxyglucose technique, which involves the use of quantitative autoradiography to localise radioactivity in the CNS, makes possible the comprehensive assessment of functional alterations throughout the CNS with a degree of localisation impossible with many other approaches[8]. Details of this method have been reported previously[7]. Our experiments were performed on conscious, restrained, male Sprague–Dawley rats weighing approximately 350 g, in which a femoral artery and vein had been catheterised at least 2 h previously. Local rates of glucose utilisation were calculated, by means of the operational equation of the method[7], from the local concentrations of ^{14}C in cerebral tissue (determined by quantitative autoradiography) and the time course of the arterial plasma ^{14}C-deoxyglucose and glucose concentrations. Drugs were administered intravenously; apomorphine was injected 10 min and haloperidol 25 min before the pulse of ^{14}C-deoxyglucose. Administration of the drugs was associated with gross behavioural alterations. With apomorphine, the pattern was characterised by sniffing, licking and movement of the upper body, all of which were replaced at higher concentrations by almost continuous gnawing. With haloperidol, all animals displayed lesser degrees of spontaneous movement, culminating, at doses of 0.1 mg per kg or greater, in a dose-dependent cataleptic state.

Administration of apomorphine resulted in statistically significant dose-dependent alterations in the rates of glucose utilisation in several regions in the CNS in which dopamine is suspected to play a major functional role. For example, glucose utilisation was increased in the caudate nucleus by 29%, in the globus pallidus by 41%, in the substantia nigra zona compacta by 41%, and in the substantia nigra zona reticulata by 76% after the administration of apomorphine (0.5 mg per kg). The effects of apomorphine in the extrapyramidal and other systems will be described in detail elsewhere. We report here only the effects observed in the cerebral cortex, which suggest that the action of apomorphine, the most widely used dopaminergic receptor agonist, on glucose utilisation in the cerebral cortex of the conscious rat is widespread and complex, in spite of the limited extent of cerebral cortical dopaminergic receptors and innervations.

The rate of glucose utilisation normally varies relatively little in different areas of the cerebral cortex, except in the primary auditory cortex where it is markedly greater than in other cortical regions[7]. Metabolic activity is also fairly uniform throughout the depths of the cortex, with the exception of cortical layer IV in which glucose utilisation is approximately 50% greater than in other cortical laminae (Figs 1 and 2).

Apomorphine effected dose-dependent reductions of glucose utilisation in the anterior cingulate cortex, a region innervated by dopaminergic neurones[1-4] and possessing dopaminergic receptor mechanisms[5] (Fig. 2*a*). In contrast, in the dorsolateral frontal cortex and the sensory motor cortex, regions not generally recognised as primary dopaminergic projection areas, apomorphine caused significant increases in glucose utilisation (Fig. 2*b*). In the frontal and sensory motor cortices, the most marked elevations of glucose utilisation were observed in the laminate corresponding to layer VI and the deeper portions of layer V (Fig. 2*c*). Thus, in apomorphine-treated animals this layer, in addition to layer IV, could readily be distinguished on the autoradiographs (Fig. 1). Quantitative determination of the rates of glucose utilisation confirmed the changes seen in the autoradiographs (Fig. 2). Statistically significant increases in the sensory motor cortex were observed even with the smallest dose of apomorphine (0.15 mg per kg) used (Fig. 2). In addition to this laminar pattern of metabolic activation in the dorsolateral

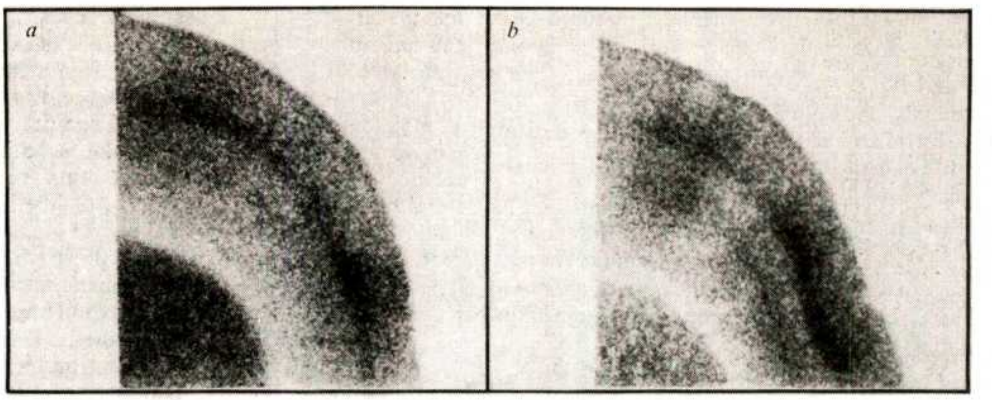

Fig. 1 Autoradiograms of brain sections illustrating the action of apomorphine on the pattern of glucose utilisation in sensory motor cortex of a control animal (*a*) and an animal which had received apomorphine (*b*) (1.5 mg per kg).

frontal and sensory motor cortices, alternating columns of increased and decreased glucose utilisation traversing the thickness of the cortex in these same regions were readily discernible in the autoradiographs (Fig. 1). The columnar and laminar alterations in cortical glucose utilisation decreased progressively in a rostro-caudal direction. In a number of major cortical regions, such as the posterior parietal cortex (Fig. 2*d*), the primary visual cortex and the primary auditory cortex, no alterations in metabolic activity were observed after administration of apomorphine. All the effects of apomorphine in all the cortical areas examined could be prevented by prior administration of haloperidol (0.1 mg per kg).

Previous investigations of the influence of dopamine-agonists and antagonists on cortical function have concentrated on the mesocortical dopaminergic system (particularly, the anterior cingulate cortex and the anteromedial frontal cortex). It is within these small cortical regions that: (1) the dopaminergic nerve terminals originating from the A9 and A10 cell groups of the mesencephalon are found[1–4]; (2) dopamine-sensitive adenyl cyclase has been characterised[5]; (3) specific uptake mechanisms for dopamine have been identified[6]; and (4) cell groupings in which the firing rate is sensitive primarily to dopamine have been localised[9]. Thus, in view of the close coupling between local functional activity and glucose utilisation in the CNS[8], the observation that glucose utilisation in the anterior cingulate cortex is sensitive to a dopaminergic agonist, such as apomorphine, is not unexpected. The marked metabolic activation in the frontal cortex and sensory motor cortex, particularly in the

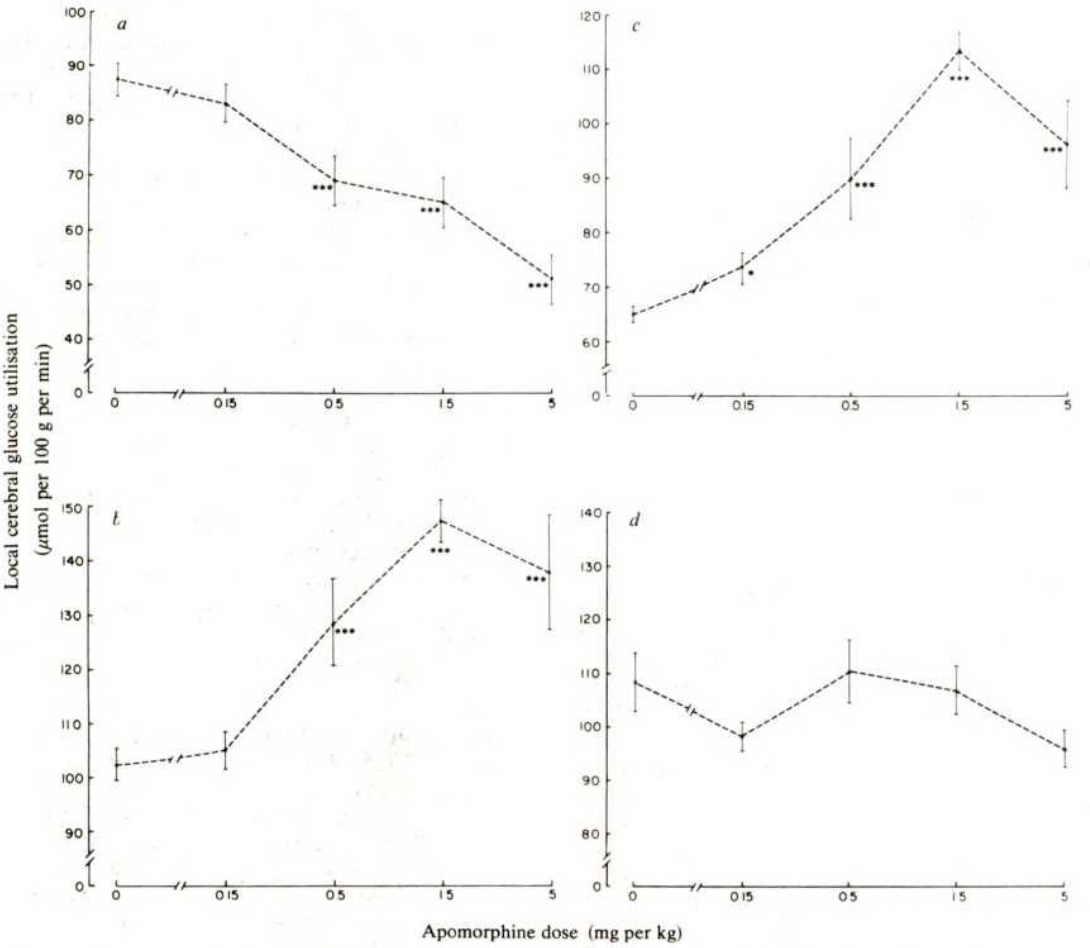

Fig. 2 Log dose–response curve for the rate of glucose utilisation in various cortical areas after intravenous injection of apomorphine. *a*, Anterior cingulate cortex; *b*, sensory motor cortex layer IV; *c*, sensory motor cortex layer VI; *d*, posterior parietal cortex. Data are from 25 animals and are presented as mean ± s.e.m.
$^{*}P < 0.05$. $^{***}P < 0.001$.

deeper laminae, after administration of apomorphine, is of considerably greater interest. It is noteworthy that it is in layer VI and the deepest portion of layer V that the dopaminergic terminals[4] and dopamine-sensitive cells[9] have been identified in the rostral area of the medial aspect of the frontal cortex. There is little evidence, however, of a similar dopaminergic system in layer VI of the dorsolateral frontal cortex and the sensory motor cortex. The regions of cortex in which glucose utilisation increased after administration of apomorphine correspond closely with those areas to which the ventral nucleus of the thalamus projects[10,11]. Glucose utilisation in this thalamic nucleus was increased after administration of apomorphine, and the metabolic activation observed in the dorsolatral frontal and sensory motor cortices may reflect, at least in part, increased activity of non-dopaminergic thalamocortical systems.

The interpretation of the results of any neuropharmacological investigation depends on the specificity of action of the agents used. In the study reported here, the sensitivity to apomorphine of glucose utilisation in areas such as layer VI of the sensory motor cortex, and the prevention of the apomorphine-induced alterations in glucose utilisation in all cortical areas by low doses of the dopamine-antagonist, haloperidol, suggest a key involvement of dopaminergic receptors in the responses observed. Our finding that the cortical involvement in the action of apomorphine extends beyond the known confines of the mesocortical dopaminergic system suggests a need for reappraisal of the mechanisms and foci of action underlying the behavioural effects of antipsychotic and other drugs, which are used to manipulate dopaminergic systems in the CNS.

Growth and differentiation of aggregating fetal brain cells in a serum-free defined medium

Paul Honegger, Dominique Lenoir & Pierric Favrod

Institut de Phsyiologie, Faculté de Médecine, Université de Lausanne, Switzerland

Aggregating cultures of mechanically dissociated fetal brain cells provide an excellent system for neurobiological studies of cellular growth and differentiation[1–5], but, in common with almost all culture systems, they have the disadvantage that crude serum is required in the medium. Although several cell lines have either been adapted to serum-free conditions[6–12] or grown normally in serum-free media supplemented with hormones, trace elements and defined serum components[12–16], this approach has never been applied to differentiating primary cells of the central nervous system. We now describe the successful cultivation of aggregating fetal rat brain cells in a chemically defined, serum-free medium.

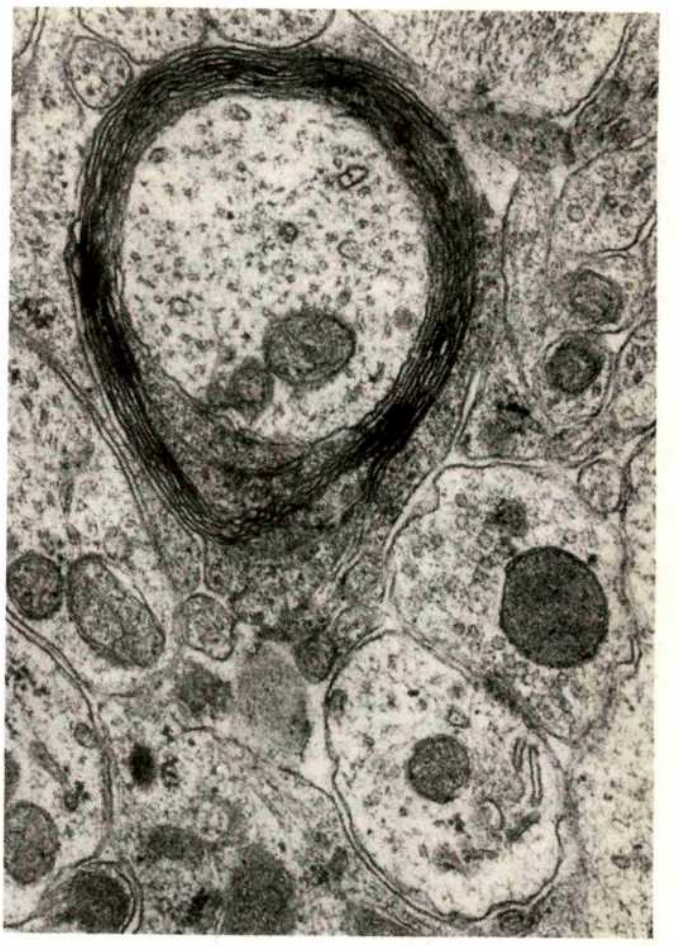

Fig. 1 Electron micrograph of a 35-d aggregate grown in S^- medium, showing a myelinated axon and a synaptic contact. The tissue was fixed in paraformaldehyde–glutaraldehyde, postfixed in osmium tetroxide and embedded in Epon. Sections were stained with uranyl acetate and lead citrate (×42,000).

Equal numbers of mechanically dissociated fetal (15–16 d gestation) rat brain cells[1,2] were inoculated either in Dulbecco–Vogt modified Eagle's medium (DMEM) containing fetal calf serum, referred to as S^+ medium, or in serum-free DMEM supplemented with insulin (5 $\mu g\,ml^{-1}$), 20 nM hydrocortisone, 0.3 nM triiodothyronine, transferrin 1 $\mu g\,ml^{-1}$ and trace elements (see Table 1 legend), referred to as S^- medium. In either case the dissociated cells re-aggregated readily to give a uniform population of aggregates. Throughout the culture period, aggregates in S^- medium remained somewhat smaller, but more numerous (two or threefold) than those in S^+ medium.

Cell proliferation was examined by measuring both the total DNA content and the incorporation of ^{3}H-thymidine into a trichloroacetic acid (TCA)-precipitable macromolecular fraction (Table 1). Cultures grown in S^- medium (S^- cultures) had a greater DNA content and a smaller protein/DNA ratio than cultures grown in S^+ medium (S^+ cultures). In addition, cell counts of thionine-stained semi-thin sections of aggregates revealed almost twice as many cells per unit area in S^- than did S^+ cultures. Both observations suggest slower cell growth (for example, protein acquisition) in S^- cultures. Incorporation of ^{3}H-thymidine (representing DNA synthesis) was demonstrated in both S^+ and S^- cultures (Table 1). During the first 10 d of culture, S^- cultures showed a higher rate of DNA synthesis, with maximum activity after about 5 d. After 10 d, DNA synthesis diminished more rapidly in S^- than in S^+ cultures and by day 20 it was only about one-third of that of S^+ cultures. Lack of either insulin or transferrin in S^- medium resulted in a reduction of both total DNA and ^{3}H-thymidine incorporation at day 5, whereas no difference was observed in the initial rate of ^{3}H-thymidine uptake between cultures grown either in the presence

0028/0836/79/460305—04$01.00

© 1979 Macmillan Journals Ltd.

or absence of insulin. These results suggest that both insulin and transferrin stimulate cell proliferation in S^- cultures, and this agrees with results of investigations with established cell cultures grown in serum-free conditions[12,14,16]. Lack of either hydrocortisone or triiodothyronine, two other hormones that stimulate the growth of some cell lines[14], had no apparent effect on DNA synthesis.

The morphological differentiation of the aggregates was followed by electron microscopy. Compared with S^+ cultures, S^- cultures underwent generally slower maturation of neuronal processes and delayed myelin synthesis. In S^- cultures no synaptic profiles were found after 4 d, but they were frequent after 8 d; the first myelinated axons appeared at about day 30. After 35 d numerous synaptic contacts and many myelinated fibres were observed (Fig. 1). The compaction of myelin sheaths often appeared incomplete.

The biochemical differentiation of the cultures was studied at regular intervals by measuring the specific activities of the following neurotransmitter metabolising enzymes: choline acetyltransferase (CAT, EC 2.3.1.6), acetylcholinesterase (ACE, EC 3.1.1.7), glutamate decarboxylase (GAD, EC 4.1.1.15), aromatic L-amino acid decarboxylase (AAD, EC 4.1.1.26) and monoamine oxidase (MAO, EC 1.4.3.4). Table 2 shows that in S^- cultures, the specific activities of all enzymes (and the protein content) increased considerably during the first month. In contrast to S^+ cultures, the phase of rapid increase in enzyme specific activities occurred later and no plateau was reached within 4 weeks (with the exception of MAO). Compared with S^+ cultures, aggregates grown for 33 d in S^- had higher specific activities of GAD (192%), AAD (148%) and ACE (168%), but lower CAT (40%) and MAO (51%). Lack of insulin in S^- medium resulted in a significant reduction of both GAD activity and protein content, the reduction of GAD activity being more pronounced at early developmental stages (57% reduction at day 11 compared with 15% reduction at day 33). Lack of transferrin in S^- caused a progressive decrease in protein content and the specific activities of all enzymes except MAO. On the other hand, lack of hydrocortisone or triiodothyronine had no apparent effect on the enzyme activities. In view of the relatively high GAD activity in S^- cultures and because the possible neuronal localisation of this enzyme required verification[20,21], we examined the formation of labelled γ-aminobutyric acid (GABA) from L-[U-^{14}C]glutamate in aggregates (Fig. 2). Compared with S^+ cultures, S^- cultures took up glutamate at a higher rate (Fig. 2*a*) and had an almost two-fold greater net synthesis of GABA (Fig. 2*b*), the latter finding agreeing with the differences in GAD activity measured in homogenates (Table 2). The formation of GABA from labelled glutamate was measured in the presence of the carbonyl-trapping agent aminooxyacetic acid (AOAA). After 30 min of incubation in the presence of 13 μM AOAA, synthesis in both S^+ and S^- aggregates of ^{14}C-GABA was less than 5% of that in control cultures. This contrasts with studies of astrocyte cultures[21], in which 13 μM AOAA did not inhibit GABA formation. Furthermore, both GAD activity and rate of GABA synthesis were higher in aggregates than in astrocytes[21] by at least an order of magnitude. Thus the GAD activity measured in aggregates probably represents the neuronal enzyme activity.

The accumulation of glutamine formed from labelled glutamate was considerably lower in S^- than in S^+ cultures (Fig. 2*c*). Glutamine synthetase (EC 6.3.1.2), the enzyme involved in the amidation of glutamate, has been shown to be localised in glial cells[22], suggesting that S^- cultures contained relatively fewer glial cells than S^+ cultures. This is corroborated by the relatively low specific activity of MAO in S^- cultures. (Several observations suggest that the MAO activity of neuronal cells in culture is considerably lower than that of glia—ref. 23 and P.H., unpublished.) Thus, a proportionately higher number of neurones in S^- aggregates could fully account for the relatively

Table 1 DNA synthesis in aggregating cultures of fetal rat brain cells

Brains of fetal (15–16 d gestation) Wistar rats (Madörin, Füllinsdorf) were dissected and dissociated mechanically as before[1,2]. The cells were washed three times with Puck's D_1 solution by trituration and centrifugation (3,700g_{av} per min), and resuspended in serum-free Dulbecco–Vogt modification of Eagle's medium (DMEM, high glucose, no pyruvate, GIBCO no. 320–1965, supplemented with: vitamin B_{12} 1.36 μg ml^{-1}, Sigma; biotin 0.007 μg ml^{-1}, Sigma; DL-α-tocopherol 10 μg ml^{-1}, Sigma; retinol 5 μg ml^{-1}, Fluka; lipoic acid 0.2 μg ml^{-1}, Sigma; linoleic acid 0.1 μg ml^{-1}, Sigma; penicillin 50 U ml^{-1}, ICN; and streptomycin sulphate 50 μg ml^{-1}, ICN). This single cell suspension of 3×10^7 viable cells per ml was divided into two equal portions and then diluted with 2 volumes of either S^+ medium (DMEM containing 15% (v/v) fetal calf serum (Seromed) or S^- medium (DMEM without serum). The complete serum-free medium (S^-) contained the following additional supplements: crystalline bovine insulin (5 μg ml^{-1}, Sigma) hydrocortisone-21-phosphate (20 nM, Sigma), 3,3',5-triiodo-L-thyronine (0.3 nM, Sigma), human transferrin (1 μg ml^{-1}, Sigma) and various trace elements as listed by Hutchings and Sato[15]. Samples (3.5 ml) of the cell suspensions were placed into 25-ml De Long flasks (Bellco) and incubated at 37 °C in an atmosphere of 10% CO_2/90% humidified air, under constant rotation at 70 r.p.m. (Infors gyratory shaker). After 2 d, the cultures were transferred to 50-ml De Long flasks (Bellco) and 5-ml samples of new media were added. Media were changed (exchange of 5 ml medium) every 3 d. Within the first week of culturing, speed of rotation was increased gradually to 80 r.p.m. DNA synthesis was determined by measuring incorporation of ^{3}H-thymidine into a TCA-precipitable macromolecular fraction[17]. Cultures were incubated for 22 h in normal conditions with [Me-^{3}H]thymidine (Amersham, 46 Ci mmol^{-1} specific activity) to give a final concentration of 25 nM (1.2 Ci ml^{-1}). Controls were incubated for 22 h at 4 °C. Aggregates were then washed three times with solution D_1, homogenised in 0.6 ml of 0.05% (v/v) Triton X-100 using a glass–Teflon homogeniser and sonicated briefly (Branson model B-12, 3 × 3 s at 10 W). Samples (25–100 μl) of the homogenate were mixed with 1.5 ml of cold 10% (w/v) TCA, kept at 0 °C for 15 min and then collected by suction onto GF/A glass fibre filter disks. The filters were washed three times with 5-ml samples of 10% TCA, transferred to glass counting vials and incubated for 12 h in 0.5 ml NCS tissue solubiliser (Amersham). After neutralisation of the digest with glacial acetic acid, 10 ml scintillation cocktail (toluene, containing 6 g l^{-1} of 2,5-diphenyloxazole (PPO) and 75 mg ml^{-1} of 1,4-*bis*-[2-(5-phenyloxazolyl)]-benzene (POPOP)) was added for liquid scintillation counting. Portions of homogenates were assayed for protein by a modification of the method of Lowry *et al.*[18] and for DNA by a modification of the method of Kissane and Robins[19]. The values given are the mean of at least two individual cultures (deviation < 10%). The average radioactivity found in controls (2,600 d.p.m. per mg protein) was subtracted.

Fetal rat brain cell aggregates were prepared and cultivated in DMEM containing 15% (v/v) fetal calf serum (S^+) or in serum-free DMEM (S^-), as described in Table 1 legend. The methods used for homogenate preparation and enzyme assays have been described before[1]. Protein was determined by a modification of the method of Lowry *et al.*[18], using bovine serum albumin as a standard. The values given represent the mean of at least five individual culture flasks (s.e.m. < 5%).

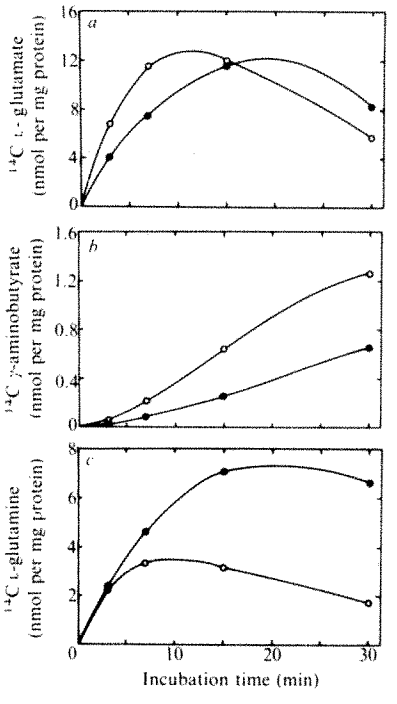

Fig. 2 Aggregates cultured for 30 d in either S^+ medium (●) or in S^- medium (○) were preincubated for 30 min in serum-free DMEM deficient in L-glutamine and subsequently incubated in the presence of 100 μM L-[U-^{14}C]glutamate (Amersham, 1.4 mCi mmol^{-1} final specific activity). The commercially available radioactive material was purified before use by TLC on cellulose plates. The solvent system was 1-butanol/glacial acetic acid/water: 12/3/5 (v/v). After various times, aggregates were analysed for their content of L-^{14}C-glutamate (*a*), ^{14}C-GABA (*b*) and L-^{14}C-glutamine (*c*). The labelled compounds were extracted from homogenates of the washed aggregates and then quantitatively separated on cellulose plates by using the following two-dimensional separation technique: high voltage electrophoresis (buffer: 0.125 M pyridine, 1.05 M acetic acid, *p*H 3.8), followed by TLC (solvent system as above). Further technical details are given in ref. 5. Quantities of products were calculated on the assumption that the specific activity of the precursor in the tissue was equal to that in the medium. Aliquots of the homogenates were assayed for protein by a modification of the method of Lowry *et al.*[18] (s.e.m. < 5%).

high GAD activity observed in these cultures. If this is the case, the relatively low specific activity of CAT, another neuronal marker enzyme, may be explained if, in S^- cultures, (1) there is a smaller proportion of cholinergic neurones; (2) there is a greater retardation in the development of cholinergic neurones; or (3) CAT is more retarded in its development than GAD. Although the present results do not enable us to distinguish between these possibilities, there is some circumstantial evidence in favour of points (2) and/or (3), that is, compared with S^- cultures of cells from the mesencephalon–diencephalon–rhombencephalon region, S^- cultures of telencephalic cells (which are presumably at an earlier stage of development) show a much higher rate of DNA synthesis, a much more pronounced delay of CAT and some delay of GAD maturation (data not shown).

In conclusion, our morphological and biochemical data demonstrate that mechanically dissociated fetal rat brain cells re-aggregate, grow and differentiate in a chemically defined, serum-free medium. Such cultures show some retardation in cellular growth and differentiation compared with their counterparts grown in the presence of 15% fetal calf serum. Although more work is needed to define their developmental characteristics further, serum-free re-aggregating brain cell cultures will be valuable for the study of nutritional and hormonal influences on brain development.

We thank Professor M. Dolivo for support and encouragement, Ms C. de Weck and Mr C. Verdan for technical assistance, and Dr G. Fagg for help with the manuscript. This work was supported by Swiss NSF grant 3.117.77.

Androgen receptors exist throughout the 'critical period' of brain sexual differentiation

Christine C. Vito, Steven J. Wieland & Thomas O. Fox

Department of Neuropathology, Harvard Medical School, and Department of Neuroscience, Children's Hospital Medical Center, 300 Longwood Avenue, Boston, Massachusetts 02115

Several studies suggest direct roles for androgens and oestrogens in the development of sexually dimorphic characteristics of mouse and rat brain[1]. To elucidate the biochemical mechanisms for such effects, investigators have asked which putative steroid receptors are present in the hypothalamus throughout the critical period of sexual differentiation. *A priori*, potential receptors would include high-affinity proteins with selectivities for active androgens, oestrogens and their metabolites. Two major classes of steroid that might be active as agonists are the androgens *per se*, including testosterone and dihydrotestosterone (DHT)[2], and the oestrogens, which are themselves androgen metabolites[3]. Normally, in sexual differentiation, a proper balance of both androgens and oestrogens may be necessary[4]. Indeed, receptors for each of these ligands do exist in the hypothalamus of neonatal and prepubertal mice[4–7]. Although the perinatal oestrogen receptor and its function have been extensively studied[7,8], the existence of perinatal androgen receptors has not been as clearly demonstrated to permit a similar acceptance[9]. In this report, we establish the existence of adult-like androgen receptors in embryonic and neonatal mouse and rat hypothalami by qualitative biochemical and genetic analyses. This is achieved by DNA–cellulose affinity chromatography and velocity sedimentation, and by analysis of the androgen-resistant mutant, testicular feminisation. The presence of sex hormone receptors in perinatal brain is discussed in the context of behavioural responses which are differentiated during the critical period of brain sexual development.

We used DNA–cellulose affinity chromatography to characterise the androgen-binding proteins in perinatal hypothalamus as it fractionates low levels of androgen receptor in prepubertal brain[10,11] and permits qualitative analysis of the DNA-adhering material[7,8]. Figure 1 shows a representative elution profile of prepubertal hypothalamic androgen receptor (triangles), and also illustrates (circles) a ^{3}H-DHT-binding activity from neonatal hypothalamus which similarly adheres to DNA–cellulose and elutes in the same manner with a linear concentration gradient of NaCl. The androgen-binding activities in both neonatal and prepubertal cytosols exhibit elution maxima in the 140–150-mM NaCl range of the gradient. Therefore, by the criteria of DNA adherence, the androgen-binding activity in perinatal mouse hypothalamus is qualitatively similar to the putative androgen receptor present in older animals.

To determine its macromolecular integrity, the material which elutes from DNA–cellulose was analysed by velocity sedimentation (Fig. 2). As indicated by the lack of radioactivity at or near the top of sucrose gradients following centrifugation, the androgen is indeed bound to macromolecular components of cytosols from prepubertal (21 days after birth; Fig. 2*a*), neonatal (3–4 days after birth; Fig. 2*b*, closed circles) and embryonic (3 days before birth; Fig. 2*b*, open circles) hypothalami. The androgen-binding activities from both neonatal and embryonic hypothalami (Fig. 2*b*) behave similarly to that from prepubertal hypothalamus (Fig. 2*a*) in that all sediment as 4S macromolecules. The sedimentation profiles shown in Fig. 2*a* and *b* are representative of data obtained at all hormone concentrations tested.

Using both DNA–cellulose chromatography and velocity sedimentation, we have assessed the saturability of the androgen-binding activities in embryonic, neonatal and prepubertal tissues. Androgen-binding activities are $92 \pm 3\%$ (s.e.m. $n = 15$) saturated at hormone concentrations below 10 nM; this is observed with both DHT and testosterone in both hypothalamic and kidney cytosols, and agrees with previous observations that putative androgen receptor from prepubertal animals saturates at hormone concentrations between 4 and 8 nM (refs 4, 7).

In mature animals with the androgen-resistant genetic syndrome, testicular feminisation (*Tfm*), the levels of androgen receptor are lower in both hypothalamus[4,10–12] and kidney[7,13–15] than in wild-type animals. As the wild-type neonatal androgen-binding activity which adheres to DNA–cellulose seems to be similar to that of older animals (Figs 1, 2), we would expect this activity in neonatal *Tfm*/Y tissues to be similarly affected if the mutation is expressed at an early age. Indeed, the androgen binding capacity of neonatal *Tfm*/Y cytosols (hypothalamus and kidney) is approximately 15% that of sibling (male and female) cytosols (Table 1); a similar observation has been made in submandibular gland and kidney cytosols using sedimentation analysis[16]. In contrast, the concentration of oestrogen receptor in mouse *Tfm*/Y hypothalamus is similar to that in sibling hypothalamus at the neonatal ages tested (data not shown), as was shown for older animals[4,10].

Thus, our data suggest that both embryonic and neonatal hypothalamus contain an androgen-binding activity which is qualitatively similar to the putative androgen receptor in the hypothalamus of older animals. However, the level of neonatal binding is lower than prepubertal binding (Figs 1, 2).

Using the qualitative DNA–cellulose and velocity sedimentation patterns presented above, we have also quantified the putative androgen receptor content of the developing mouse hypothalamus. These data are summarised in Fig. 3. The concentration of androgen receptor detected in mouse hypothalamus between embryonic and prepubertal ages increases approximately sevenfold. In contrast, between 3 days before and 3 days after birth, only a twofold increase in the concentration of androgen receptor is detected. These data augment earlier quantitative measurements which also indicate an increase between late postnatal and prepubertal ages[6,17]. Thus, the phase of most rapid appearance of androgen receptor seems to coincide with the late phase of the critical period of brain sexual differentiation. This ontogeny differs significantly from that of oestrogen receptors in mouse hypothalamus, as the overall increase in the concentration of oestrogen receptor from embryonic to prepubertal ages is only twofold[7,8]. It is possible that technical or biological factors which differentially affect the detectability of androgen receptors cause this apparent difference. However, in spite of this qualification concerning the levels of androgen receptors, the significance of our report is that it establishes their presence in the hypothalamus throughout perinatal development.

Table 1 Androgen receptors in neonatal *Tfm*/Y and sibling mice

		Testosterone bound (mol × 10^{18} per mg tissue)*	
Age (d)	Genotype	Hypothalamic–preoptic area	Kidney
5	♀	6.7	42.0
	Tfm/Y	1.1	3.9
7	♀	7.0	50.0
	♂	7.5	64.0
	Tfm/Y	0.9	5.5

* Quantification was by DNA–cellulose affinity chromatography, using a protocol similar to that described in Fig. 1 legend.

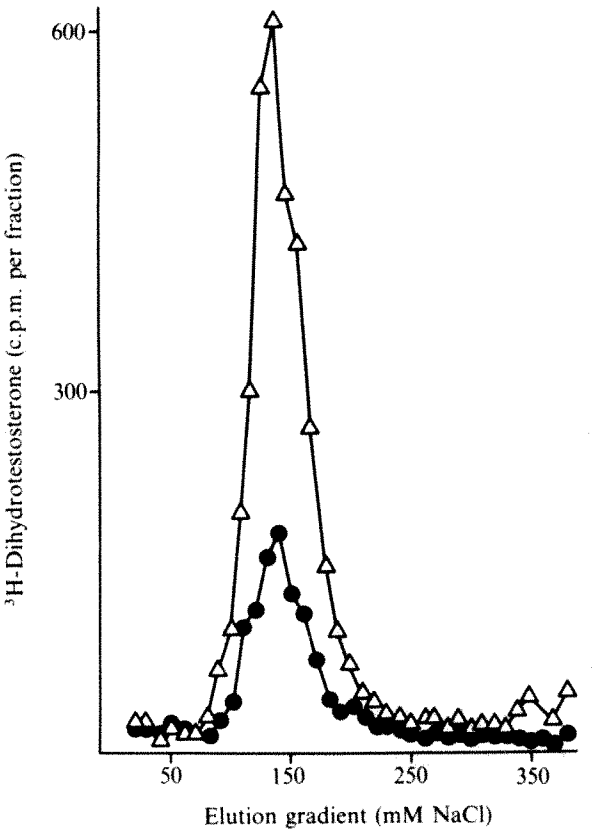

Fig. 1 DNA–cellulose affinity chromatography of androgen receptor from cytosols of neonatal and prepubertal mouse hypothalamus. C57BL/6J mice were obtained from the timed-pregnancy colony in our department. To prepare cytosol extracts, hypothalamic–preoptic area blocks from either 4- and 5-d-old mice (●) or 20- and 21-d-old mice (△) were homogenised at 2 °C, using a Kontes Teflon/glass homogeniser, in buffer containing: 10 nM Tris-HCl (*p*H 8.1, 21 °C), 1 mM mercaptoethanol, 1 mM Na_3EDTA, 10% glycerol and 50 mM NaCl. After the homogenate had been centrifuged at 140,000 *g* for 60 min, the resulting cytosol was collected and incubated with 10 nM [1,2,4,5,6,7-^{3}H(*N*)]5α-dihydrotestosterone (DHT; 152 Ci mmol^{-1}, NEN). Before use, we determined the purity of radioactively labelled steroid by HPLC (high-performance liquid chromatography: Waters Associates Inc.) or TLC (thin-layer chromatography); it was necessary to use purified ^{3}H-DHT which was obtained by HPLC. Following a 60-min incubation with ^{3}H-DHT, the cytosol preparations (each containing an equivalent of 970 mg tissue) were loaded on columns containing 5 ml DNA–cellulose which had been equilibrated with buffer containing 50 mM NaCl. The columns were then washed with approximately 60 ml of buffer during a 12-h period. The ^{3}H-DHT-bound content of the column was eluted with a 60-ml linear gradient of NaCl, ranging from 50 to 500 mM. For each column, fractions were collected and the NaCl concentrations were determined using a Radiometer conductivity meter. Radioactivity was measured after the addition of 5.0 ml of Omnifluor (NEN)–toluene scintillation fluid.

In rat hypothalami at embryonic, neonatal and prepubertal ages, we have also detected androgen-binding activities which adhere to DNA–cellulose and elute sharply at a NaCl concentration of approximately 140 mM. These elution characteristics are similar to those shown in Fig. 1. Saturable androgen-binding capacities of rat hypothalamic cytosols are, respectively, 5.8 ± 1.4 (2–4 days before birth; $n = 3$), 7.7 ± 0.3 (4 days after birth; $n = 2$) and 37.8 ± 8.4 (21–35 days after birth; $n = 3$) mol × 10^{18} per mg tissue (±s.e.m.). In keeping with the mutant mouse results, the androgen-binding activity in the hypothalamus of the androgen-resistant rat[18] is approximately 20% that of the wild type.

Perinatal administration of DHT masculinises some features of both sexual behaviour in rats[19] and guinea pigs[20], and social play in monkeys[21]. The masculine behavioural potential of both aggressive behaviour in female mice[22,23] and sexual behaviour in female rats[24] is influenced by the *in utero* proximity to males, presumably by androgens from testicular secretions. These *in utero* masculinising effects on sexual behaviour are blocked by flutamide[24], a presumed antagonist of direct androgen action. However, masculinisation can occur fully[25,26], or in part[27], after postnatal administration of presumed inhibitors of androgen conversion to oestrogens.

In addition to masculinisation, perinatal administration of androgens or oestrogens can suppress some features of female sexual behaviour in mice and rats[28]. Moreover, androgens including DHT can defeminise some features of sexual behaviour in hamsters[29]. On the other hand, prenatal exposure to flutamide[30] and 1,4,6-androstatsiene-3,17-dione(ATD)[31], which presumably block direct androgen action and oestrogen formation, respectively, enhance lordotic behaviour in female rats. As female sexual behaviour can be suppressed by both androgens and oestrogens and enhanced by agents which block their direct actions, both hormones may mediate these developmental processes. These experiments suggest that androgen receptors could be involved in some aspects of masculinisation and defeminisation of sexually dimorphic behaviours. The present findings provide one possible molecular mechanism

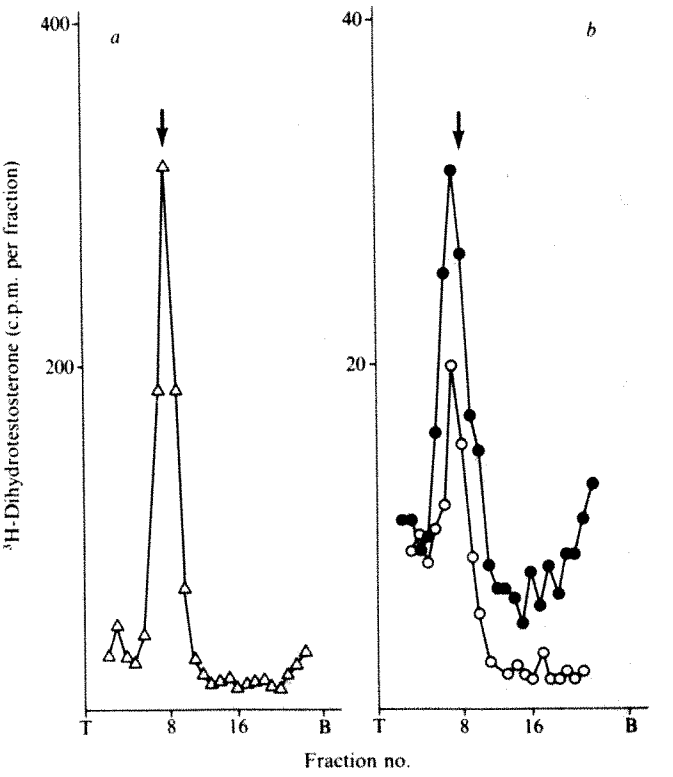

Fig. 2 Velocity sedimentation analysis of androgen receptor from embryonic, neonatal and prepubertal mouse hypothalamus. Hypothalamic blocks from C57BL/6J mice of determined embryonic, neonatal and prepubertal ages were used. Cytosols (containing an equivalent of 300 mg tissue) were prepared, incubated with 20 nM ^{3}H-DHT and chromatographed with DNA–cellulose as described in Fig. 1 legend. The ^{3}H-DHT-bound contents of each column were eluted with a single step of buffer containing 400 mM NaCl and then layered on a sucrose gradient (5 ml; 5% to 20%, w/v) containing the same buffer. Gradients were centrifuged for 20 h at 234,000*g* (average force) and contained the internal fluorescent marker dansyl-BSA (4.7S), the position of which is indicated by the arrow. *a*, Prepubertal cytosols (21 days after birth), △----△. *b*, Embryonic cytosols (3 days before birth), ○----○; neonatal cytosols (4 and 5 days after birth), ●----●.

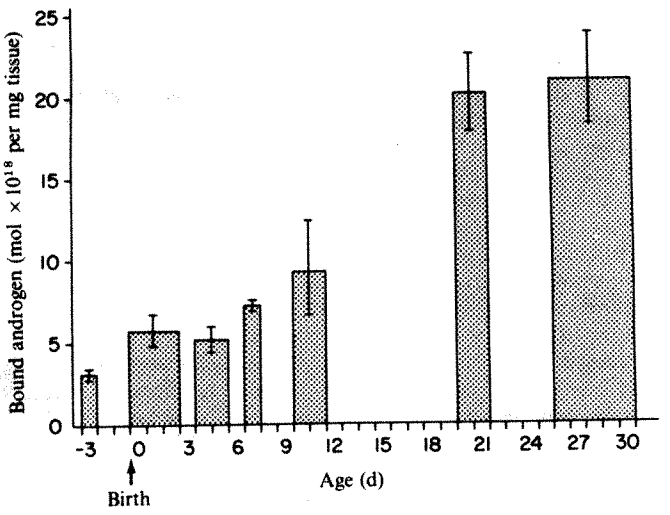

Fig. 3 Concentration of androgen receptors detected in the developing mouse hypothalamus. The horizontal axis represents time in days, with the distance between two markings representing one 24-h period. The vertical axis represents mol of bound androgen obtained by DNA–cellulose chromatography alone or in combination with velocity sedimentation. Velocity sedimentation analysis following DNA–cellulose chromatography was carried out at ages considered representative of embryonic (3 days before birth), neonatal (4–5 days post-birth) and prepubertal (21 days post-birth) development; the macromolecular material recovered following sedimentation was 95.6 ± 3.9% (s.e.m., $n = 8$) of the DNA–cellulose eluate applied to the sucrose gradient. The hormone-binding activities which are quantified as receptor activities are those which adhere to and eluate from DNA–cellulose in a specific manner. For example, in Fig. 1, the neonatal binding activity which elutes within the 75–225-mM region of the NaCl gradient is quantified by summing all those data points. This type of analysis serves as a qualitative control for the quantitative determinations reported above. Error bars indicate the s.e.m. The number of determinations (n) and the mean number of hypothalami per determination (HPOA) for the ages represented above are: 3 days before birth ($n = 2$, HPOA = 95); 0–2 days post-birth ($n = 2$, HPOA = 32); 4–5 days post-birth ($n = 6$, HPOA = 26); 7 days post-birth ($n = 2$, HPOA = 10); 10–11 days post-birth ($n = 3$, HPOA = 10); 20–21 days post-birth ($n = 6$, HPOA = 11); 25–30 days post-birth ($n = 2$, HPOA = 10). Our assignment system for embryonic ages has been described previously[8]. Records of vaginal plugs and births were used for all the age determinations illustrated above.

through which androgens may act as effectors of sexual differentiation.

We thank Sarah E. Bates and Kathie L. Olsen for their contributions to this work. Parts of the work were supported by a postdoctoral National Research Service Award (NICHD, to C.C.V.), a predoctoral National Research Service Award in Cell and Developmental Biology (grant 5 T32 GM 07226 to S.J.W.), a grant (HD 10818) and Research Career Development Award (NICHD to T.O.F.), and a grant from The National Foundation-March of Dimes. The work was carried out in the facilities of the Mental Retardation Research Center (NICHD) at the Children's Hospital Medical Center.

A region of the *Drosophila* genome necessary for CNS development

F. Jiménez & J. A. Campos-Ortega

Institut für Biologie III, Schänzlestr. 1, 7800 Freiburg i.Br., FRG

Mutations in genes involved in essential aspects of central nervous system development in *Drosophila melanogaster* are expected to be lethal. Thus, when searching for neurogenic mutants attention should be focused on embryonic lethal point mutants[1], for many of these might affect neural development. However, this approach can be very time consuming, for the location of neurogenic genes is unknown. A more convenient approach, which allows a faster screening of the genome, is to use relatively small chromosome deletions[2,3] to determine whether the lack of a definite part of the genome affects neurogenesis. Once any region producing an interesting neural phenotype is found, it can be further analysed by the use of smaller deletions or point lethal mutants mapping within it, until the gene(s) responsible can be more precisely localised[1,4]. We report here on a region of the *Drosophila* genome which has been found necessary for normal neurogenesis.

Using the technique designed by Zalokar and Erk[5] for staining embryos as whole mounts, we have studied the effect on embryogenesis of deficiencies (a total of 52) covering ~1,000 bands distributed throughout all major chromosomes of *Drosophila*. We have found that some of them, even large ones, have no effect on the overall morphological pattern of the embryo, whereas others produce rather general morphogenetic defects. We intend to describe these defects in detail elsewhere. In addition to those deficiencies, however, we have found that some at the tip of the first chromosome exclusively alter the morphology of the embryonic nervous system in hemizygous animals, almost entirely eliminating neural tissue without modifying that of the remaining organs. Part of the chromosome region responsible for this abnormal phenotype is the *achaete-scute* system, which it has recently been suggested participates in neural development[6,7]. We have examined the neural phenotype produced by terminal deficiencies of increasing size—*Df(1)sc*^{8}, *Df(1)sc*^{H}, *Df(1)260-1*, *Df(1)y*^{74k}, *Df(1)svr* and *Df(1)Bld*— as well as some intercalary ones—*In(1)sc*^{4L}*sc*^{9R}, *Df(1)sc*^{19}—with the following results (see Fig. 1). *Df(1)sc*^{8}, the smallest terminal deficiency studied, does not seem to change the pattern of the nervous system observed in wild-type embryos. However, all remaining deletions eliminate increasing amounts of neural tissue, the extent of the lesion being correlated with the size of the chromosome deletion considered. The smallest intercalary deficiency studied (*In(1)sc*^{4L}*sc*^{9R}) only produces a main constriction in the middle of the ventral cord, whereas embryos hemizygous for the largest terminal deficien-

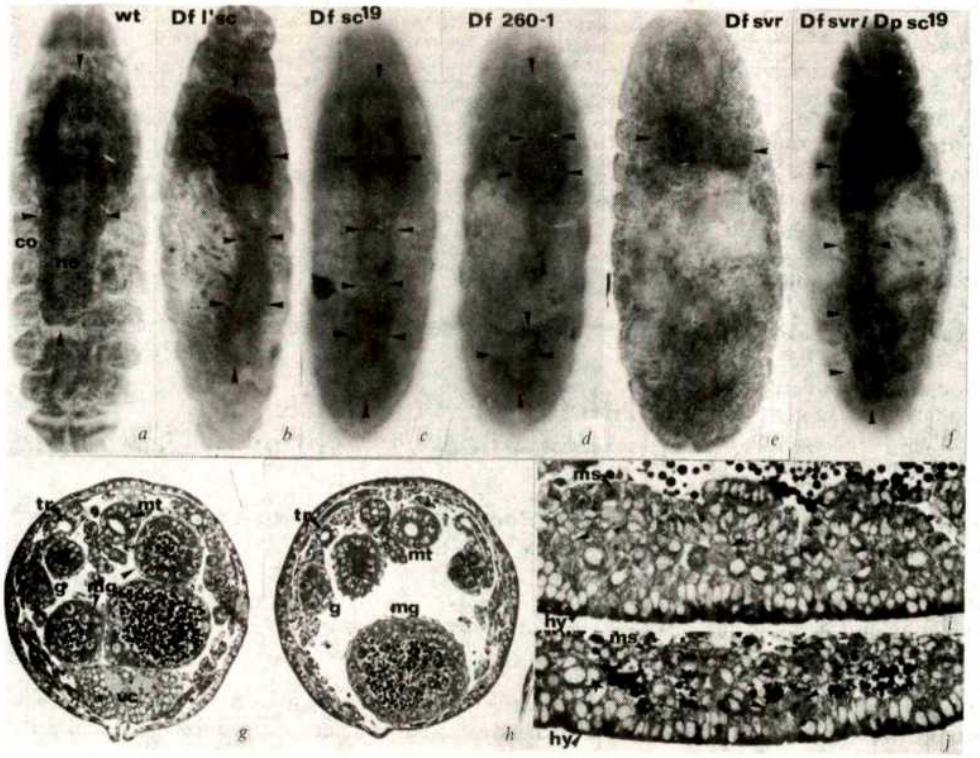

Fig. 1 Neural phenotype found in embryos hemizygous for deficiencies at the tip of the first chromosome. The experimental crosses were made with F_1 females, derived from an outcross of the deficiency-carrying stock to a wild-type (Oregon S) stock and wild-type males. The only exception was *Df(1)svr-Dp(1)sc*^{19}, in which $\widehat{XX}$/ *Y; Dp(1)sc*^{19}/*CyO* females were crossed with *Df(1)svr/ y*^{2}*Y67g* males. Embryos collected at 17 ± 1 (*a–h*) and 7 ± 0.5 (i, j) h after oviposition (25 °C) were fixed either with alcohol/acetic acid/formaldehyde for fuchsin staining of whole mounts or with glutaraldehyde–osmium tetroxide for Durcupan embedding for light and electron microscopy[5]. *a* Shows a whole mount of a wild-type embryo. *Df(l'sc (b)*, corresponding to *In(1)sc*^{4L}*sc*^{9R} which includes the lethal of *scute* (*l'sc*)[7,11], produces a constriction in the abdominal ganglia in the ventral cord, which has not completely undergone the condensation normally occurring at this time[8] (16–18 h of development). Constrictions and lack of condensation become more evident in *Df(1)sc*^{19} *(c)* or in *Df(1)sc*^{H} (not shown) embryos, both deficiencies producing a comparable phenotype. *d* Is an example of *Df(1)260-1* embryos, showing a large gap between rostral and caudal parts of the ventral cord. *e* Illustrates the phenotype found in *Df(1)svr* embryos, in which only remnants of the brain lobes are visible. *f* Shows the result of covering the left part of the region of interest with the *Dp(1; 2)sc*^{19}; the phenotype obtained is similar to that of the deficiency for the *achaete-scute* system *Df(1)sc*^{19} shown in *c*. Photographs were taken focusing the suboesophageal ganglion and the ventral cord so that the brain lobes are not clearly defined. The arrowheads mark the borers of the nervous system, co, cortex; ne, neuropile. *g, h*, Transverse sections at the level of the gonads through wild-type (g) and *Df(1)y*^{74k} (*h*) embryos. g, gonads; mg, midgut; mt, malphighian tubules; tr, tracheae; vc, ventral cord. *i, j* Sagittal sections through the ventral region of wild-type (*i*) and *DF(1)svr* (*j*) 7-h-old embryos. Dividing neuroblasts[9] (arrowheads) in both instances and clusters of degenerating cells (asterisks) in the mutant are evident. hy, hypodermis; ms, mesoderm.

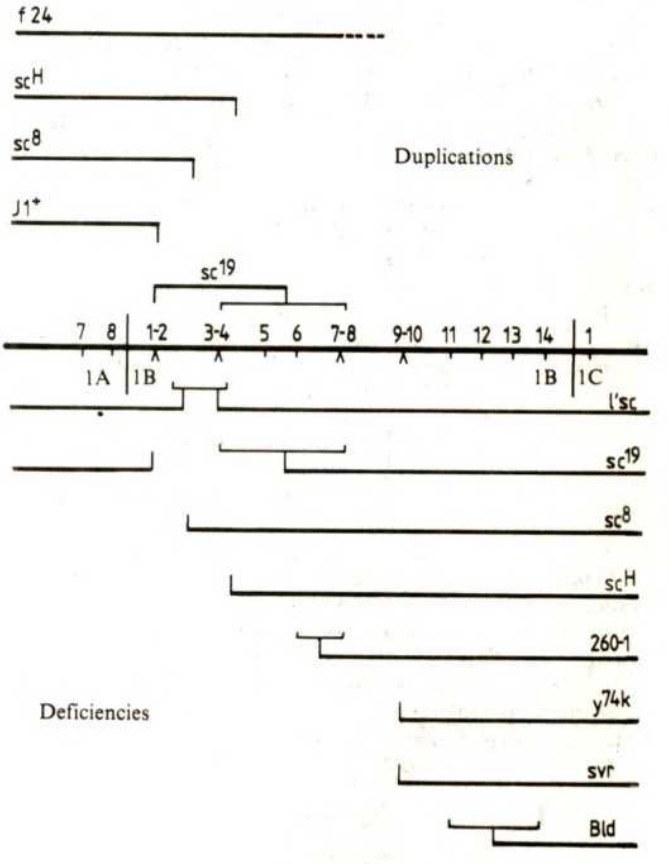

Fig. 2 Cytogenic location and extent of deficiencies and duplications used in the present work. In the centre of the figure, bands within subdivision 1B of the X chromosome are given according to Bridges' revised map[12]. The lower half of the figure shows the deficiencies studied. Data of breakpoints are taken from refs 7, 10, 11 and 13. Some uncertainties exist concerning the location of deficiency breakpoints. For example, in *Df(1)l'sc*, corresponding to *In(1)sc*^{4L}*sc*^{9R}, genetic data[7,14] demonstrate that *In(1)sc*^{9} has a distal breakpoint to the right of that of *In(1)sc*^{4}; cytogenetically, however, the sequence is the inverse[11]. The right breakpoint of *Df(1)sc*^{19} has been found[11] at 1B4-7; genetically (ref. 7 and present work), it should be at the same location as that of *Df(1)sc*^{H}—1B4—as the phenotype produced by both deficiencies is very similar. Finally, the breakpoint of *Df(1)Bld* has been genetically and cytogenetically localised at 1B11-14. The upper half of the figure shows the extent of duplications according to refs 7 and 11 and to data from the present work.

cies (*Df(1)y*^{74k}, *Df(1)svr* and *Df(1)Bld*) do not show any organised ventral cord structure but only some cell clusters in the brain lobes (Fig. 1*a–f*).

We then studied serial sections of mutant embryos, and confirmed the previous observations. Note that in the mutants studied, all other embryonic structures that we are able to recognise on histological sections seem to be entirely normal at 17 ± 1 h of development. This can be seen, for example, in the sections shown in Fig. 1*g* and *h*, corresponding to comparable levels of wild-type and *Df(1)y*^{74k} embryos, where the only appreciable difference is the absence of the ventral cord in the mutant. However, a small but increasing number of dead cells is visible in the hypodermis of developing 10–14-h-old *Df(1)260-1*, *Df(1)svr* and *Df(1)Bld* embryos, although the hypodermis of 17 ± 1-h-old embryos shows no defect in any of these mutants.

The nature of the lesion found at late stages of development was traced back by analysing younger mutant embryos—*Df(1)sc*^{19}, *Df(1)260-1* and *Df(1)svr*. No abnormalities were detected at 4 h, but 7-h-old animals already displayed extensive cell death throughout both brain lobes and ventral cord anlagen (Fig. 1*i*, *j*), the extent being largely dependent on the deficiency considered, and the definitive phenotype being eventually attained at 13 h of development. As dividing neuroblasts seem to be present[8] in the mutant, cell death must chiefly affect ganglion mother cells[9] and/or differentiating neurones. From the above results, we suggest that the part of the genome responsible for this phenotype codes for functions necessary for the development of the nervous system. A more detailed analysis has been made feasible by covering part of the deleted region with corresponding pieces of the wild-type first chromosome translocated into other chromosomes. This analysis has demonstrated that the region to the right of *scute* also affects neural development (see Fig. 2). For example, by covering the left part of the region of interest with duplications, as in *Df(1)svr-Dp(1; 2)sc*^{19} (Fig. 1*f*) or *Df(1)svr-Dp(1; 4)sc*^{H}, a phenotype roughly comparable to that of deletions of the *achaete–scute* system (for example, *Df(1)sc*^{19}, (Fig. 1*c*) or *Df(1)sc*^{H}) is obtained. Thus, the analysis of deficiency–duplication combinations demonstrates that both the *achaete–scute* system and the region to its right might contain qualitatively similar signals.

The left border of the region under study is defined by *Dp(1; Y)l(1)J1*$^{+}$; it is the largest terminal duplication of those we have studied which is unable to rescue the phenotype of either *Df(1)260-1* or *Df(1)svr*. The right border may be tentatively placed in the vicinity of the breakpoint of *Df(1)Bld* (see Fig. 2). This leaves us with a relatively large fraction of the *Drosophila* genome—almost all the subdivision 1B of the first chromosome—apparently coding for functions of related nature, as judged from the resulting phenotype. The problem of how specifically the whole region controls neural functions requires further investigation. Cell death in the developing hypodermis of some mutants, and the fact that *Df(1)svr* has been reported to be inviable in clones of imaginal epidermal cells whereas clones of *Df(1)260-1* cells are viable[10], suggest that some gene functions included in the *Df(1)svr* might also be needed by tissues other than the nervous system. However, *Df(1)svr* is a large deletion, comprising at least 16 complementation groups[10], so that these findings do not necessarily exclude a specific control of nervous system development by genes from this region. Even so, the results described here clearly demonstrate the efficacy of chromosome deletions as a tool with which to screen for neurogenic loci within the *Drosophila* genome.

We thank Sigrid Krien for technical assistance, Loring Craymer and A. Garcia-Bellido for mutant stocks, A. Garcia-Bellido, G. Jürgens, W. Michalke and P. A. Lawrence for discussions and for commenting on the manuscript, and the Deutsche Forschungsgemeinschaft (SFB 46) for financial support. F.J. holds an EMBO long-term fellowship.

Histone gene deficiencies and position–effect variegation in *Drosophila*

Gerald D. Moore, James D. Procunier, David P. Cross* & Thomas A. Grigliatti

Department of Zoology, The University of British Columbia, Vancouver, British Columbia, Canada V6T 1W5

Position–effect variegation, originally observed in insects, has since been demonstrated in plants and mammals. When cells bear a chromosomal rearrangement which juxtaposes a euchromatic gene near to heterochromatin, a fraction of the cells exhibit no expression of that gene. The resultant organism is a mosaic for activity of the rearranged gene. The degree of mosaicism can be modified; such factors as elevated developmental temperature, additional Y chromosome heterochromatin in the genome, and various modifier genes enhance the proportion of cells in which the gene is active[1]. Although the phenomenon has been extensively documented, the underlying molecular mechanism of position–effect variegation remains unclear. The proportion of cells exhibiting gene inactivation increases with greater proximity of the rearranged gene locus to heterochromatin. It has been proposed that the variegating gene is inactivated by a 'spreading effect', or limited spatial diffusion of molecules from the adjacent heterochromatin[2]. This explanation supposes that the juxtaposed gene locus is condensed into a transcriptionally inactive state, possibly by a phosphorylated histone protein subspecies characteristic of *Drosophila* heterochromatin[3]. Such a model leads to the prediction that an alteration in the amount of cellular histone protein would affect the expression of variegating genes. To test this prediction, we have investigated the effect of a reduction in the number of genes coding for histone protein on the degree of mosaicism observed in two variegating gene systems. Our results suggest that the amount of variegating gene expression is a function of histone gene multiplicity.

The histone genes of *Drosophila melanogaster* have been localised to a discrete region on the left arm of the second chromosome (polytene bands 39D3–E2)[4]. This region contains a nucleotide sequence coding for all five histone protein species, tandemly reiterated about 100 times[5]. Individuals whose genotypes contain single or triple histone clusters instead of the normal diploid complement are viable and phenotypically normal. Deficiencies in the left arm of the second chromosome have been generated, and characterised with respect to their breakpoints[6]. Five of these deficiency chromosome stocks were obtained; all have similar breakpoints to the left of the histone gene cluster. Two of the deficiencies, *Df(2L)1* and *Df(2L)12*, extend rightwards towards the histone gene cluster, but do not include it (Fig. 1). They serve as controls for any effect of deleting euchromatic segments to the left of the histone gene cluster. One deficiency, *Df(2L)84*, has its right breakpoint in the

$w^{m4}/Y;CyO/+$	2	8	1.7	
$w^{m4}/Y;+/+$	2	4	0.9	

F_1 progeny were reared at 17 °C and allowed to age to 1–7 d post-eclosion. Approximately 50 flies of each type were decapitated by freezing and agitation. Single heads were crushed on cellulose chromatography plates (Eastman 13255) and pigments were separated with a 2:1 propanol: 1% NH_3 solution. The drosopterin spots were located, and relative levels of fluorescence measured, using a Zeiss microscope equipped with a UV light source and a photomultiplier. The fluorometer was standardised against the amount of drosopterin fluorescence from w^+ (Oregon-R strain) heads. Significance of difference in mean drosopterin amounts between $Df(2L)/+$ and $CyO/+$ siblings was tested using a t-test.

histone gene cluster. The proportion of the cluster which it deletes is uncertain. The remaining deficiencies, *Df(2L)65* and *Df(2L)161*, delete the entire histone gene cluster. The five deficiencies were tested on two chromosomal rearrangements which exhibit position–effect variegation. The first was $In(1)w^{m4}$, an inversion which relocates the *white*$^+$ gene from its normal position at the tip of the X chromosome to the centromeric heterochromatin. The *white*$^+$ gene is responsible for the formation of pigment granules in the pigment cells[7]. Individual cells of a *white* variegated, mosaic eye have either a normal complement of pigment granules, or are devoid of them[8]. A $w^{m4}/Y;+/+$ eye contains about 4% of the wild-type amount of the red pigment drosopterin, when flies are raised at 17 °C. The control deficiencies on the second chromosome (*Df(2L)1*, *Df(2L)12*) do not significantly alter this level (Table 1). $In(1)w^{m4}$ flies heterozygous for the other three deficiencies which delete all, or a portion of the histone gene cluster, exhibit significantly elevated levels of eye drosopterin. Active expression of the *white*$^+$ gene occurs in a greater proportion of $In(1)w^{m4}$ pigment cells with a single histone gene cluster than in those with the normal diploid complement.

The narrow eye phenotype associated with the mutation *Bar* is the result of a tandem duplication in the X chromosome region 16A (ref. 9). The rearrangement $B^{SV}Y$ attaches this duplicated region to the heterochromatin of the Y chromosome[10]. As this transposed region is inactivated by position–effect variegation in a proportion of the presumptive ommatidial (eye facet) cells, B^{SV} flies exhibit a phenotype intermediate between the narrow eye of *Bar* and the normal, oval *Bar*$^+$ eye. In this case, suppression of the spreading effect should result in a narrower eye phenotype in B^{SV} flies, as the transposed duplication segment would be actively expressed in a greater proportion of presumptive ommatidial cells. This was observed in B^{SV} flies heterozygous for deficiencies of the histone gene cluster (Table 2). The effect of deficiency *Df(2L)84*, which deletes a portion of the histone gene cluster, is not as pronounced as that of deficiencies *Df(2L)65,161* which delete the entire cluster.

The results obtained using these two variegating gene systems confirm the prediction that a reduction in histone gene dosage will enhance active expression of variegating genes. Khesin and Liebovitch[11] obtained similar results using the variegating *white* allele associated with translocation $T(1;3)w^{vco}$. Their methodology was seriously flawed, however, by constructing segmentally aneuploid histone gene deficiencies from translocation $T(Y;2)$ chromosomes[12]. In addition to deleting euchromatic portions of the chromosome, this technique produces poorly defined deficiencies and duplications of Y chromosome material. The Y chromosome contains regions which are potent suppressors of variegation[13] and whose integrity in $T(Y;2)$ chromosomes is questionable. We have tested a series of deficiencies, non-deficiencies and duplications of the histone gene cluster constructed from $(Y;2)$ translocations. The translocated Y chromosomes vary widely and unpredictably in their ability to suppress or enhance variegation. Hence, we have confined our study to the use of deficiencies restricted to small euchromatic portions of chromosome 2. These deficiencies allow us to control for any effect of Y heterochromatin by utilising uniform Y chromosomes. Of the five deficiency chromosomes tested, four (*Df(2L)1*, *12*, *65* and *84*) were generated from a chromosome bearing *Tft l(2)74i* while *Df(2L)161* was imposed on a *cn bw* chromosome. Although it is possible that the two source chromosomes vary with respect to undefined variegation modifying loci, this seems unlikely given the similarity of modification observed with the *Df(2L)65* and *Df(2L)161* chromosomes.

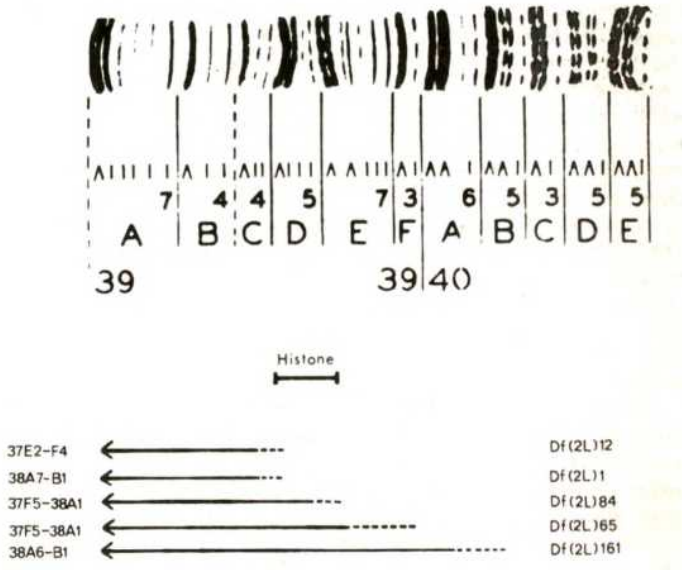

Fig. 1 A segment of the polytene chromosome map of *D. melanogaster* second chromosome showing the location of the histone gene cluster. The extent of each deficiency is indicated by a horizontal bar. Left breakpoints are listed; the right breakpoints fall within the broken portion of the bars. Cytological examination was originally performed by Wright *et al.*[6] and has been reconfirmed in our laboratory.

results obtained, it must be tightly linked to the left of the cluster.

Reduction in the number of histone genes has not been directly correlated to a decrease in the amount of cellular histone protein; indeed, it seems improbable that the reduction in histone protein amount is equivalent to the reduction in gene multiplicity. However, we interpret our results to suggest that compensation for the reduced histone coding capacity is incomplete, and that the level of cellular histone protein is partially reduced during the period when the transcriptional fate of the variegating genes is determined, since reduction in the coding capacity for histone protein markedly affected the level of variegating gene expression.

Table 2 Mean percentage of wild-type (B^+) eye surface in $+/B^{SV}Y$ F_1 ♂ flies from the cross: $+/Y; CyO/Df(2L)$♂♂ × $\widehat{XX}/B^{SV}Y; +/+$♀♀

F_1 progeny were reared at 21 °C. Approximately 100 eyes of each type were sketched with the aid of a dissecting microscope equipped with an ocular micrometer. Outlines were cut out and weighed to estimate relative surface area. An ANOVA test revealed no significant difference between $CyO/+$ sibling values. $Df(2L)/+$ values were compared to the sibling $CyO/+$ values using a t-test.

Intensity of gene inactivation is proportional to the fraction of salivary gland chromosomes in which the variegating gene locus has been heterochromatinised[14]. Our results implicate histone proteins as agents of heterochromatinisation. The role of Y chromosome heterochromatin in suppressing position–effect variegation can be envisaged as that of a competitor for free histone protein, which would otherwise be available to condense variegating gene loci[2]. Substances which affect the function of histone proteins in chromatin, such as sodium butyrate which inhibits histone deacetylation[15], can also be expected to have an effect on variegating gene expression. Modification of position–effect variegation may be useful property for testing presumptive mutations of histone gene function and multiplicity.

Cis-active control of mouse β-galactosidase biosynthesis by a systemic regulatory locus

Franklin G. Berger & Kenneth Paigen

Department of Molecular Biology, Roswell Park Memorial Institute, Buffalo, New York 14263

Several higher organisms have been reported in which enzyme levels are determined genetically by sites located in close proximity to the corresponding structural genes. In several cases, these sites have been shown to act by controlling the rates of enzyme synthesis[1–4]. *Cis* compared with *trans* action has been tested for those proximate regulatory sites controlling enzymes for which appropriate structural variants exist[2,5–8]. The rate of synthesis of β-galactosidase in mouse tissues is under the control of a regulatory locus, *Bgl-s*, that is tightly linked to the enzyme structural gene[4,9]; we have tested the *cis*/*trans* nature of *Bgl-s* action by analysis of the electrophoretic mobility of the enzyme from animals heterozygous for the appropriate regulatory and structural alleles. Our results indicate that *Bgl-s* acts *cis*, controlling the expression of the structural gene located on the same chromosome.

A genetic complex, termed [*Bgl*], mapping near the *Mod*-1 locus on chromosome 9, contains within it elements governing the structure, development and rate of synthesis of β-galactosidase[4,9–15]. The structural gene *Bgl-e* is defined by an electrophoretic polymorphism which affects the enzyme in all tissues[9].

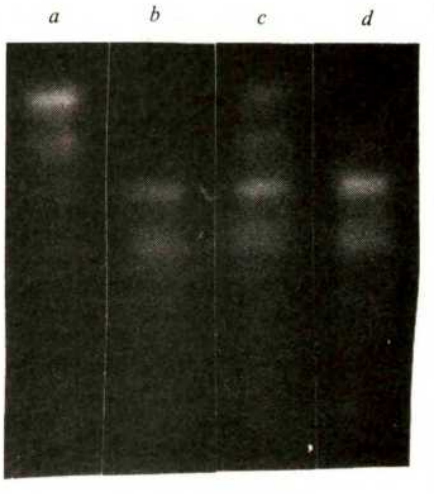

Fig. 1 Mobility patterns for kidney β-galactosidase as observed by enzyme activity stain. Kidneys from the appropriate animals were homogenised in 10 volumes (w/v) of 0.02 M imidazole-Cl, *p*H 7.4, containing 0.25 M sucrose. Homogenates were treated at *p*H 5.0 and 37 °C, and adjusted to a β-galactosidase concentration of 2 U ml^{-1}. Samples were subjected to isoelectric focusing on Ampholine PAG plates (*p*H 3.5–9.5) (LKB) for 2 h at 15 °C; β-galactosidase was stained by incubating the gels for 30 min in 0.1 M sodium citrate, *p*H 4.1, containing 0.05% Triton X-100 and 0.25 mM 4-methylumbelliferyl-β-D-galactoside (Sigma). Bands were observed and photographed under long wavelength ultraviolet light. *a*, Strain C57BL/6J, genotype $Bgl\text{-}e^{b/b}s^{h/h}$; *b*, strain B10.C(47N)/Sn, genotype $Bgl\text{-}e^{a/b}s^{h/h}$; *c*, F_1 (C57BL/6J × B10.C(47N)/Sn), genotype $Bgl\text{-}e^{a/b}s^{h/h}$; *d*, F_1 (B10.C(47N)/Sn × B6.CBA-$Trf^aBgl\text{-}s^d$), genotype $Bgl\text{-}e^{a/b}s^{h/d}$. B10.C(47N)/Sn animals were obtained from Dr M. Cherry, Jackson Laboratory; B6.CBA-$Trf^aBg\text{-}s^d$ animals were obtained from Dr Verne Chapman, Roswell Park Memorial Institute; C57BL/6J animals were purchased from the Jackson Laboratory.

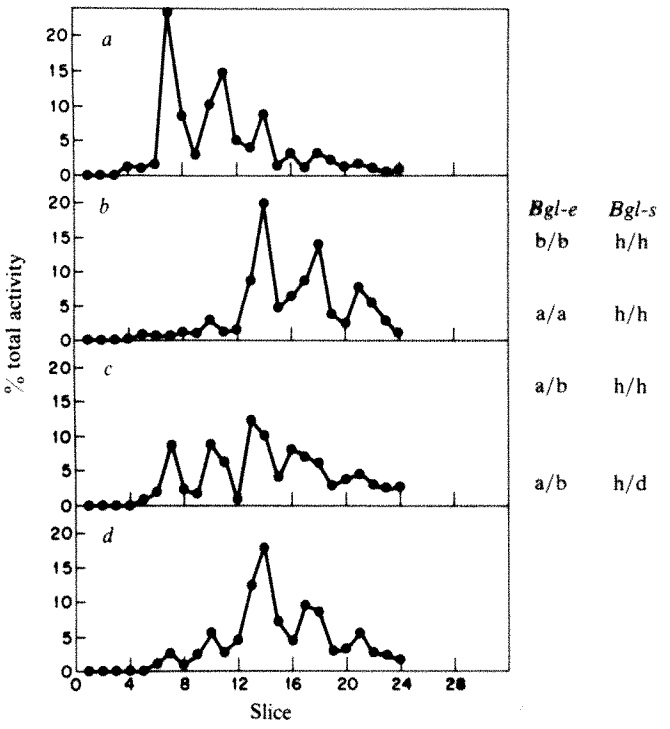

Fig. 2 Mobility patterns for kidney β-galactosidase as observed by direct assay. Kidney homogenates were prepared and isoelectric focusing was performed as described in Fig. 1 legend. After electrophoresis, gels were cut by hand into 2-mm slices, each slice was incubated for 2–4 h in 0.8 ml of 0.1 M sodium citrate containing 0.05% Triton X-100 and 0.25 mM 4-methylumbelliferyl-β-D-galactoside at 37 °C. After addition of 0.6 ml of 1 M sodium carbonate, fluorescence was measured in an Aminco fluorimeter[9]. The percentage of total activity recovered was plotted as a function of the number of slices from the cathode. (*a*), (*b*), (*c*) and (*d*) are the same as in Fig. 1 legend.

The allele coding for the more acidic form is designated *Bgl-e*^{a} and that for the more basic form is designated *Bgl-e*^{b}. A systemic regulatory element, *Bgl-s*, controls β-galactosidase concentration in all tissues at all stages during development[10–12]. It is tightly linked to *Bgl-e* and controls the rate of β-galactosidase synthesis[4]. The high activity allele is designated *Bgl-s*^{h} while the low activity allele is designated *Bgl-s*^{d}. Finally, the developmental programme for β-galactosidase synthesis in liver is genetically controlled by a temporal element within [*Bgl*], termed *Bgl-t*, as well as by one or more elements separate from the complex[4,13,15]. This last aspect of β-galactosidase regulation will not be considered further in this report.

Analysis of the β-galactosidase phenotype in more than 100 inbred mouse strains has made possible identification of three haplotypes of the [*Bgl*] complex[13,15]. The [*Bgl*]^{B6} haplotype, exemplified by strain C57BL/6J, is *Bgl-e*^{b}*s*^{h}; the [*Bgl*]^C haplotype, exemplified by strain BALB/cJ, is *Bgl-e*^{a}*s*^{h}; finally, the [*Bgl*]^{D2} haplotype, exemplified by strain DBA/2J, is *Bgl-e*^{b}*s*^{d}. Table 1 summarises the biochemical and genetic relationships among the three haplotypes. Each haplotype is now available in the C57BL/6J or C57BL/10Sn genetic background, which seem to be equivalent with respect to effects on β-galactosidase expression[15]. The [*Bgl*]^C haplotype of strain BALB/cJ has been transferred genetically into the C57BL/10Sn background to produce congenic strain B10.C(47N)/Sn; similarly the [*Bgl*]^{D2} haplotype of strain CBA/J has been transferred genetically into the C57BL/6J background to produce congenic strain B6.CBA-*Trf*^{a}*Bgl-s*^{d}. The ability to construct animals heterozygous for the appropriate structural and regulatory elements of the [*Bgl*] complex within a constant genetic background allows a test of the *cis* compared with *trans* nature of *Bgl-s* action.

The mobility patterns after isoelectric focusing of kidney β-galactosidase from various animals were determined. Figure 1*a* shows the pattern for animals of strain C57BL/6J, which is homozygous for the [*Bgl*]^{B6} haplotype. The multiple banding pattern represents charge heterogeneity resulting from unknown post-translation events affecting the product of a single structural gene[14,16]. The same pattern is seen in C57BL/10Sn animals, which also carry the [*Bgl*]^{B6} haplotype, and in strains carrying the [*Bgl*]^{D2} haplotype, containing the *Bgl-e*^{b} structural allele. Figure 1*b* shows the mobility pattern for the enzyme from congenic strain B10.C(47N)/Sn, which is homozygous for the [*Bgl*]^C haplotype containing the structural gene coding for the more acidic enzyme. Figure 1*c* shows the enzyme pattern from F_1 progeny of a mating of strains C57BL/6J and B10.C(47N)/Sn; these animals are heterozygous for the [*Bgl*] complex in that they carry the [*Bgl*]^{B6} haplotype on one chromosome and the [*Bgl*]^C haplotype on the other. Because these haplotypes differ only at *Bgl-e* and not at *Bgl-s* (Table 1), the pattern represents equal expression of both structural alleles. Figure 1*d* shows the pattern in F_1 progeny arising from a mating of strains B10.C(47N)/Sn and B6.CBA-*Trf*^{a}*Bgl-s*^{d}; these animals carry the [*Bgl*]^C haplotype on one chromosome and the [*Bgl*]^{D2} haplotype on the other and are therefore heterozygous for both the *Bgl-e* structural and *Bgl-s* regulatory elements of the complex (Table 1). They show predominant expression of the *Bgl-e*^{a} structural type, which is *cis* to the high activity *Bgl-s*^{h} regulatory allele within the complex. Because the relative expression of the two structural alleles in the heterozygote parallels the relative levels in the respective parental strains, the *Bgl-s* genetic element governing these levels acts *cis*.

This conclusion is supported by slicing the gels and assaying the β-galactosidase activity in each slice. Figure 2 shows the results for the kidney enzyme from animals homozygous for the [*Bgl*]^{B6} haplotype (Fig. 2*a*), animals homozygous for the [*Bgl*]^C haplotype (Fig. 2*b*), F_1 heterozygotes carrying both the [*Bgl*]^{B6} and [*Bgl*]^C haplotypes (Fig. 2*c*), and F_1 heterozygotes carrying both the [*Bgl*]^C and [*Bgl*]^{D2} haplotypes (Fig. 2*d*). In the last case, the shift in mobility toward that of the *Bgl-e*^{a} structural type, which is *cis* to the high activity *Bgl-s*^{h} regulatory allele, supports the contention that the *Bgl-s* locus is *cis*-active.

The assignment of the *Bgl-s* element as *cis*-active is qualitative. Quantification of expression of each *Bgl-e* allele in F_1 heterozygotes is complicated by the charge heterogeneity of each allelic product. This heterogeneity, along with the dimeric nature of β-galactosidase in the conditions of these experiments[14], results in a complicated array of overlapping charge forms in *Bgl-e*$^{a/b}$ heterozygotes. This makes accurate determination of the level of expression of each *Bgl-e* allele impossible. Attempts to remove the charge heterogeneity by chemical

treatment (sulphydryl reagents, EDTA, periodate) or enzymatic treatment (neuraminidase, alkaline phosphatase, endoglycosidases) have been unsuccessful (ref. 14; F.G.B., unpublished work). Thus, quantitative measurement of expression of each structural allele must await more elaborate physicochemical techniques.

The lack of information concerning genetic fine structure of the [*Bgl*] region of chromosome 9 makes it difficult to speculate in detail on the mechanism of action of the *Bgl-s* element in regulating the rate of β-galactosidase synthesis. Our finding that *Bgl-s* acts *cis* is consistent with previous hypotheses that *Bgl-s* represents either a germ line change in the number of active β-galactosidase structural genes[11,12], or an alteration in a regulatory element adjacent to the structural gene[11]. Although *Bgl-s* and the structural gene are inseparable by recombination[9], the discordant distribution of the two determinants among inbred strains, as exemplified by the difference between the $[Bgl]^{B6}$ and $[Bgl]^{C}$ haplotypes, suggests that they are not identical sites. However, it has yet to be determined whether the *Bgl-s* site is located within the structural gene or is a closely linked element outside of it.

In summary, the *Bgl-s* locus, which determines the rate of β-galactosidase synthesis and is tightly linked to the structural gene within the [*Bgl*] complex on chromosome 9, seems to act *cis*, regulating the expression of the structural allele located on the same chromosome; it is therefore unlikely that it codes for a diffusible regulatory molecule. Other *cis*-active elements, mapping in close proximity to their respective structural genes, have been identified in higher organisms[2,5–8]. One of these, the *Gus-r* locus controlling androgen induction of β-glucuronidase in mouse kidney, has been shown to act at the level of enzyme synthesis[2]. The *Bgl-s* locus is interesting in that it is the first systemic regulator of enzyme synthesis for which *cis/trans* action has been testable.

This study was supported in part by USPHS grant GM-19521. We thank Drs M. Cherry and V. Chapman for mice.

During normal human fetal development, two γ-globin genes are expressed to give γ-globin chains, one of which contains an alanine residue and the other a glycine residue at amino acid position 136 ($^{A}\gamma$ and $^{G}\gamma$, respectively)[1]. Recently, a human γ-globin chain mutant has been described in $HbF_{Sardinia}$ in which threonine replaces isoleucine at position 75 (ref. 2). This haemoglobin is frequently found in varying levels in Italian patients with β-thalassaemia (29 out of 32 patients), and in normal fetal cord blood in some populations (9 out of 19)[3]. In England the proportion of infants expressing this variant (usually at low levels but [illegible] **to 40% of the total fetal globin). Using the techniques of restriction enzyme analysis, we have recently studied the number and arrangement of γ-globin genes in humans. The map obtained is shown in Fig. 1. There are two γ-globin genes per haploid genome, separated by 3.5 kilobases. Each gene is split into at least two segments by an intervening sequence (intron)[10] at some position along the DNA coding for amino acids 100–121, the same position as for the human β- and δ-globin genes[3]. Other investigators[11,12] have also shown by molecular cloning that the $^{A}\gamma$-globin gene has two introns at precisely the same positions as those in the human β-globin gene. In our previous study[9], we had no information on the level of expression of $HbF_{Sardinia}$ in the individuals studied. Therefore, we still did not know whether the gene specifying the so-called $^{T}\gamma$ chain was a polymorphism of γ-globin gene number within the human population or whether the $^{T}\gamma$-globin gene was allelic

Table 1 Samples used in the study of γ-globin gene number in Mediterranean populations

Description	Origin	DNA sample source	Level of $HbF_{Sardinia}$
1. Normal	Dutch	Placenta	Unknown
2. Normal	British	Placenta	Unknown
3. Normal	Dutch	Cord blood	0%
4. Normal	Dutch	Cord blood	20%
5. Lepore	Southern Italy	Spleen	0%
6. β^0 thalassaemia	Southern Italy	Spleen	0%
7. β^+ thalassaemia	Northern Italy	Spleen	8%
8. β^0 thalassaemia	Sardinia	Spleen	20%
9. β^0 thalassaemia	Italy	Spleen	20%
10. β^+ thalassaemia	Southern Italy	Spleen	25%
11. β^0 thalassaemia	Northern Italy	Spleen	30%

The proportion of $HbF_{Sardinia}$ in cord blood samples of normal humans and peripheral blood samples of thalassaemia patients was estimated by separation of γ chains by CM-cellulose chromatography and subsequent tryptic digestion as detailed in ref. 17.

with either the $^{A}\gamma$- or $^{G}\gamma$-globin gene, the two genes defined on the map we obtained[9]. The techniques of restriction enzyme site mapping[13] allow a simple test for this possibility.

We have made DNA from the spleens of seven β-thalassaemics and two non-thalassaemics with known levels of $HbF_{Sardinia}$ in their peripheral blood. The various samples used are detailed in Table 1. We have analysed the γ-globin gene region of these DNA samples. Briefly, this analysis involves digestion of the DNA with restriction endonucleases, denaturation and separation of DNA fragments according to size by electrophoresis on 1.0% or 1.2% agarose gels, transfer of DNA from gel to nitrocellulose filter sheets by 'blotting' according to the method of Southern[13], and detection of the fragments containing γ-globin gene sequences by hybridisation with ^{32}P-labelled pHγGl and subsequent autoradiography. pHγGl is a pCRI recombinant plasmid which contains a fragment of 500 base pairs of double-stranded $^{G}\gamma$-globin cDNA prepared from mRNA γ (ref. 14).

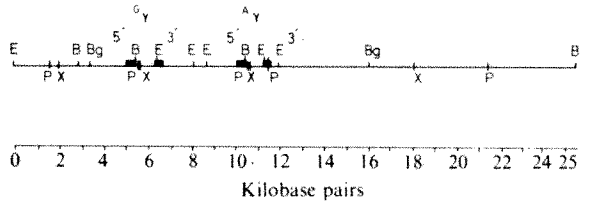

Fig. 1 The physical map of the human fetal globin genes. The position of each gene is marked by a filled box. Note that only those restriction enzyme sites that generate fragments containing part or all of the γ-globin genes are shown on this map. Although the genes are shown as split by a single intron, it is not possible to exclude the existence of further, small, introns in the $^{G}\gamma$-globin gene. The small intron in the $^{A}\gamma$-globin gene is not shown. The map is derived from ref. 9. E, *Eco*RI; B, *Bam*HI; Bg, *Bgl*II; P, *Pst*I; X, *Xba*I.

We have examined the γ-globin fragment patterns generated by *Eco*RI for all the samples in Table 1, and have also used the enzymes *Bgl*II, *Bam*HI (samples 3, 4, Table 1) and *Kpn*I (samples 5–11, Table 1). In all cases the size and number of fragments are identical to those given in Table 2, generated from normal individuals (samples 1, 2) shown previously to contain only two γ-globin genes per haploid genome[9]. These data strongly suggest that there are only two γ-globin genes per haploid genome present in individuals expressing $HbF_{Sardinia}$. An alternative explanation would be that a third γ-globin gene exists coding for the '$^{T}\gamma$' chain, but that in each digest it is present on a DNA fragment which co-migrates with one of the $^{A}\gamma$- or $^{G}\gamma$-globin gene fragments. We consider this unlikely; the fragment pattern is the same for DNA digested with four enzymes, whether they give separate $^{A}\gamma$ and $^{G}\gamma$ pieces (*Eco*RI and *Bam*HI), a fragment bridging the $^{G}\gamma$- and $^{A}\gamma$-globin genes (*Bam*HI), a fragment containing both genes (*Bgl*II) or a fragment containing the entire $^{G}\gamma^{A}\gamma\delta\beta$ complex (*Kpn*I, see ref. 15). The only reasonable objection to this would be a reduplication of the $^{G}\gamma^{A}\gamma\delta\beta$ locus; this is inconsistent with the available evidence on the inheritence of β-globin variants.

It could be argued that a putative $^{T}\gamma$-globin gene would not cross-hybridise well with the $^{G}\gamma$ cDNA plasmid probe used here due to extensive third position codon changes in the coding sequences. It would then be possible to miss new $^{T}\gamma$-globin gene-specific fragments because they would not be stable in the washing conditions used. To eliminate this possibility, *Eco*RI digests of three DNA samples from β-thalassaemic patients with 0%, 8% and 20% $HbF_{Sardinia}$, and DNA from a non-thalassaemic control known to contain only two γ-globin genes were hybridised with pHγGl and the filters subjected to increasingly stringent salt washes ranging from 3 × SSC (SSC = 0.15 M NaCl, 0.015 M Na citrate) to 0.01 × SSC at 65 °C (Fig. 2). Washing of filters at low salt concentrations (in this case, 0.1 × SSC) causes mismatched hybrids to melt, and as a result only hybrids between γ-globin gene sequences (both $^{A}\gamma$ and $^{G}\gamma$) and the γ cDNA plasmid probe are seen. Filters washed only with high salt (greater than 0.1 × SSC) show heterologous hybridisation (for example, with the β-globin gene sequences) in addition to the $^{A}\gamma$- and $^{G}\gamma$-globin gene hybridisation. In all conditions, the γ-globin gene-specific fragments seen are identical. This demonstrates that no third globin gene distantly related to that coding for $^{G}\gamma$-globin exists in persons expressing $HbF_{Sardinia}$ which would be absent in those people not expressing this protein.

The gene coding for the γ-globin chain of $HbF_{Sardinia}$ must, therefore, be allelic with either the $^{A}\gamma$- or the $^{G}\gamma$-globin gene. There is evidence[16,17] that the threonine residue at position 75 is present only in γ-globin chains that contain alanine at position 136 and we therefore conclude that the γ-globin chain of $HbF_{Sardinia}$ is an allele of the $^{A}\gamma$ gene.

The high level of occurrence of $HbF_{Sardinia}$ remains to be explained. In one study[3], the incidence of $HbF_{Sardinia}$ in β-thalassaemics in Italy was 90%, compared with only 40% in normal Italians. It is possible that the $HbF_{Sardinia}$ mutation is in linkage disequilibrium with either the β-thalassaemic gene or some other gene. It is not known whether the Ile 75 → Thr 75 substitution in $HbF_{Sardinia}$ alters the physiological properties of the haemoglobin molecule. It is therefore impossible to distinguish between mechanisms of selection, drift or linkage disequilibrium in accounting for the high frequency of this haemoglobin molecule. Indeed, the presence of the fixed mutations in $^{A}\gamma$ and $^{G}\gamma$ in the otherwise identical γ-globin chains seems to be an earlier example of a similar phenomenon.

As duplicated γ-globin genes have been demonstrated in the pig-tailed macaque (*Macaca nemestrina*)[18], orang-utan, gorilla and chimpanzee[19,20], we conclude that the duplication occurred at least 30 Myr ago[21]. It is remarkable that the two γ-globin genes have remained so similar during this time; some mechanism may exist to maintain sequence homology between these two genes.

Unequal cross-over events have been invoked to explain the conservation of multi-copy genes such as those for ribosomal RNAs[22–24]. This involves a contraction/expansion of gene numbers by unequal cross-over events and re-amplification by a further cross-over between two gene families of different sizes. In contrast to the ribosomal RNA genes, the only simple way in which a single γ-globin gene may be amplified is by a cross-over with a chromosome containing three γ-globin genes. This makes unequal cross-over a less attractive mechanism for sequence conservation. In addition, data on 810 humans showed that none of them synthesised only $^{A}\gamma$- or only $^{G}\gamma$-globin chains[25]. These experiments were not designed to detect 'heterozygotes' in which one chromosome had duplicated γ genes and the other had only a single γ-globin gene. From these data we calculate that the frequency of chromosomes carrying only a single γ-globin gene is less than 0.06 ($P = 0.05$).

It would be interesting to examine a large number of $HbF_{Sardinia}$ γ-globin chains at position 136. If there is a mechanism for spreading mutational changes between the $^{A}\gamma$

Table 2 Sizes of DNA fragments containing γ-globin genes generated by four restriction endonucleases

Enzyme	Fragment sizes (kilobase pairs)
*Bam*HI	15, 5.0, 2.6
*Eco*RI	6.5, 2.5, 1.65, 0.65
*Bgl*II	13
*Kpn*I	46

The human DNA used has been shown by restriction endonuclease mapping to contain only two γ-globin genes per haploid genome[17]. The relative positions of each fragment are as given in Fig. 1 or ref. 15.

and $^{G}\gamma$ genes it would be predicted that γ^{75Thr} should be found associated with γ^{136Gly}. The frequency of this occurrence would be an indicator of the rate of exchange of genetic information between $^{A}\gamma$ and $^{G}\gamma$. A precise study of the $HbF_{Sardinia}$ mutation would provide an interesting insight into mechanisms of gene conservation.

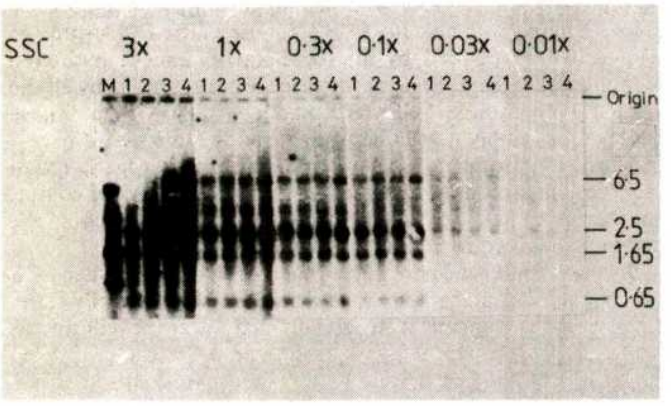

Fig. 2 The pattern of γ-gene fragments generated by *Eco*RI. DNA digestion, gel electrophoresis and hybridisation were carried out as in ref. 17. After hybridisation, duplicate filters were washed in various concentrations of SSC buffer (1 × SSC is 0.15 M NaCl, 0.015 M Na citrate, *p*H 7.5, 0.1% (w/v) SDS). The weakly hybridising bands at approximately 4–5 kilobases are due to cross-hybridisation between the γ-globin probe and β- and ε-globin gene sequences. Samples used expressed different levels of $HbF_{Sardinia}$: 1, 20%; 2, 8%; 3, 0%; 4, control DNA; and correspond, respectively, to samples 5, 7, 8 and 2 in Table 1. Sizes are in kilobases.

We thank Dr Alec Jeffreys for helpful discussions, and Caroline Rogers for help with the manuscript. This work was supported by grants to R.W. from the MRC and NIH (1RO1AM20125-01A1), and to R.A.F. from the Netherlands Foundation for Chemical Research (SON) with financial aid from the Netherlands Organization for the Advancement of Pure Science (ZWO). A grant from NATO made the collaboration possible.

Relationships between sister chromatid exchange and mutagenicity, toxicity and DNA damage

Matthews O. Bradley*, Ih Chang Hsu & Curtis C. Harris

Human Tissue Studies Section, Laboratory of Experimental Pathology, National Cancer Institute, Bethesda, Maryland 20205

Reciprocal exchanges of DNA in sister chromatids (SCEs) are induced by various carcinogens and mutagens[1–5], although the quantitative relationship between the number of mutations and SCEs induced varies among chemicals[5]. Nevertheless, the analysis of SCE production by various agents is often proposed as a sensitive and quantitative assay for genetic damage of the sort leading to mutation and cancer. In V-79 Chinese hamster cells we have been measuring DNA damage by alkaline elution, mutation induction as detected by 6-thioguanine resistance, and cytotoxicity as detected by colony formation for different physical and chemical agents. Some of the agents produced varying forms of DNA damage but undetectable increases in either mutation or toxicity. We report here that some undetectably mutagenic and/or toxic agents produce increases in SCE frequency and that DNA single-strand breaks, DNA–DNA interstrand cross-links, and DNA–protein cross-links are not necessary for SCE.

The toxic, mutagenic and DNA-damaging properties of the agents used here are summarised in columns (1)–(7) of Table 1. All the data in Table 1 were obtained from the same line of V-79-4 previously described[6,7]. Toxicity was measured by the loss of cell plating efficiency[6,7], mutation was measured as resistance to 6-thioguanine[6,7] over a complete dose range that inactivated up to 90% of the cells, and DNA single-strand breaks, DNA–protein cross-links and DNA–DNA cross-links were measured by alkaline elution[8–10]. Both *cis*- and *trans*-Pt(II) diammine dichloride (PDD) make DNA–DNA and DNA–protein cross-links, but the *cis* isomer is highly mutagenic in a dose-dependent manner whereas the *trans* isomer is not detectably mutagenic over a dose range of 25–450 μM (ref. 8). Both the fluorescent lamp and the sunlamp cause mutation and toxicity as well as DNA single-strand breaks and DNA cross-links[6,10,11]. If a filter of *p*-aminobenzoic acid is placed between the lamps and the cells, only light of wavelength >345 nm passes through to the cells. At the doses used, this light produced DNA single-strand breaks and DNA–protein cross-links but no detectable mutation or toxicity[10]. Hydrogen peroxide produces both toxicity and DNA single-strand breaks but is not detectably mutagenic even at doses up to 530 μM (ref. 12).

In these experiments the doses of the toxic agents were chosen to give approximately 10–45% survival (exact value given in Table 1). The SCE frequency was measured in V-79 cells by the technique described by Perry and Wolff[13]. Two flasks of the V-79 cells (5×10^5 cells per 25-cm^2 flasks in log growth) in each group were treated with the doses shown in Table 1. Immediately after treatment the medium was changed to one containing 10 μM bromodeoxyuridine. The cells were kept at 37 °C in the dark for two cycles of DNA replication before treatment with colcemid (0.1 μg ml^{-1}). Preliminary growth curves were first measured to determine the time after treatment for two population doublings to occur. The mitotic cells were collected by trypsinisation 2 h after the start of colcemid treatment. Drops of cells in fixative were placed on clean microscope slides and allowed to dry in air. The air-dried preparations were stained by the fluorochrome plus Giemsa procedure[13] and scored for SCE by one person who had no prior knowledge of the treatments. At least 60 metaphases were scored for each treatment group.

The results of the SCE measurements are shown in columns (8) and (9) of Table 1. The statistical significance of the results was determined by the Wilcoxon rank sum test[14], a non-parametric method of analysis. *trans*-PDD, which is not detectably mutagenic, produces almost as many SCEs as does the highly mutagenic *cis*-PDD. As neither of these drugs produce DNA single-strand breaks, SCEs must be due to some other lesion, such as DNA–DNA and/or DNA–protein cross-links (Table 1). Although approximately equal numbers of SCEs are made by the two drugs at these concentrations, *trans*-PDD produces approximately 20-fold higher levels of DNA–protein cross-linking than does *cis*-PDD but equal numbers of DNA–DNA cross-links[8]. Therefore, in this instance, a closer quantitative relationship exists between DNA–DNA cross-links and SCEs than between DNA–protein cross-links and SCEs.

The radiation emitted from the sunlamp (General Electric 275-W sunlamp) produces many SCEs in V-79 cells (Table 1). The radiation was filtered with 3 cm of a 5-g l^{-1} solution of potassium hydrogen phthalate to allow only wavelengths >305 nm to pass through. The sunlamp has a broad emission spectrum in the near UV and visible regions, with peaks at the mercury emission lines[15]. In these conditions, the sunlamp causes mutagenicity, toxicity, DNA–protein cross-links and DNA single-strand breaks[10,11]. However, when a second filter of *p*-aminobenzoic acid is used to block wavelengths below 345 nm, the sunlamp radiation is no longer either mutagenic or toxic, but still producesce numbers of SCEs. Thus, SCEs can be formed in conditions that produce neither detectable toxicity nor mutagenicity.

The fluorescent lamp radiation induces small but significant ($P < 0.01$) increases in SCE frequency (Table 1). The *p*-aminobenzoic acid filter reduces the mutagenicity and toxicity of the light to undetectable levels whereas the number of SCEs is slightly decreased although still significantly higher than the controls ($P < 0.05$). Again, toxicity and mutagenicity are not correlatedhq SCE frequency.

Hydrogen peroxide produces toxicity and large numbers of DNA single-strand breaks but no detectable mutagenicigi[2]. Nevertheless, it causes significant increases in the SCE frequency, as seen in Table 1.

All the agents except *cis*- and *trans*-PDD make single-strand breaks and/or alkali-labile lesions in DNA. These platinum compounds produce the greatest increase in the frequency of SCEs, so single-strand DNA breaks are not required for SCE production. Hydrogen peroxide and both the filtered and unfiltered fluorescent lamp and sunlamp make SCEs but no detectable DNA–DNA cross-links, suggesting that these lesions are not uniquely involved in SCE formation. The DNA–protein cross-link is produced by all these agents except hydrogen peroxide. Therefore, none of the three lesions is made by all the agents, even though SCEs are made by all of them. These observations imply that none of the lesions examined is necessary for SCE production, although each of them, together with other lesions, could be sufficient for SCE formation. Of course, another lesion(s), not measured in these studies, could be uniquely involved in SCE formation.

The data presented here imply that correlations between SCE frequency and mutagenicity or toxicity are not necessarily close. Although it is difficult to be certain that an agent will not be weakly mutagenic in any conditions, nevertheless, given the limitations of the V-79 assay, four of the treatments in Table 1 are not detectably mutagenic but increase SCE frequencies. Resistance to 6-thioguanine as an assay for mutant colonies should score for many kinds of genetic or epi-genetic alterations in the enzyme hypoxanthine–guanine phosphoribosyl transferase. Although other genetic markers might give different quantitative results, we suggest that the qualitative conclusions would be similar.

The findings that *trans*-PDD and the filtered sunlamp cause large increases in SCE but no detectable mutagenicity suggest that the lesions causing SCEs in these cases differ from those causing 6-thioguanine-resistant mutations. Toxicity and SCEs are not necessarily correlated, as previously suggested by Wolff *et al.*[4], because the filtered sunlamp and fluorescent lamp both increase SCE frequency but are not detectably toxic.

Recent work by Kinsella and Radman[16] supports our contention that increased SCE frequency is not necessarily equivalent

Table 1 Relationships between sister chromatid exchanges, mutagenicity, toxicity and DNA damage

Agent	Quantity of agent	% survival (±s.e.m.)	Mutant frequency relative to control*	DNA Single-strand breaks and/or alkali-labile lesions†	DNA–Protein cross-links†	DNA–DNA cross-links†	SCEs per chromosome (±s.e.m.) Control	–	100 ± 4.8	1	–	–	–	0.351 ± 0.23	–	–
trans-Pt (II) diammine dichloride	250 μM	16 ± 1.0	1	±‡	++	+	2.911 ± 0.131	$P < 0.01$	8
cis-Pt (II) diammine dichloride	10 μM	11 ± 0.5	40	–	+	+	3.960 ± 0.200	$P < 0.01$	8
GE 275-W sunlamp	2.4×10^5 Jm^{-2}	45 ± 3.6	23	++	+	–	1.772 ± 0.135	$P < 0.01$	10,11
Sunlamp plus *p*-amino benzoic acid filter	1.8×10^5 Jm^{-2}	100 ± 5.4	1	+	+	–	1.556 ± 0.139	$P < 0.01$	10,11
Sylvania F15T8 cool white fluorescent lamp	5.9×10^4 Jm^{-2}	35 ± 3.2	53	++	+	–	0.580 ± 0.034	$P < 0.01$	6,10
Fluorescent lamp plus *p*-aminobenzoic acid filter	$3.2. \times 10^4$ Jm^{-2}	100 ± 3.2	1	+	+	–	0.452 ± 0.019	$P < 0.05$	6,10
Hydrogen peroxide	353 μM	20 ± 1.6	1	++	–	–	0.616 ± 0.048	$P < 0.01$	12

Per cent survival was determined as the decrease in plating efficiency relative to the controls. The control plating efficiency varied between 75 and 95%.

* The numbers are the mutant frequency of the experimental group divided by the mutant frequency of the controls. Mutant frequency is defined as the number of colonies resistant to 6-thioguanine per survivor in appropriate expression and selection conditions as previously described[6,7]. 1 Indicates that the treatments were not detectably mutagenic as defined by the lack of a dose–response relationship. The mutant frequencies of the various controls were within the limits of $1.3 \pm 0.9 \times 10^{-6}$.

† The symbols are: –, no lesions detectable; ±, barely detectable lesions; +, small numbers of lesions; ++, large numbers of lesions.

‡ The quantitative significance of the small number of apparent breaks has not been determined.

to increased mutant frequency. These workers have shown that the non-mutagenic tumour promoter, 12-*O*-tetradecanoyl-phorbol-13-acetate (TPA) induces SCEs, whereas the non-promoting derivative 4-*O*-methyl TPA does not. Further support comes from the finding that saccharin also induces SCEs in both hamster and human cells[17], although it is considered to be non-mutagenic[18,19]. From these and our own results, we conclude that, although the analysis of SCEs can often be very useful, definitive interpretations of SCE data await a molecular mechanism for their formation.

The role of contractile proteins in the structural organisation of the interphase nucleus and of metaphase chromosomes is largely unknown. Actin has been found in interphase nuclei of different species, especially in association with condensed chromatin[1–6]. In the germinal vesicle (nucleus) of *Xenopus* oocytes, actin has been localised in the nuclear gel supporting the chromosomes and the extrachromosomal nucleoli[7–10]. It has been reported that the premeiotic lampbrush chromosomes in these germinal vesicles are positively stained for actin and tubulin by the immunoperoxidase technique[11]. Moreover, the longitudinal contraction of these chromosomes is ATP dependent[12]. Therefore it has been suggested that actin participates in the structural organisation of the highly specialised lampbrush chromosomes. However, actin is not a major component of the metaphase chromosome scaffold[13]. The results reported here suggest that actin is involved in the condensation of *Xenopus* chromosomes.

We studied chromosome condensation and meiotic spindle formation in the presence of antibodies directed against actin and myosin in maturing oocytes of *Xenopus laevis*. Affinity purified human anti-actin antibodies (AAA), characterised elsewhere[14,15], and a γ-globulin fraction from rabbit serum containing antibodies against human uterine myosin (AMA)[16] were injected into the cytoplasm or into the germinal vesicle of fully grown oocytes. As a control, we injected nonspecific human or rabbit γ-globulins. The injection technique has been described in detail elsewhere[17]. Progesterone was added to induce *in vitro* maturation[18]. The hormone treated oocytes undergo breakdown of the germinal vesicle and the first meiotic division, and then remain arrested in the second meiotic metaphase. The eggs were fixed, embedded in paraffin, cut

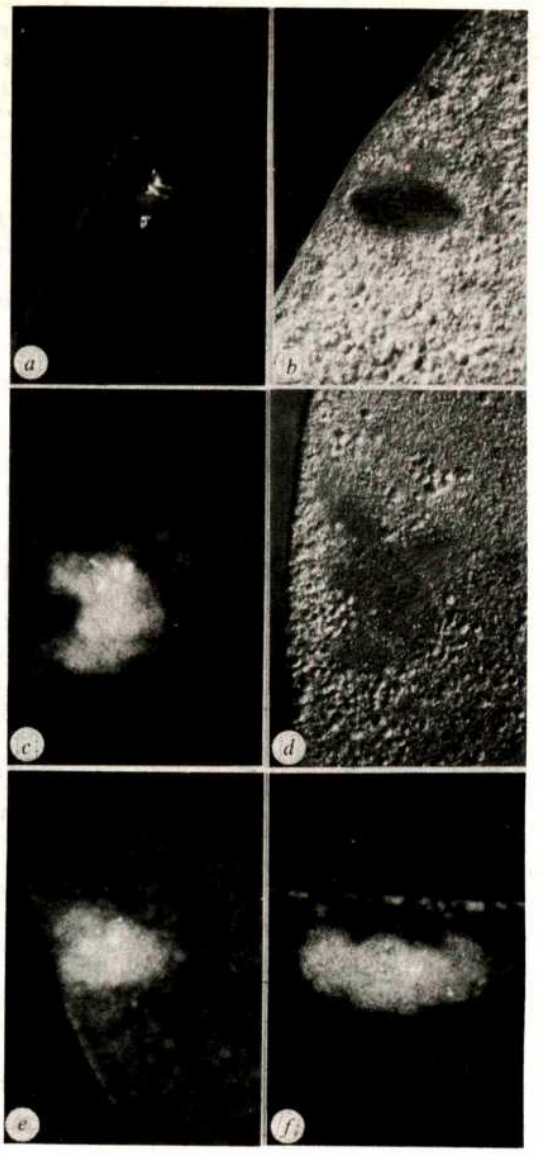

Fig. 1 Effect of AAA injection into the germinal vesicle of *Xenopus* oocyte on chromosome condensation and spindle formation. Fully grown *Xenopus laevis* oocytes were centrifuged[19] (400*g*, 10 min, allowing nuclei to sink back into the cytoplasm after injection) and injected intranuclearly with 20 nl of injection buffer containing 0.4 mg per ml of either AAA or nonspecific human γ-globulins (Fluka) equivalent to 8 ng of proteins per nucleus. After 1 h, 10^{-5} M progesterone was added to induce meiosis. Oocytes showing a distinct white spot indicative of maturation were fixed in Smith's solution[20], dehydrated in butanol, embedded in paraffin, cut into 6-μm thick serial sections, stained by the Feulgen technique and counterstained with light green. *a*, Fluorescence micrograph at wavelength 546 nm to demonstrate Feulgen-positive chromosomes in metaphase of an egg injected with nonspecific γ-globulins. Condensed chromosomes are normally organised on the spindle. *b*, Nomarski differential interference microscopy of the same field; the spindle appears normal. *c*, Fluorescence micrograph of Feulgen-positive material in a meiotic metaphase of an egg injected with AAA. Chromatin appears as a loosely arranged large spot with dense bodies scattered between. Note the positivity in the areas corresponding to asters. *d*, Nomarski differential intereference microscopy of the same field as in (*c*); asters are present but the spindle is disorganised. *e*, And *f*, fluorescence microscopy of other examples of loose chromatin in meiotic metaphases of eggs after injection of AAA (×700).

serially and stained by the Feulgen technique. Our experimental system, which thus facilitates cytological observation of chromosome condensation and spindle formation, is described in detail in the legend to Fig. 1.

Centrifuged oocytes injected with nonspecific human or rabbit γ globulins into either the cytoplasm or the nucleus produced normal meiotic spindles in three series of experiments. After nuclear injection of nonspecific γ-globulins, seven normal spindles were found in eight cases (Fig. 1*a* and *b*), the remaining egg having probably lost its spindle and chromatin through the injection hole—no Feulgen-positive material was found on any of the serial sections. In a few cases, we observed anaphase or telophase of the first meiotic division instead of second metaphase. This does not influence the observation of chromosome condensation because there is no despiralisation of chromosomes between the two meiotic divisions. These observations show that normal meiosis takes place in the oocytes after chemical defolliculation, centrifugation and nuclear injection of nonspecific human or rabbit γ globulins.

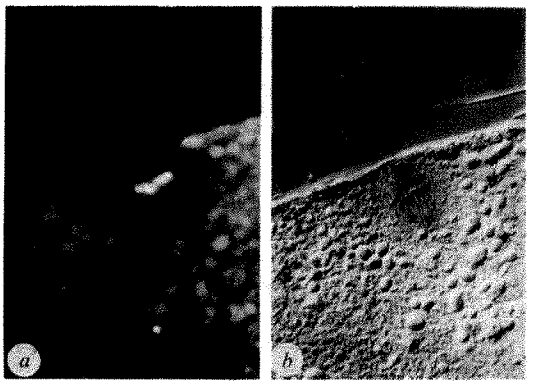

Fig. 2 Normal meiotic metaphase after injection of AMA into the nucleus of a *Xenopus* oocyte. Techniques are explained in the legend to Fig. 1. Nuclei were injected with 20 nl of injection buffer containing 2 mg per ml AMA γ-globulin fraction (DE 52 cellulose column) equivalent to 40 ng of proteins per nucleus. *a*, Fluorescence micrograph showing condensed Feulgen-positive chromosomes normally organised on the spindle. *b*, Nomarski differential interference microscopy of the same field; the spindle appears normal (×700).

Injection of AAA into the cytoplasm did not affect germinal vesicle breakdown, chromosome condensation or spindle formation, although three times more AAA was injected than into the nucleus. In all five cases, normally condensed chromosomes were observed, associated with normal spindles.

By constrast, the injection of AAA into the germinal vesicle of the oocyte severely affected chromosome condensation. In none of the 11 oocytes examined from three independent series were normal meiotic metaphase chromosomes formed. In all nine cases where chromatin was found in the sections, it was loosely arranged but in part associated with spindle asters. Figure 1*c–f* shows examples of the deficient chromosome condensation in the presence of intranuclear AAA. No effect on normal meiotic metaphase formation was observed after injection of rabbit γ-globulins containing AMA into the nucleus (Fig. 2).

These results show that in our experimental conditions, AAA, but not AMA, affected chromatin condensation when injected into the germinal vesicle of *Xenopus* oocytes. The lack of effect of AMA does not necessarily mean that myosin does not have a role in chromosome condensation. Alternatively, we could have used insufficient AMA, nuclear *Xenopus* myosin could be antigenically different from human uterine myosin, or the binding of AMA to myosin may not affect the activity of the protein in this respect. We do not know the mechanism of the inhibitory action of AAA on chromosome condensation. Since AAA are precipitating antibodies[15], it is possible that they precipitate out the amount of protein that is instrumental in chromosome condensation.

After intracytoplasmic injection of AAA, metaphase spindles looked normal, perhaps because the nuclear envelope acted as a barrier—chromosome condensation probably starts before germinal vesicle breakdown. Moreover, large quantities of cytoplasmic actin could bind to the injected AAA and block their activity.

Actin and myosin have been described as constituents of the mitotic spindle[21–25]. In our experiments, mitotic spindle formation was perturbed after intranuclear injection of AAA (Fig. 1*d*). However, asters were formed and small portions of the loose chromatin were found closely associated with the aster fibres (Fig. 1*c*). These experiments thus do not elucidate the possible role of actin in the attachment of chromosomes to spindle fibres and in spindle pole formation.

At any rate, our results suggest that actin is involved in chromosome condensation. Further work is needed to clarify whether actin exerts its influence by being an integral component of the prophase chromosome structure.

Mouse epidermal Ia molecules have a bone marrow origin

John G. Frelinger*, Leroy Hood*, Sharon Hill† & Jeffrey A. Frelinger†

* Division of Biology, California Institute of Technology, Pasadena, California 91125
† Department of Microbiology, University of Southern California Medical School, Los Angeles, California 90033

The major histocompatibility or H-2 complex of the mouse is divided into five regions (K, I, S, G and D)[1]. Genes in the I region regulate immune responses[2]. The I region has several subregions which are designated I-A, I-B, I-J, I-E and I-C. The I-A and I-E subregions also code for a set of serologically detected cell-surface alloantigens, designated Ia antigens[3]. The relationship between the genes regulating the immune

0028/0836/79/460322—02$01.00

© 1979 Macmillan Journals Ltd.

response and those encoding the serologically detectable alloantigens is still unknown. A number of species including man, rats and guinea pigs contain genetic regions apparently equivalent to the murine I region. Ia molecules are integral cell-surface glycoproteins that consist of two subunits of approximate molecular weights 35,000 (α) and 28,000 (β). Unlike the classical transplantation antigens which are present on almost all cells, the Ia antigens are found primarily on cells of the immune system—lymphocytes and macrophages[4–6]. A notable exception has been the demonstration of Ia antigens in mice, or Ia-like antigens in other mammals, on epidermal cells[6–13]. There is controversy about the numbers of Ia-positive cells in the epidermis. Fluorescence studies in humans[11,12], guinea pigs[14] and mice[15] indicate that only about 5% of epidermal cells are Ia positive. These cells were identified by morphological criteria as the macrophage-like Langerhans cells. However, cytotoxicity studies in mice using anti-Ia sera indicate that a majority of epidermal cells (up to 90%) are Ia positive[6–8]. The reason for this discrepancy is not known. Here we demonstrate that the epidermal Ia molecules are synthesised by bone marrow-derived cells, presumably Langerhans cells.

We replaced the entire population of bone marrow-derived cells in one animal with bone marrow cells from a second animal capable of synthesising Ia molecules distinct from the first. These chimaeric animals are constructed by the injection of donor bone marrow cells into lethally irradiated recipients. In chimaeric animals all cells except those of bone marrow origin are of the recipient genotype. We reasoned that if the Ia molecules synthesised in epidermal cell preparations (mouse tail cells) are synthesised by bone marrow-derived cells, the Ia molecules isolated from long-term (>3 months) chimaeras should be of donor origin. Alternatively, if the Ia molecules are synthesised by a majority of epidermal cells, the Ia molecules should be of recipient origin.

Table 1 Source of haematopoietic cells in chimaeric mice

(B10×1R)F_1	>640 (>90)	NT	320 (>90)	NT

Chimaeras were produced as described by Von Boehmer[20]. Mice were irradiated with 925 rads from a linear accelerator and reconstituted with $1–2\times10^7$ anti-mouse brain ($\alpha\theta$) plus complement-treated bone marrow cells. Mice were tested for chimaerism after 3 months. NT, not tested.

*Tested by dye exclusion microcytotoxicity on peripheral blood leukocytes. Numbers represent reciprocal of the antiserum dilution giving 50% killing of targets and in parentheses, the maximum attainable killing. Sera for cytotoxicity: anti-H-2.33 (A×B10.D2)F_1 anti-B10.A(5R); anti-H-2.23, (B10×A.TL)F_1 anti-A.AL.

†Tested by polyvinylpyrrolidone (PVP) haemagglutination of red blood cells. Number represents the reciprocal of the greatest antiserum dilution which permits detectable agglutination reaction. Sera for haemagglutination: anti-H-2.2, (A×B10.D2)F_1 anti-B10.A(2R); anti-H-2.4, (B10.A(1R)×A.SW)F_1 anti-B10.A.

Our experimental design requires almost complete replacement of recipient bone marrow-derived cells with donor cells. Direct tests confirmed that this had occurred (Table 1). Two types of chimaeric animal were constructed: parental (P) cells were transplanted to F_1 offspring (P→F_1) and vice versa (F_1→P). For the P→F_1 chimaeras, the analysis of bone marrow-derived cells used cytotoxicity and haemagglutination assays. In the case of the F_1→P chimaeras, the donor cells in the recipient were measured by haemagglutination. In both cases, the results indicated that the haematopoietic system was almost completely reconstituted with donor cells (Table 1).

We isolated epidermal Ia molecules by indirect immunoprecipitation using mouse alloantisera as previously described[10]. The specificity of the antisera is critical in determining whether the Ia is contributed by donor or recipient cells in these chimaeras. The sera were characterised extensively by cytotoxicity, absorption and immunoprecipitation (data not shown). They were tested on strains identical to those used in these experiments to demonstrate unequivocally that the observed reaction was specific for recipient or donor strains. An F_1 animal

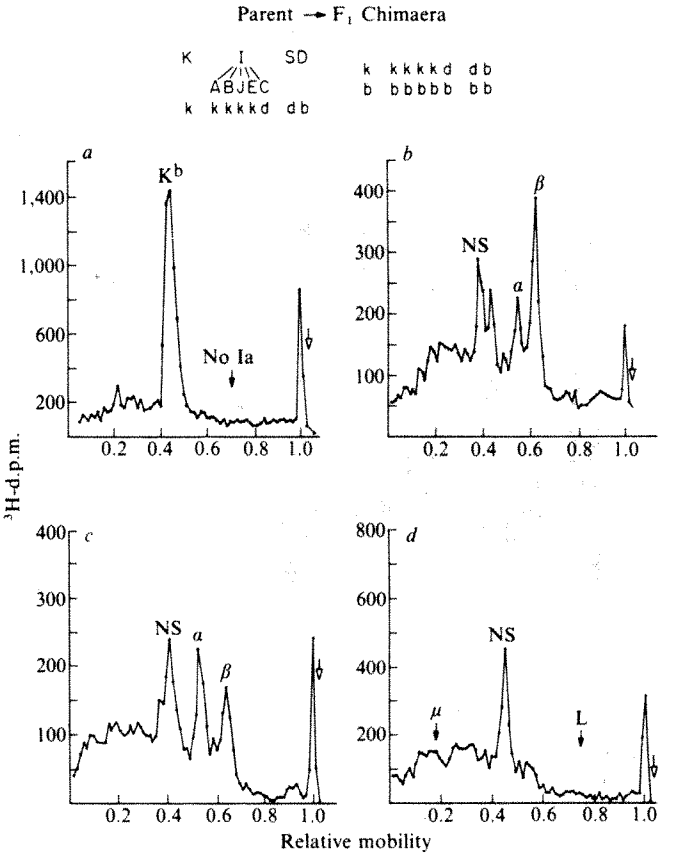

Fig. 1 SDS-polyacrylamide gel electrophoresis of epidermal Ia molecules isolated from parent→F_1 bone marrow chimaeras. Epidermal Ia was isolated as previously described[10]. Briefly, single cell suspensions of trypsinised epidermal cells were biosynthetically labelled with ^{3}H-amino acids and lysed in 0.5% NP40. The glycoprotein fraction was isolated by *Lens culinaris* lectin affinity chromatography, concentrated fivefold in a B-15 Minicon, and indirectly immunoprecipitated with specific antisera and fixed *Staphylococcus aureus* (Cowan I strain). The parent→F_1 chimaera extracts were precipitated with (A×B10.D2)F_1 α B10.A(5R) [$\alpha K^b I–A^b I–B^b$] (*a*) (B10×HTI)F_1 α B10.A(5R) [$\alpha I–E^d I–C^k$] (*b*) (A.TH×B10.HTT)F_1 α A.TL[$\alpha I–A^k I–B^k I–J^k$] (*c*) rabbit anti-MOPC 104E [R$\alpha\mu$] (*d*). ↓Arrows indicate MOPC 104E heavy chain (μ) and light chain markers; | arrows indicate the dye front. NS represents nonspecific 45K peaks, possibly actin.

[B10.A(1R)×B10] is heterozygous for the H-2 complex and expresses Ia molecules encoded by both the H-2^{h1} and H-2^b haplotypes (Fig. 1). In F_1 chimaeras (P→F_1), only Ia molecules from the donor animal can be isolated from epidermal cells. Both I-A and I-E subregion products can be detected (Fig. 1*b*, *c*). In these chimaeras, we cannot detect Ia molecules of the H-2^b haplotype from the B10 parent (Fig. 1*a*). In contrast, transplantation antigens of both haplotypes can readily be detected in these chimaeric animals. The results in Fig. 1*a* also provide direct evidence that transplantation molecules (K^b) can be synthesised by a non-bone marrow-derived cell. We should stress that immunoprecipitation with a rabbit anti-μ serum

showed no evidence of contaminating IgM-positive cells in the epidermal cell population (Fig. 1*d*). Thus, the donor Ia must be derived from a population of bone marrow cells distinct from B cells.

In the chimaera described above, we could only demonstrate a loss of one haplotype of Ia antigens from tail cell preparations derived from P→F_1 chimaeras. To demonstrate directly the appearance of new Ia antigens not present in the host, F_1→P chimaeras were constructed. The [B6×A]F_1 animal has Ia molecules of the H-2^b (B6) and H-2^a (A) haplotypes. In [B6×A]F_1→B6 chimaeras, we could detect the presence of Ia molecules of both the H-2^a and H-2^b haplotypes by immunoprecipitation. I-A Subregion products from both H-2^b and H-2^a haplotypes were easily detected (Fig. 2*a*, *b*). The A^k molecules can only be derived from the bone marrow cells. Both A^k and E^k molecules are present in these chimaeras (E^k not shown). Thus, new epidermal Ia antigens are derived from the donor bone marrow cells. These data from the P→F_1 and F_1→P chimaeras strongly suggest that the Ia molecules from chimaeric epidermal cells originate from bone marrow-derived cells.

The original reports of Ia molecules on mouse epidermal cells were based on adsorption analysis and antibody-mediated cytotoxicity using dye exclusion[6]. Other investigators independently confirmed these results[7,8]. Using an indirect immunofluorescence assay, investigators working with guinea pigs, man and mouse, have suggested that the Ia is confined to a small subpopulation of epidermal cells, the macrophage-like Langerhans cells[11,12,14,15]. In guinea pigs, biosynthetically labelled Ia molecules can only be immunoprecipitated from a Langerhans cell-enriched fraction, and not from a Langerhans cell-depleted fraction of epidermal cells[16]. Our experiments suggest that the biosynthetically labelled Ia molecules are derived from a cell of bone marrow origin. These observations suggest that a small number of cells in the epidermis are derived from the bone marrow and express Ia molecules. Although we have no direct evidence for the bone marrow origin of Langerhans cells, the fluorescence studies in guinea pigs, man and mouse[15], together with the present results, suggest that the Langerhans cell produces the epidermal Ia molecules and has a bone marrow origin. This possibility is not surprising considering the macrophage-like functions ascribed to the Langerhans cells[17,18]. Macrophages are generally thought to be derived from bone marrow precursors. However, our experiments detect only newly synthesised Ia molecules. The sensitivity of detection is a function of both the number of Ia molecules and their turnover rate. We are aware that Ia molecules could be synthesised by non-bone marrow-derived cells, and not detected in our experiments, if the Ia molecules were in much lower concentration per cell or turning over more slowly.

Differential sensitivity of immunofluorescence and cytotoxicity assays, or bystander effects in the cytotoxic assays or contaminating Sk antibody might explain the conflicting cytotoxicity[6–8] and immunofluorescence[11,12,14,15] data. At present, we feel the simplest interpretation of our data is that the Ia molecules present in the epidermis are synthesised by bone marrow-derived cells, probably the Langerhans cells.

Phagocytic macrophage cells are involved in the presentation of antigen to T cells. The subsequent activation and proliferation of the T cells involves the Ia molecules on the antigen-presenting macrophage[19]. In guinea pigs, Langerhans cells can function both as stimulators in a mixed lymphocyte reaction and as antigen-presenting cells[16]. Perhaps Langerhans cells in the epidermis function like macrophages[18]. A high concentration of antigen-presenting cells in the skin is reasonable, as the skin is the first line of defence against pathogens. It was suggested that non-lymphoid Ia-positive epithelial tissues also might be immunologically relevant[13]. The precise immunological implications of Ia molecules on cells in the epidermis are unknown. However, the observations reported here are intriguing because they clearly raise the possibility that Ia molecules may be restricted to cells involved in the immune response.

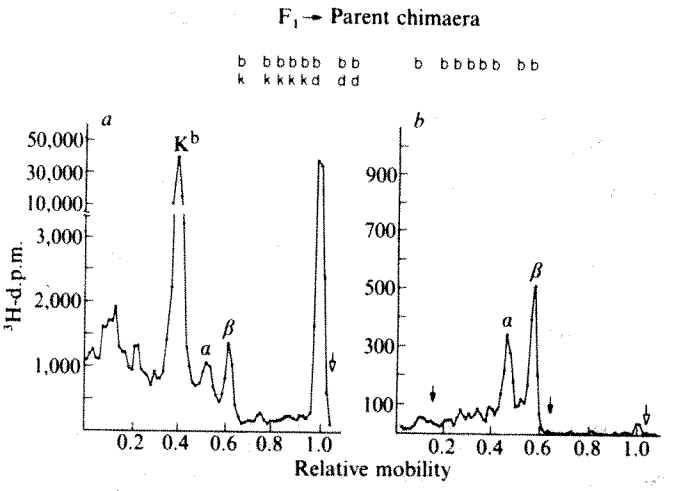

Fig. 2 SDS-polyacrylamide gel electrophoresis of epidermal Ia molecules isolated from F_1→parent bone marrow chimaeras. The F_1→parent chimaera extracts were precipitated with (A×B10.D2)F_1 αB10.A(5R) [$\alpha K^bI\text{-}A^bI\text{-}B^b$] (*a*) and CWBαC3H hybridoma 10-2.15 [$\alpha\text{-}A^k$] (*b*). This reagent has been characterised to react with A^k (ref. 21). We tested the hybridoma reagent using a two-stage dye exclusion cytotoxicity assay. No killing of B10 spleen cell targets was seen with this reagent (cytotoxic titre <1/10). A/Sn spleen cell targets were efficiently lysed (titre of >1/640 with 50% maximum cytotoxicity). In tail skin preparations from chimaeras, the ratio of transplantation antigens (K^b) to Ia molecules is altered compared with normal tail skin preparations[10] (*a*). In chimaeras, there are fewer Ia molecules relative to transplantation antigens. The reason for this altered ratio is not clear. It seems likely that it represents the partial repopulation of epidermal Ia-bearing cells from bone marrow precursors. The monoclonal antibody used in *b* always gives smaller nonspecific peaks than immunoprecipitations using alloantisera. See Fig. 1 legend for explanation of markers.

We thank Glen Matsushima for technical assistance in antiserum production, Marilyn Kehry for donating the rabbit anti-MOPC 104E (Rαμ), Dr Len Herzenberg for providing the anti-I-A^k-producing hybridoma through the Salk Institute, and Mitch Kronenberg for helpful discussions. Epidermal Langerhans cells are derived from cells originating in bone marrow

Stephen I. Katz, Kunihiko Tamaki & David H. Sachs*

Dermatology and *Immunology Branches, National Cancer Institute, Bethesda, Maryland 20205

Langerhans cells constitute a morphologically well characterised subpopulation (3–8%) of mammalian epidermal cells which, in contrast to the bulk of epidermal cells, bear Fc-IgG and C3 receptors[1], express immune response-associated (Ia) antigens and function as antigen-presenting cells and allogeneic stimulatory cells to primed T lymphocytes[2–5]. The ontogeny of Langerhans cells has been a subject of considerable debate since their discovery[6]. Although some studies suggest that Langerhans cells are of mesenchymal as opposed to neural or melanocytic origin[7], direct evidence for this has not been presented. In this study we demonstrate that, after 3 weeks, most of the Langerhans cells (LC) in parental skin which had been transplanted on to F_1 hybrids were of recipient origin whereas keratinocytes remained of donor origin; this indicates that the LC are derived from a mobile pool of cells. Furthermore, in studies of skin from radiation-induced bone marrow chimaeric animals we found that, depending on the strain combination, up to 80% of the epidermal LC were derived from the bone marrow of the donor animals.

Previous studies have demonstrated that in mice[8,9] as well as in guinea pigs and humans, H–2 (B region in guinea pigs and HLA-A or -B in humans) antigens are expressed on the great majority of epidermal cells. In contrast, Ia antigens or their equivalents in mice, guinea pigs and humans are detected only on epidermal Langerhans cells[1–5,8,9]. Langerhans cells can also be identified by light microscopy when they are incubated with IgG-coated ox red blood cells (EA-IgG), as they form rosettes through their Fc receptors. Our studies used epidermal cell suspensions prepared by trypsinisation (1% for 60 min at 37 °C), and epidermal cell-surface characteristics were identified by using a simultaneous rosette and indirect immunofluorescence (IF) assay[9].

First, we transplanted sex-matched parental skin from A/J mice on to CAF_1 (BALB/c×A/J) hybrid mice and, after various time periods, determined whether the H–2 and Ia antigens of the LC and other epidermal cells were those of the donor or recipient. Table 1 shows that using an anti-Ia.8 antiserum which detects the Ia of BALB/c but not of A/J mice, 3.5–4% of the epidermal cells of the A/J transplants bore Ia antigens characteristic of the CAF_1 mice. The great majority of these were LC, as from 61% (11 d post-transplantation) to 100% (49 d post-transplantation) of the Fc-IgG-rosetting cells (Langerhans cells) were positive with the anti-Ia.8 reagent. Using an anti-H–2^d antiserum [$(B10\times A)F_1$ anti-B10.D2] we found that most of the epidermal cells were not of CAF_1 origin. Furthermore when syngeneic transplants (A/J skin on to A/J mice) were carried out, the anti-Ia.8 antiserum did not stain any of the A/J epidermal cells whereas 4.2% of these epidermal

The antisera used have been extensively characterised by cytoxicity and absorption analyses on spleen and lymph node cells. Serum 1 is a $(B10.A\times A)F_1$ anti-B10 which is negative on H–2^a(A/J) and when tested on H–2^d(BALB/c) reacts only with the I–A specificity Ia.8. Serum 2 is a $(B10\times A)F_1$ anti-B10.D2 which is also negative on H–2^a and when tested on BALB/c reacts with the H–2K specificities H–2.31 and the Ia specificities Ia.8 and 11. Serum 3 is an A.TH anti-A.TL which is a polyvalent anti-Ia antiserum, and reacts with multiple Ia specificities of both H–2^a and H–2^d. NT, Not tested.

cells were IF positive with a polyvalent anti-Ia antiserum (A.TH anti-A.TL) detecting Ia antigens of H-2^a origin. These findings suggest that the Langerhans cells of the transplanted skin were derived from a mobile pool of recipient cells.

Our second set of experiments was designed to assess more directly the origin of the Langerhans cells. Chimaeric animals were prepared by irradiating mice with 750–900 R and reconstituting with $2.5–3 \times 10^7$ allogeneic or semi-allogeneic bone marrow cells. All mice used in our studies were shown to be 'totally' chimaeric by the demonstration of H-2 and Ia antigens of the donor strain on spleen and peripheral blood cells. Table 2 demonstrates that after various periods of time following chimaerisation (BALB/c into C57BL/6) 20–45% of the Fc-IgG-bearing cells were of donor origin whereas the remainder of the Fc-IgG-bearing cells were of recipient origin. These studies also show that the bulk of the epidermal cells (keratinocytes) come from the recipient animal, as most of the epidermal cells were IF positive with the anti H-2^b (B10.D2 anti-B10) antiserum. In another strain combination $(B10 \times B10.A)F_1$ into B10.A a much larger percentage of Fc-IgG-bearing cells were found to be of donor origin 80–85 d after chimaerisation (Table 3). Here we determined that 68% [using a $(B10.A \times A)F_1$ anti-B10.D2 antiserum] to 80% [using a $(B10.A \times A)F_1$ anti-B10 antiserum] of the Fc-IgG-rosetted cells were of donor bone marrow origin. Electron microscopic studies of the Fc-IgG-bearing rosetted cells demonstrated that most of the cells had all the characteristics of Langerhans cells, including the unique cytoplasmic organelles (Fig. 1).

Taken together, these studies indicate that epidermal Langerhans cells are derived from and are continually repopulated by a mobile pool of precursor cells which for the most part originate in the bone marrow. The most likely precursor cell is the monocyte, as Langerhans cells exhibit similar, if not identical, surface marker characteristics to cells of the monocyte–macrophage series. None of our chimaera studies produced total replacement of epidermal LC by donor precursor cells. This may be due to the fact that residual host precursor monocytes remain in the bone marrow at the dose of irradiation used, even though the peripheral lymphoid cells are completely replaced. This possibility is under study. The demonstration of the non-total replacement of the monocyte pool may be important for the interpretation of mechanistic studies using allogeneic chimaeras.

Langerhans cells probably subserve functions of the Ia-rich relatively non-phagocytic macrophages and may not only function in an antigen-presenting capacity for exogenous allergens but also represent the 'passenger leukocyte' which is thought to induce graft rejection. In this regard, Steinmuller has reported sensitisation of animals by transplantation of skin from chimaeras[10]. In these experiments, skin was transplanted from chimaeras (A recipient, $(A \times B)F_1$ donor) on to strain A mice. The grafts were accepted, but when skin was then transplanted from B animals on to the same A mice, the second grafts were rejected in an accelerated fashion. The most likely source of the B antigens in the chimaera skin was the haematopoietically derived cells from the donor. Our data indicate that the chimaeric skin becomes rich in donor Ia because of the appearance of donor Langerhans cells in the epidermis. It is likely that these cells have an important role in allogeneic graft rejection. Such conclusions are consistent with our previous studies

Table 3 Detection of major histocompatibility alloantigens on epidermal cells of chimaeric mice

Corneal allografts fail to express Ia antigens

J. Wayne Streilein, Galen B. Toews & Paul R. Bergstresser

Departments of Cell Biology and Internal Medicine, University of Texas Health Science Center at Dallas, 5323 Harry Hines Blvd, Dallas, Texas 75235

Although the surface determinants encoded by class I genes of the major histocompatibility complex (murine K/D; human HLA-A/B/C) are expressed on virtually all nucleated cells, the molecular products of class II genes (murine I, human HLA-D/DR) are expressed only on B lymphocytes, macrophages, sperm and certain subsets of T lymphocytes, especially suppressor cells[1,2]. Controversy exists concerning the expression of class II antigens on cells of the epidermis. On the one hand, Hammerling *et al.*[3] and Frelinger *et al.*[4] have used serological methods to detect Ia antigens on epidermal cells. On the other hand, fluorescein isothiocyanate-conjugated antisera have been used to show that human and guinea pig class II alloantigens are only expressed on Langerhans cells in the epidermis[5–7]. Recently, Rowden *et al.*[8] have convincingly demonstrated that Ia antigens are expressed exclusively on Langerhans cells within murine epidermis. We have now shown that cornea, which is an epidermal tissue devoid of Langerhans cells, does not express Ia antigens.

Langerhans cells have been found to be closely associated with the induction and expression of delayed cutaneous hypersensitivity reactions elicited by chemical contactants[9,10], but not all cutaneous sites are equally endowed with these cells, the density of which varies considerably in skin from mouse ears, foot pad and body wall[11]. Similarly, we have recently demonstrated marked variation in Langerhans cell-surface density using an ATPase staining method in mice[12]. The most dramatic difference from body wall skin, which contains approximately 800 ± 200 Langerhans cells per mm^2, was found in the cornea which is completely free of ATPase-positive, dendritic cells, that is, Langerhans cells. This observation is consistent with a previous series of studies[12–15]. Recently, it has been claimed that Langerhans cells, as defined by surface Ia antigens, are present at the periphery of the cornea and the limbus[16]. We also find ATPase-positive cells at the corneal limbus. In the grafting experiments described below, we took special care to prepare corneal grafts by severely cutting away peripheral tissues, including the limbus.

To determine whether alloantigens encoded by the I region of the murine H-2 complex can be expressed functionally in epidermal tissue if Langerhans cells are not present we placed corneal grafts on prepared beds on thoracic walls of recipient mice that differed from their corneal graft donors at the K region alone, at combined K and I regions, and at the I region alone. These corneal allografts were observed for evidence of rejection over a 45-d interval. Recipients were then rechallenged with conventional body wall skin grafts syngeneic to the original corneal allografts. Median survival times (MSTs) were calculated and compared with appropriate controls to determine whether first- or second-set patterns of rejection had taken place.

The fate of syngeneic corneal grafts must first be described. All grafts were carefully trimmed of scleral and limbic tissues and placed, endothelial-side down, on the raw sub-dermal surface. Each graft bed received three corneal grafts. The site was covered with Vaseline-impregnated gauze and wrapped with plaster of Paris bandage. Plaster casts were first removed for graft inspection 8 d later. At that time, three circular, transparent corneal grafts were usually found. When one of the grafts had been placed strategically over a subcutaneous blood vessel of significant size, blood could be seen coursing through the vessel directly beneath the transparent graft. Corneal grafts retained their transparency so long as they were covered and dressed with the Vaseline gauze. After exposure to room air, corneal transparency gradually gave way over several days to translucency which then persisted indefinitely. Thereafter, corneal grafts were identifiable by their smooth surface, and by the slightly dome-shaped contour due to the inherent structure of the corneal stroma. Healthy autografts of this type have been observed beyond 60 d. There was very little wound contracture at these graft sites during the observation period.

The results of the allografting experiments described in outline above are presented in Table 1. H-2-congeneic strains B10.A and B10.AQR differ at the K region: B10.A possesses the K^k allele, whereas B10.AQR possesses the K^q allele. The MST of first-set B10.A body wall skin grafts placed in B10.AQR recipients was 16 ± 1.1 d. The MST of B10.A corneal allografts on B10.AQR recipients was similar, 13 ± 1.1 d. During their early course the gross appearance of these corneal allografts was quite similar to that of syngeneic corneal grafts. However, 1–2 d before rejection, the graft beds became acutely inflamed; the surface epidermis of the grafts developed hyperkeratotic changes and then quickly sloughed, to be replaced by a dried eschar. Within the next 24–48 h, wound contracture began and by 5 d, only a small, crusted wound, a few millimetres in diameter, remained.

Table 1 Comparative sensitising capacities of allografts prepared from cornea and body wall skin

	First-set graft					Second-set graft			
Recipient	Donor	H-2 Disp.	Graft source	*n*	MST	Donor	H-2 Disp.	*n*	MST
1. B10.AQR	B10.A	K^k	Body wall	13	16.0 ± 1.1	B10.A	K^k	13	9.0 ± 1.1
2. B10.AQR	B10.A	K^k	Cornea	11	13 ± 1.1	B10.A	K^k	11	9.0 ± 1.2
3. A.TH	A.TL	I^k	Body wall	10	16 ± 1.3	A.AL	K^kI^k	10	9.5 ± 1.3
4. A.TH	A.AL	K^kI^k	Body wall	10	14.8 ± 1.1	A.AL	K^kI^k	10	9.0 ± 1.0
5. A.TH	A.TL	I^k	Cornea	13	>45	A.AL	K^kI^k	13	14.8 ± 1.1
6. A.TH	None					A.AL	K^kI^k	8	15.0 ± 1.1

All second-set grafts were prepared from body wall skin. H-2 disp. refers to H-2 differences between donor and recipient. I = ABJEC subregions plus the S and G regions of H-2. MST = Median survival time in days, ±1 s.d.

H-2-congeneic strains A.TL and A.TH differ from each other across the entire I region of H-2, plus the S and G regions: A.TL expresses the I-ABJECSG alleles of k, whereas A.TH expresses comparable alleles of the s halotype. First-set body wall skin grafts from A.TL on A.TH recipients were rejected acutely, MST 16 ± 1.3 d (Table 1, line 3). In contrast, A.TL corneal allografts survived on A.TH recipients beyond 45 d (line 5). No grafts were rejected. In fact, the appearance of these grafts throughout the observation interval was virtually identical to that of syngeneic corneal grafts. These data indicate that epidermis deficient in Langerhans cells is similarly deficient in expression of alloantigenic products of I-region genes and support the claim that only Langerhans cells within the epidermis express I-region determinants in an immunogenically important way.

This interpretation was strengthened by the findings of the next experiments. Recipients of body wall and corneal first-set allografts were regrafted with body wall skin prepared from donors expressing the alloantigens putatively present on the first-set grafts. Thus, when B10.AQR animals were rechallenged with B10.A body wall skin grafts, they rejected these grafts in an accelerated, second-set manner, indicating that body wall skin and cornea are equally able to sensitise to the alloantigens of the K region (Table 1, lines 1, 2). Similarly, A.TH animals grafted first with A.TL body wall skin rejected test grafts of A.AL skin bearing identical I^k determinants in a second-set fashion (MST of 9.5 compared with 16 d, Table 1, line 3). However, when A.TH recipients of I-region-disparate A.TL corneal grafts were challenged with body wall skin from A.AL donors (expressing the same I region disparity), the test grafts were rejected in first-set fashion, indicating that these animals had not been sensitised by their prior experience with the corneal graft (MST of 14.8 and 15 compared with 9.0 d, Table 1, lines 5–6). We conclude that corneas in which the epithelium is essentially devoid of a resident Langerhans cell population are unable to display class II alloantigens in a manner capable of inciting transplantation immunity. We recognise that, as the corneal allografts failed to sensitise to Ia alloantigens, the stromal elements and endothelium of these grafts must also be unable to express these antigens effectively.

Our findings have immediate relevance to clinical corneal transplantation. Even without tissue typing to assist donor selection, corneal allografts have been surprisingly, although not regularly, successful in man[17]. Our results suggest that deficiency of Langerhans cells in the cornea may be important in this. HLA-D/DR alloantigens are potent transplantation immunogens in man. If, by extrapolation from the mouse data, human corneas fail to express D/DR determinants, then the alloantigenic burden of cornea is significantly less. Perhaps for the success of corneal transplants in man, matching for HLA-A, B, C may be sufficient. A recent report indicates that donor–recipient matching for HLA-A, B, C corresponds to improved corneal allograft survival[18].

The absence of Langerhans cells from the cornea has other interesting implications. It has been demonstrated that, shortly after vaccinia virus vaccination in man, virtually all viral particles become associated with epidermal Langerhans cells[19]. These cells have been ascribed the general property of antigen processing; perhaps the processing and/or handling of cutaneous viral infections is also a function of the dendritic Langerhans cell. Indolent and persistent infections of corneal epithelium often caused by herpes simplex virus may be another expression of the virally related function of this interesting epidermal cell type. The absence of Langerhans cells from the cornea (assuming that they are important in defence against viral infection) would render this epidermal tissue especially vulnerable to persistent and chronic virus infection.

A defect in the antigen-presenting function of macrophages from neonatal mice

Christopher Y. Lu, Edward G. Calamai & Emil R. Unanue

Department of Pathology, Harvard Medical School, Boston, Massachusetts 02115

The newborn mammal has a limited ability to mount an immune response[1–5]. As the individual matures, the potential for immunological reactivity develops and expands. During the early period of relative immune incompetence, tolerance to some foreign antigens is easily induced[6,7]. It is thought that the individual may be acquiring tolerance to self antigens during this period, hence its importance for immunological homeostasis. The contribution of mononuclear phagocytes to the initiation of immune responses is now well established. These phagocytes are essential for the development of various lymphocyte functions, in particular, those of the T lymphocytes. Most T-lymphocyte activities require that the macrophage take up and 'present' the antigen in a process modulated by the I region of the major histocompatibility gene complex (for review see ref. 8). Although some earlier studies[5,9–13] have indicated deficient macrophage function in the neonate, precise definition of the putative deficiency is lacking. We show here that macrophages from neonatal mice present antigen poorly and that this can be correlated with the small number of macrophages that bear Ia antigens.

In our tissue culture assay system, T lymphocytes from mice immunised to *Listeria monocytogenes* were cultured with macrophages which had taken up heat-killed *Listeria* organisms. The macrophages were always obtained from non-immune mice. It had been previously established that effective interaction between T lymphocyte, macrophage and *Listeria* resulted in T-lymphocyte proliferation[14]. Proliferation of the *Listeria*-immune T lymphocytes was antigen specific and required uptake of *Listeria* by a subpopulation of macrophages bearing Ia antigen and homology between T lymphocyte and macrophage at the I-A region of the major histocompatibility gene complex. This assay system is similar to other systems[8,15] using soluble protein antigens and measures an antigen-presentation function of the macrophage regulated by the major histocompatibility gene complex.

The data in Table 1 demonstrate that culturing *Listeria*-immune T lymphocytes from adult (2–3-month-old) mice with *Listeria*-pulsed macrophages also from adults resulted in T-lymphocyte proliferation. A weak proliferative response was observed when the same number of macrophages from neonatal mice was substituted for the macrophages from adults. Direct microscopic counts established that equal numbers of adherent

Macrophages were obtained from the peptone-elicited peritoneal exudate of non-infected C57BL/6J mice of various ages. Sterile proteose peptone, 10% (75 μl per g body weight) was injected intraperitoneally (i.p.), and the resulting exudate collected 4 d later by lavage with Hank's balanced salt solution containing 2% fetal calf serum (FCS), 10 mM HEPES and 10 $U l^{-1}$ heparin. Peritoneal exudate cells (10^4) were incubated on flat-bottom 1.0 × 0.7-cm^2 Linbro wells for 1 h, and then nonadherent cells were removed by washing the wells three times. The adherent cells were pulsed with heat-killed *Listeria for* 1 h. Unbound *Listeria* was removed by washing the wells five times, after which 4×10^5 *Listeria*-immune T lymphocytes were added to each well in 200 μl of RPMI 1640 supplemented with 10% FCS, 2 mM L-glutamine and 5×10^{-5} M 2-mercaptoethanol. The immune non-adherent T lymphocytes were cultured with the *Listeria*-pulsed macrophages for 4 d at 37°C in humidified 5% CO_2. Each well then received 0.2 μCi ^{3}H-thymidine, and trichloroacetic acid-precipitable counts were measured 18 h later. Results indicate the mean of three cultures with the s.e.m. Further technical details are given in ref. 14. The *Listeria*-immune T lymphocytes were isolated from adult C57BL/6 mice injected i.p. with 10^4–10^5 live *Listeria*. Seven days after infection, the mice received 1.5 ml of sterile 10% proteose peptone i.p., and the resulting exudate was collected 3 d later. The T lymphocytes were isolated by removing macrophages through adherence on plastic dishes and nylon-wool filtration. Other experiments from this laboratory have firmly established that T lymphocytes cultured without macrophages but with *Listeria* continuously show no proliferation or a modest proliferative response never exceeding about one-quarter of that shown with macrophage-bound *Listeria*[14]. By doing the experiment, as above, pulsing the macrophages with *Listeria* before addition of T cells, we minimise any possible effect of residual macrophages in the T-cell population.

cells from neonatal and adult mice were being compared. The adherent cell population from neonates and adults had the same composition—greater than 99% macrophages as determined by morphology and positive, nonspecific esterase staining. Furthermore, the macrophages from adult and neonatal mice had exactly the same ability to take up *Listeria* and similar distributions of Fc and C3 receptors.

Figure 1 shows that only optimal numbers of macrophages from adults, 10^4–3×10^4 per microwell, stimulated immune T-cell proliferation. Macrophages from neonatal mice weakly stimulated T-lymphocyte proliferation regardless of the number of macrophages in the microwells. Furthermore, increasing the amount of *Listeria* given to the macrophages from neonatal

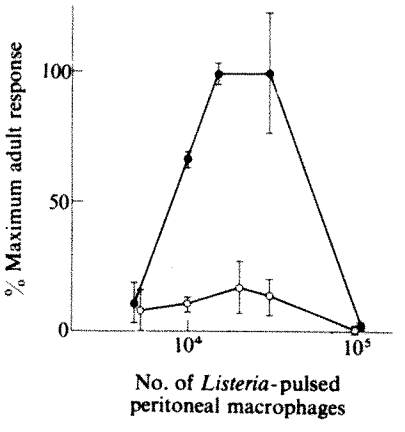

Fig. 1 Immune T-lymphocyte stimulation by antigen-pulsed macrophages as a function of the number of macrophages. The assay of *Listeria*-immune T-lymphocyte stimulation by *Listeria*-pulsed macrophages is described in Table 1 legend. Macrophages from neonatal (○) or adult (●) mice were pulsed with 10^7 *Listeria* for 1 h. The figure summarises three experiments.

animals did not overcome their deficient ability to stimulate immune T-lymphocyte proliferation (data not shown).

Figure 2 shows that the ability of macrophages to interact effectively with T lymphocytes did not occur until 3–4 weeks after birth, approximately the time of weaning. In each of nine experiments, peritoneal macrophages were taken from C57BL/6J mice of various ages, given *Listeria*, and used to stimulate immune syngeneic T-lymphocyte proliferation. The deficiency detailed above also applied to neonatal splenic adherent cells (not shown). The deficiency was also found in macrophages taken from neonatal mice of a different strain, the A/St strain ($H\text{-}2^a$ haplotype).

We have also investigated effects of T-lymphocyte–macrophage interaction other than proliferation. Macrophages secrete a 15,000-molecular weight protein mitogenic for thymocytes[14,16]. This secretion is optimal when the macrophage, antigen and T lymphocyte interaction occurs with I–A homology between the two cells. Although macrophages from adults secreted the mitogen when mixed with *Listeria*-immune T lymphocytes and *Listeria*, this was not the case with macrophages from neonatal animals (not shown).

There are several possible explanations for the deficient ability of macrophages from neonatal mice to stimulate T-lymphocyte proliferation. First, a possible contamination of the macrophage population with suppressor T cells seems unlikely because of the purity of the macrophage populations. Furthermore, treatment of macrophages with anti-Thy-1.2 and complement did not change the results. Second, a possible nonspecific suppressive influence of macrophages from neonatal mice on lymphocyte proliferation[17] was investigated by mixing macrophages from neonatal animals with syngeneic splenic T lymphocytes stimulated with concanavalin A. Table 2 shows that the macrophages from the neonatal mouse did not suppress the concanavalin A response. In several experiments, we have found that macrophages from adults can stimulate *Listeria*-immune T-lymphocyte proliferation in cultures containing equal numbers of macrophages from neonatal animals. In one example, the response of immune T lymphocytes to 10^4 macrophages from adults, 10^4 from neonatal animals and a mixture of 10^4 cells of both was 19,218, 3,227 and 16,950 c.p.m., respectively.

The inability of macrophages from neonatal mice to stimulate T-lymphocyte proliferation effectively may be due to the small number of Ia-bearing macrophages in the neonatal animals (Table 3). The macrophage population fron neonatal mice was deficient in a subpopulation carrying surface Ia antigen. This observation was made with various antisera–target cell combinations. The appearance of Ia-positive macrophages in ontogeny varied from experiment to experiment, perhaps reflecting uncontrollable environmental conditions. It has been

Table 2 Macrophages from neonatal and adult mice do not inhibit concanavalin A-stimulated splenocyte proliferation

Macrophages (10^4 per well) were collected from neonatal or adult mice and pulsed with 10^7 heat-killed *Listeria* as described in Table 1 legend. Splenocytes were collected from 2–3-month-old C57BL/6J mice and enriched for T lymphocytes by passage over nylon-wool columns. Nylon-wool-filtered cells (4×10^5) were placed in 1.0 × 0.7 cm^2 Linbro wells containing the *Listeria*-pulsed macrophages. Concanavalin A (4 μg ml^{-1}) was added to the wells. After 4 d of culture, each well received 0.2 μCi ^{3}H-thymidine, and trichloroacetic acid-precipitable counts were measured 18 h later. Similar results were obtained when 5×10^4 instead of 10^4 macrophages per microwell were used.

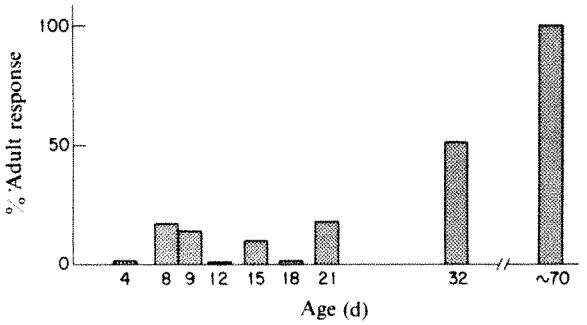

Fig. 2 Ontogeny of immune T-cell stimulation by *Listeria*-pulsed macrophages. Table 1 legend described the assay system for measuring immune T-lymphocyte stimulation by *Listeria*-pulsed macrophages taken from C57BL/6J mice of various ages. The immune T-cell stimulation by macrophages from mice of various ages is expressed as a percentage of the immune T-cells stimulation by macrophages from adult mice. The results were obtained from nine separate experiments.

established in the adult that only Ia-bearing macrophages present *Listeria* and that the cooperation between macrophage and T lymphocyte which allows antigen-driven T-lymphocyte proliferation requires homology between macrophage and T lymphocyte at the I-A region of the major histocompatibility gene complex[14,16]. Extrapolating from these data, one would predict that a macrophage population with a few Ia-positive cells would present antigen poorly, and this may be the case for the neonatal animal. Whether other factors in the neonatal macrophage population are involved is not known.

Table 3 Detection of Ia antigens on peptone-elicited macrophages

Macrophages were isolated from peptone peritoneal exudates by adherence and then incubated for 1 h in antisera at 0 °C in flat-bottom 10-mm culture plates. After washing the macrophages at 0 °C, these cells were incubated in a mixture of 6% rabbit and 4% guinea pig complement for 1 h at 37°C. The sera had been absorbed extensively with mouse spleen cells to remove natural anti-membrane antibodies. The complement was washed away, and the macrophages were incubated in 0.4% trypan blue in normal saline at room temperature for 15 min. Dead and living cells were scored under a Nikon inverted microscope. Neither dead (trypan-blue-positive) nor living (trypan-blue-negative) macrophages were lost from the microwells during the antiserum-complement treatment. The number of dead macrophages following treatment with normal mouse serum (NMS) plus complement was never greater than 5%. The results are expressed as the cytotoxic index: ([% Ia positive − % NMS positive] × 100)/(100 − % NMS positive). The A.TH-anti-A.TL antiserum used in expts 1 and 2 has been previously used[14] and shown to be Ia specific by appropriate absorptions. Used against C57BL/6J macrophages, this antiserum will detect Ia specificity 3 (ref. 25). The A.TH-anti-A.TL antiserum used in expts 3 and 5 (Cedarlane Laboratories) had also been previously standardised. The antiserum used in expt 4 was raised by injecting (LP × A.TH)F_1 mice with (LP × A.TL)F_1 and C157 splenocytes and was absorbed with B10.7R spleen cells. The antiserum should detect Ia specificities 1, 2 and 7 (refs 25, 26). This antiserum did not kill control C57BL/6J spleen cells, which do not have Ia specificities 1, 2 or 7. None of these antisera killed control nylon-wool-purified A/St or C57BL/6J splenic T lymphocytes which lack significant amounts of Ia. All antisera were used at an optimal dilution. The cytotoxic index of macrophages taken from mice of similar ages varies from experiment to experiment. This may be attributed to variation in the rate of development of individual litters.

Our study demonstrates that macrophages from neonatal mice do not present antigen efficiently and that this can be correlated with the small number of macrophages bearing Ia antigens. These results allow us to speculate about the two major characteristics of the neonatal immune response. First, with few antigen-presenting macrophages, the T-lymphocyte responses regulated by the major histocompatibility complex (helper, cellular immunity) would not be induced. This would contribute to the limited immune response capacity of the neonatal mouse. Second, interaction of antigen directly with T lymphocytes in the absence of Ia-positive macrophages may induce antigen-specific suppressor T lymphocytes[18,19]. This would suggest another mechanism for control of self-recognition and the ease of tolerance induction seen in the newborn. Of course, the macrophage is not the only immature cell in the neonatal animal. B lymphocytes[20–23] and T lymphocytes[5,24], each with unique properties during early life, have been described and also contribute to the special characteristics of the neonatal immune response.

We thank Kevin Cunningham, Thomas Manning, Joseph Scrima and Willie Washington for their care of the breeding colony. Antiserum used in expts 1 and 2 of Table 3 was from Dr David Sachs, and that used in expt 4 was from Dr Martin E. Dorf. Our work was supported by grants from the NIH and from the Council for Tobacco Research.

Acetylcholine receptor-controlled ion fluxes in membrane vesicles investigated by fast reaction techniques

George P. Hess, Derek J. Cash & Hitoshi Aoshima

Section of Biochemistry, Molecular and Cell Biology, 270 Clark Hall, Cornell University, Ithaca, New York 14853

The ability of a nerve cell to integrate its response to chemical signals (neurotransmitters) arriving from many other cells is central to the function of the nervous system. This integration process depends on the ability of the neurotransmitters to bind to specific receptors which modulate the flow of specific inorganic ions through the cell membrane, and on the ability of the cell to transmit a (chemical) signal to an adjacent cell[1–3] only if the resulting change in transmembrane potential is of appropriate sign and magnitude. The controlling sign and magnitude of the cell transmembrane potential can be predicted from measurement of the rates of movement of specific inorganic ions across the membrane[4–6] and their dependence on neurotransmitter concentration. However, there have been two main

0028/0836/79/460329—03$01.00

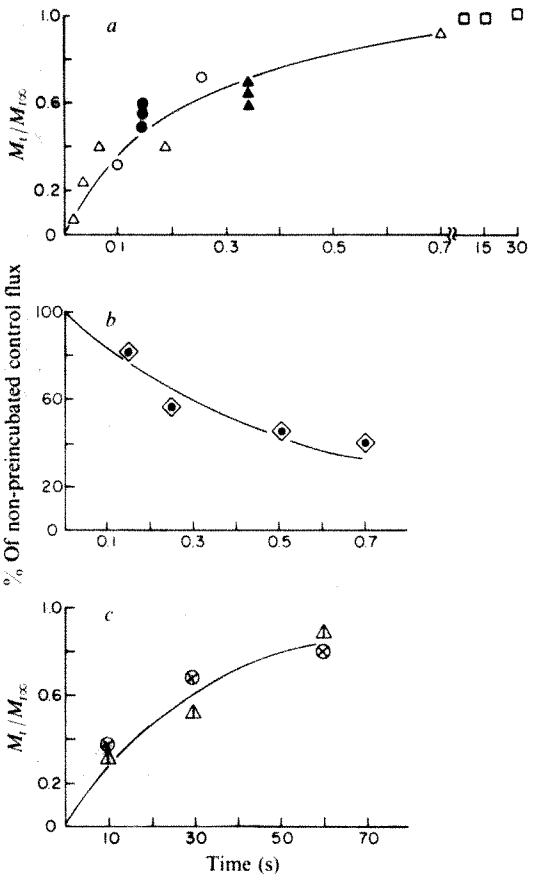
© 1979 Macmillan Journals Ltd.

obstacles to the development of a suitable preparation for such measurements. First, Kasai and Changeux[7] obtained a membrane vesicle preparation from the electric organ of *Electrophorus electricus* (electroplax vesicles) in which acetylcholine receptor-controlled fluxes of inorganic ions could be observed, but the flux rates seemed too slow to be of physiological significance[8]. We have shown that these slow flux rates were associated with a large fraction of the vesicle preparation which did not respond to acetylcholine and yet dominated the measurements[9]. We then accomplished the separation of the receptor-controlled fluxes from other processes[9,10]. Second, the receptor-controlled flux was found to be biphasic, with an initial phase too fast to be measured by available techniques[11]. We have now succeeded in applying a quench flow technique[12] to the determination of the flux rate of specific inorganic ions across vesicle membranes in the millisecond time region, a time resolution sufficient for measuring the initial phase of receptor-controlled fluxes with these vesicles.

The receptor-controlled fluxes were characterised by obtaining three different kinetic measurements using the quench flow technique. Figure 1*a* shows rapid receptor-mediated flux of $^{86}Rb^+$ into the vesicles in the presence of 1 mM carbamylcholine, a stable analogue of acetylcholine. The influx was stopped after various times by mixing the reaction solution with (+)tubocurarine solution to give a final concentration of 10 mM. The $^{86}Rb^+$ content of the vesicles was determined by a Millipore filter assay as previously described[7]. Half of the $^{86}Rb^+$ influx occurs in 160 ms and the process is complete within 1 s, no further influx being observed at least within 30 s. The data in Fig. 1*b* demonstrate that receptor-controlled flux is affected by preincubation of the vesicles with 1 mM carbamylcholine. After the various preincubation times indicated, the vesicles were mixed with $^{86}Rb^+$ and influx was allowed to proceed for 6 s in the presence of 1 mM carbamylcholine. In vesicles which had not been preincubated with 1 mM carbamylcholine, influx was complete within this assay period. With vesicles which had first been preincubated with 1 mM carbamylcholine for 450 ms, influx was only 50% complete within the assay period. As Fig. 1*c* shows, a relatively slow rate of flux is observed after preincubation of the vesicles with 1 mM carbamylcholine for 10 s. After this preincubation, influx of $^{86}Rb^+$ in the presence of 1 mM carbamylcholine was measured at the times indicated. The final concentration of $^{86}Rb^+$ in the vesicles was the same as in the experiment shown in Fig. 1*a*, but ~25 s were required for half the $^{86}Rb^+$ influx to occur, that is, 150 times longer than when the vesicles had not been preincubated with carbamylcholine.

The model in Fig. 2 was used to evaluate the data shown in Fig. 1. It is based on the observation that acetylcholine receptor-mediated changes in the transmembrane potential of nerve and muscle cells often last less than 1 s, even though acetylcholine or carbamylcholine remains. This decrease in response to neurotransmitter is called desensitisation. To explain the phenomenon, Katz and Thesleff[13] suggested that the receptor exists predominantly in an active conformation and that this conformation is converted to an inactive form by these compounds. On the basis of the observation that receptor-controlled flux consists of an initial fast phase which is followed by a slow phase[11], we suggested that the active conformation is associated with a large flux rate constant (J_1, Fig. 2), and the inactive conformation with a much smaller one (J_2, Fig. 2).

The terms of the integrated rate equation pertaining to the model (Fig. 2) are readily evaluated from kinetic measurements because the two phases of the flux occur in separate time regions (Fig. 1). (1) At high concentrations of carbamylcholine the flux associated with the active form of the receptor, indicated by △ in Fig. 2, dominates the kinetics. The solid line in Fig. 1*a* was computed using equation (1) (Fig. 2), a β value of 1.5 s^{-1} obtained from the data in Fig. 1*b*, and a value for $J_1(L_0/L_0+K_1)$ of 4.8 s^{-1}, which was obtained by a curve-fitting procedure. (2) The disappearance of the fast flux observed in Fig. 1*b* is a measure of the disappearance of the active form of the receptor. β contains the rate constants, k_{12}, k_{23}, k_{34} and k_{43}, for the



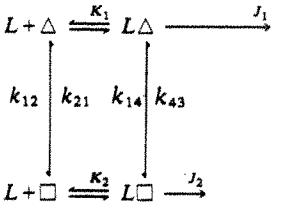


Fig. 1 Acetylcholine receptor-controlled $^{86}Rb^+$ flux in electroplax membrane vesicles, *p*H 7.0, 1 °C. *a*, Flux of $^{86}Rb^+$ into vesicles in the presence of 1 mM carbamylcholine. $[M^+]$ is proportional to the concentration of $^{86}Rb^+$ in the vesicles. The subscript t indicates the time of measurement. *b*, Inactivation of the acetylcholine receptor-controlled $^{86}Rb^+$ influx by preincubation of the vesicles with 1 mM carbamylcholine for various periods of time, after which influx was allowed to proceed for 6 s in the presence of $^{86}Rb^+$ and 1 mM carbamylcholine. The ordinate gives the results as a percentage of the flux measured when carbamylcholine was absent during preincubation. *c*, Flux of $^{86}Rb^+$ into vesicles in the presence of 1 mM carbamylcholine, after preincubation of the vesicles for 10 s with 1 mM carbamylcholine. The different symbols refer to different eel preparations: solid symbols represent single measurements; the symbols in *b* represent the average values obtained in four different experiments using membrane preparations from four different eels. The quench flow apparatus has been described by Fersht and Jakes[12]. Vesicles (800 μg membrane protein per ml) were equilibrated for at least 12 h with *E. electricus* Ringer solution[18] (169 mM NaCl, 5 mM KCl, 3 mM $CaCl_2$, 1.5 mM $MgCl_2$, 1.5 mM phosphate buffer, *p*H 7.0). In the influx experiments the vesicles were mixed with an equal volume of eel Ringer solution containing either $^{86}Rb^+$ (100 μCi ml^{-1}) or $^{86}Rb^+$ and 2 mM carbamylcholine. After the predetermined time 2 volumes of the above solution were mixed with 1 volume of 30 mM (+)tubocurarine chloride which quenched the reaction. The $^{86}Rb^+$ content of the vesicles was measured using a Millipore filter assay[7]. The effectiveness of quenching was demonstrated by mixing a solution containing vesicles, carbamylcholine and (+)tubocurarine with a solution containing $^{86}Rb^+$ and observing no influx in 5 s, and also by sequentially mixing the vesicles with carbamylcholine and $^{86}Rb^+$ and then with (+)tubocurarine and observing no influx. In the desensitisation experiments the vesicles were mixed with an equal volume of 2 mM carbamylcholine or eel Ringer solution. After the predetermined preincubation period 2 volumes of the above solution were mixed with 1 volume of $^{86}Rb^+$ and 1 mM or 3 mM carbamylcholine (the final concentration always being 1 mM), and the mixtures incubated for 5 s before Millipore assay. To ensure that vesicle breakage was not significant, the total $^{86}Rb^+$ influx measured in the quench flow apparatus was compared with the total influx measured outside the apparatus. The method for isolating the vesicles, the kinetic techniques which allow measurement of the carbamylcholine-induced fluxes of inorganic ions without interference from other fluxes, and the sources of chemicals used, have been described elsewhere[9–11].

isomerisation of receptor conformations[14], and was evaluated from a linear plot of the data according to equation (2) with the concentration of the active form of the receptor at zero time, $[L\Delta]_{t=0}$, set equal to 100% (Fig. 1*b*). $[L\Delta]_t$ represents the concentration of the active receptor conformation at time t, and is obtained from the ordinate of the graph in Fig. 1*b*. The solid

line was computed using a value for β of 1.5 s^{-1}. (3) Preincubation of the vesicles with carbamylcholine for 10 s leads to a relatively slow $^{86}Rb^+$ influx which follows a first-order rate law. The solid line in Fig. 1*c* was computed using a value for $J_2(L_0/L_0+K_2)$ of 0.03 s^{-1}. We cannot determine *a priori* which receptor conformation gives rise to this slow flux. If we assume that it arises only from a small concentration of active receptor in an equilibrium mixture of active and inactive forms, $J_2 = K_{c2}J_1$.

Desensitisation of the acetylcholine receptor has previously been observed in flux experiments with electroplax membrane vesicles[14], and in electrophysiological measurements with intact electroplax cells[15,16]. The suggestion that these observations are due to the isomerisation of receptor conformations, each associated with very different efficiencies in mediating the equilibration of inorganic ions across the cell membrane, is supported by the data in Fig. 1. Furthermore, the overall rate constant for this process, β, measured in flux experiments with electroplax vesicles, is kinetically competent to account for the time course of the electrophysiologically observed desensitisation process in intact, single electroplax cells. The observation that the desensitised form of the receptor also allows inorganic ions to cross the membrane may account for several electrophysiological observations. The extent to which flux rates controlled by particular receptors perturb the transmembrane voltage depends on the extent to which they perturb the relative rates with which inorganic ions move through the cell membrane in the absence of the particular receptors[4-6,17]. The change in transmembrane potential due to the relatively slow rates associated with the desensitised form of the receptor, is expected to be particularly sensitive to these other fluxes of inorganic ions. Differences in the desensitisation behaviour of different cells, observed in electrophysiological experiments, may therefore reflect characteristics of the cell unrelated to the receptor.

The prediction of the sign and magnitude of the transmembrane potential of a cell, and therefore of the propagation of a signal in a variety of conditions, requires additional measurements. J_1 and J_2 can be evaluated from measurements of the effect of ligand concentration on the flux kinetics. Intrinsic flux rate constants can be determined from a knowledge of the effect of inorganic ion concentrations on J_1 and J_2, and of the number of receptor sites per vesicle and the internal volume of the vesicles. The results presented in Fig. 1 show that the technique which we have developed enable the required kinetic measurements to be made.

$$\ln\frac{[M^+]_t}{[M^+]_{t=0}} = -\frac{J_1L_0}{L_0+K_1}\left(\frac{1-e^{-\beta t}}{\beta}\right) - \frac{J_2L_0}{L_0+K_2}t \quad (1)$$

$$\ln\frac{[L\triangle]_{t=0}-[L\triangle]_t}{[L\triangle]_{t=0}} = -\beta t \quad (2)$$

$$\beta = \frac{k_{12}K_1}{L_0+K_1} + \frac{k_{34}L_0}{L_0+K_1} + \frac{k_{21}K_2}{L_0+K_2} + \frac{k_{43}L_0}{L_0+K_2} \quad (3)$$

$$K_{c2} = \frac{k_{43}}{k_{34}}, \qquad K_{c1} = \frac{k_{21}}{k_{12}} \quad (4)$$

Fig. 2 Minimum mechanism for acetylcholine receptor-controlled ion flux. The conformations referred to as active and inactive by Katz and Thesleff[13] on the basis of electrophysiological experiments are represented by △ and □, respectively. J_1 and J_2 are the rate coefficients for ion fluxes associated with the different receptor conformations (△ and □). Omitted from the scheme for simplicity are the equilibria between the open and closed channel forms of the receptor: ligand complexes, differences in which may be responsible for the differences between J_1 and J_2. K_1 and K_2 are the ligand dissociation constants pertaining to the two conformations. $[L\Delta]$ in equation (2) represents the concentration of the receptor: ligand complex and the subscript t refers to the time of measurement. β reflects the rate constants for the isomerisation of receptor conformations[11]. The integrated rate equation published previously[11] has been simplified, recognising that the two phases of the reaction occur in widely different time regions.

Aggregation of human platelets *in vitro* can occur in two phases—primary and secondary aggregation[1]. Primary aggregation is due to the direct interaction of the aggregating agent with its receptor[2,3], whereas secondary aggregation is associated with both the secretion of dense granule constituents, including the aggregating agents, serotonin and ADP (ref. 4) and the activation of a pathway for the conversion of arachidonic acid to prostaglandins (PGs)[5]. Both secondary aggregation and the associated secretion of dense granule constituents are contingent on the formation of PGG_2 and PGH_2 which can, in part, be transformed into thromboxane (TX) A_2 (refs 1, 3, 6, 7). TXA_2 is a potent aggregating agent and apparently the functionally active compound in the arachidonate pathway[8-10]. However, the precise role of TXA_2 in mediating secondary aggregation is a matter of controversy as it is not clear whether secondary aggregation can occur independently of secretion. We report here that platelets from cats with the Chediak–Higashi (CH) syndrome[11] aggregate with arachidonate in a cyclooxygenase-dependent manner and that biphasic aggregation produced by serotonin is accompanied by TXB_2 formation without detectable ADP secretion. These results demonstrate that secondary platelet aggregation can be mediated through thromboxane formation without participation of secreted ADP.

We have studied the aggregation and secretion of CH cat platelets and simultaneously measured TX formation. Most human patients and all animals, including the cats in this study,

2	0.004	0.131	0.143
3	0.004	0.087	0.508
Normal	0.248	—	0.465‡

* Total adenine nucleotides (ATP and ADP) and ATP were determined in ethanol–EDTA extracts by a firefly luciferin/luciferase method[23].

† TXA_2 is unstable and rapidly decomposes to TXB_2 (ref. 7) which was measured by radioimmunoassay[24].

‡ TXB_2 formation was only assessed in platelets which exhibited serotonin-induced secondary aggregation.

with CH syndrome have an intrinsic platelet defect. In the one human patient studied[12] and all CH animals[13,14], there is a virtual absence of serotonin and stored adenine nucleotides. Therefore, aggregation of CH platelets should be independent of secreted ADP and serotonin.

Aggregation responses in platelet-rich-plasma (PRP) from CH cats were monitored with an aggregometer (Chrono-log Corporation). Figure 1 shows that arachidonate induced monophasic irreversible aggregation of CH cat platelets and that this aggregation was completely inhibited by the cyclooxygenase inhibitor indomethacin. Three minutes after the addition of arachidonate the extracellular ADP concentration of normal PRP was 2.14 μM whereas CH PRP contained less than 0.01 μM. These results indicate that metabolites of arachidonic acid can aggregate platelets in the absence of ADP or serotonin secretion and confirms the findings of other workers using rabbit

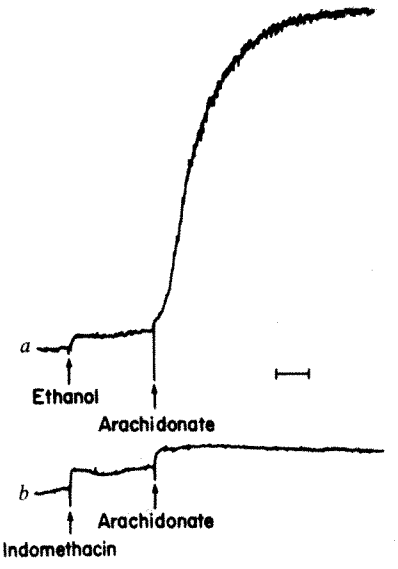

Fig. 1 Aggregation of platelets from CH cat no. 1 to 0.5 mM arachidonate following absolute ethanol treatment (20 μl ml^{-1}) (*a*) and its inhibition by 20 μM indomethacin in absolute ethanol (20 μl ml^{-1}) (*b*). Blood samples were withdrawn from the jugular vein from fasted cats anaesthetised with thiamylal sodium. Sodium citrate was used as the anticoagulant (1 part citrate: 9 parts blood). PRP was prepared by centrifugation at 160*g* at room temperature, and the platelet counts adjusted to 400,000 per μl using autologous platelet-poor plasma (PPP). Scale bar represents 20 s and the aggregation response of *a* represents 95% of change in light transmission between PRP and PPP. Arachidonate-induced aggregation of feline CH platelets was also inhibited by aspirin (20 μM) in sodium acetate, and platelets from normal cats gave monophasic aggregation with 0.5 mM arachidonate (data not shown).

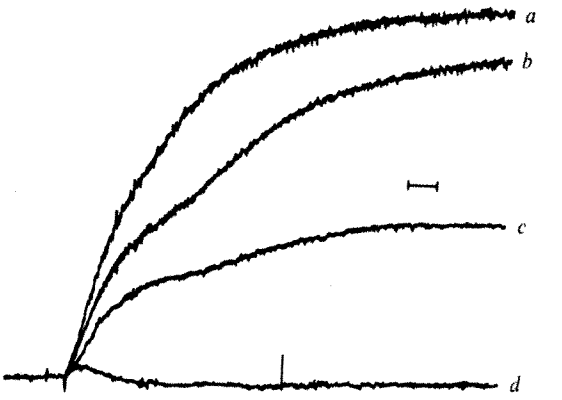

Fig. 2 Aggregation response of platelets from CH cat no. 1 to serotonin. *a*, 50; *b*, 12.5; *c*, 3; *d*, 1.5 μM. The scale bar represents 20 s and the aggregation response of *a* is 90% of the change in light transmission between PRP and PPP.

platelets depleted of the constituents of dense granules[15] and human platelets with nucleotide storage pool deficiency[16].

Serotonin is a potent inducer of the aggregation of normal cat platelets[17]. The aggregation is biphasic[17] and associated with nucleotide secretion (Table 1). Serotonin also induced biphasic aggregation of CH cat platelets (Fig. 2) which was not accompanied by ADP secretion (Table 1). With increasing concentrations, platelets exhibited first primary reversible aggregation, then biphasic aggregation and finally, monophasic irreversible aggregation. This finding clearly demonstrates that secondary aggregation may occur by processes independent of dense granule secretion.

The serotonin-induced aggregation of CH cat platelets was progressively inhibited by increasing concentrations of three serotonergic receptor antagonists, methysergide, SQ-10,631 and cyproheptadine (Fig. 3). Therefore, both the primary and secondary phases of aggregation seem to depend on the interaction between serotonin and its specific platelet receptor[2,3]. Although the impulse for the secondary wave of aggregation may have been initiated by the platelet–platelet contact which occurs during serotonin-induced primary aggregation, this seems unlikely as ADP induced primary, but not secondary, aggregation of CH cat platelets (data not shown).

The serotonin-induced secondary aggregation of CH cat platelets required arachidonic acid metabolism. When the formation of PGs was inhibited by treating CH cat platelets with either aspirin or indomethacin, secondary aggregation was abolished (Fig. 4). Furthermore, serotonin caused untreated

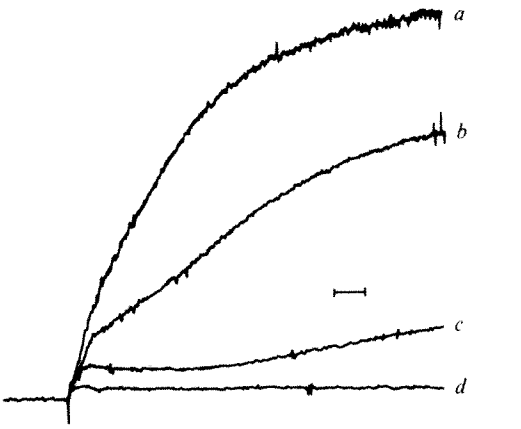

Fig. 3 Aggregation of platelets from CH cat no. 1 to 50 μM serotonin in the presence of increasing cyproheptadine concentrations: *a*, 0.31; *b*, 0.63; *c*, 1.25; *d*, 10 μM. Scale bar represents 20 s. Aggregation responses of *a*–*d* were, respectively, 88, 62, 16 and 1% of the change in light transmission between PRP and PPP. Similar aggregation curves were obtained with both methysergide and SQ-10,631 (data not shown).

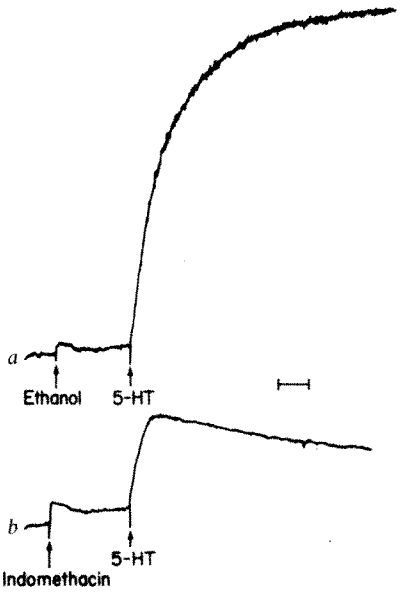

Fig. 4 Aggregation of platelets from CH cat no. 1 to 50 μM serotonin in the presence of indomethacin (20 μM) in absolute ethanol. *a*, Represents serotonin-induced aggregation 1 min after absolute ethanol treatment (20 μl ml^{-1} PRP). *b*, Represents serotonin-induced aggregation 1 min after indomethacin treatment. Scale bar represents 20 s. Similar aggregation was observed with aspirin (20 μM) in sodium acetate (data not shown).

normal and CH cat platelets to produce TXB_2 in a concentration-dependent fashion (Table 1).

It has been suggested that secretion precedes secondary aggregation, which is regarded as being due to increased extracellular levels of ADP and serotonin because PG endoperoxides and TXA_2 can induce a rapid release of serotonin and ADP from platelets[7,18]. This hypothesis is supported by the demonstration of an absence of secondary aggregation of platelets from most, but not all, patients with storage pool deficiency (a group of congenital disorders with a deficiency of platelet dense granules[19,20]). On the other hand, arachidonic acid, PGG_2 and PGH_2 cause aggregation of platelets from these patients[16] and of normal rabbit platelets depleted of dense granular constituents[15]. PGG_2 and PGH_2 can also cause aggregation of normal platelets without demonstrable nucleotide secretion[21]. These results suggest that secondary aggregation may be the result of a direct aggregating effect of TXA_2 and is independent of secretion. Indeed, secondary aggregation frequently precedes secretion and it has been suggested that secretion and secondary aggregation are parallel events which are not causally related[22].

It is clear that in the case of serotonin-induced aggregation of platelets from CH cats, secondary aggregation is not the consequence of increased extracellular levels to ADP and serotonin, but is directly related to the formation of TXA_2. The results, therefore, support the hypothesis of Charo and associates[21] that secondary platelet aggregation can occur independently of secretion. The reason that human platelets from some patients with storage pool deficiency have defective secondary aggregation is not clear. If these platelets are not deficient in cyclooxygenase or thromboxane synthetase, the lack of secondary aggregation could be explained by a positive feedback loop in which secreted substances are required to enhance the formation of TXA_2 to give complete secondary aggregation[3].

Vanadate inhibits $(Na^+ + K^+)$ATPase by blocking a conformational change of the unphosphorylated form

Physiological Laboratory, University of Cambridge, Cambridge, UK

In the presence of extracellular K, intracellular orthovanadate is a potent inhibitor of $(Na^+ + K^+)$ATPase[1–3], and because this effect may have a physiological role[3–6], it is interesting to ask at which step in the enzyme cycle vanadate acts. In experiments with red cells and squid axons containing high concentrations of ATP, Beaugé and DiPolo[7,8] found that added vanadate modified the effects of extracellular K, or congeners of K, in a similar way to lowered ATP concentration. They suggested that vanadate might act by retarding the relatively slow, ATP-sensitive, conformational change that is thought to follow the hydrolysis of phosphoenzyme, when that hydrolysis is catalysed by extracellular K (ref. 9). There are several reasons for thinking that the same conformational change ($E_2K \rightarrow E_1K$) is the rate-limiting step in the conversion of E_2K to E_1Na that occurs when sufficient Na is added to $(Na^+ + K^+)$ATPase preparations suspended in low-K media in conditions which preclude phosphorylation[10–14]. The speed of the $E_2K \rightarrow E_1K$ change, in those circumstances, can be measured by the use of several different fluorescent techniques[10–12,15], and we report here experiments with a fluorescein-labelled enzyme to investigate the effects of vanadate. It turns out that, in the same conditions in which vanadate inhibits $(Na^+ + K^+)$ATPase activity, it greatly slows the rate of the conformational change $E_2K \rightarrow E_1K$.

Our method takes advantage of the increase in fluorescence that occurs when fluorescein-labelled enzyme changes from the form that exists in Na-free, K-containing media (E_2K), to the form that exists in high-Na media containing little or no K (E_1Na)[12,15]. The increase in fluorescence is thought to reflect a change in the immediate environment of the fluorescent groups brought about by the change in conformation of the enzyme.

Enzyme prepared from the outer medulla of pig kidney, by the method of Jørgensen[16], was labelled with fluorescein as described in Fig. 1 legend. (The procedure leads to the

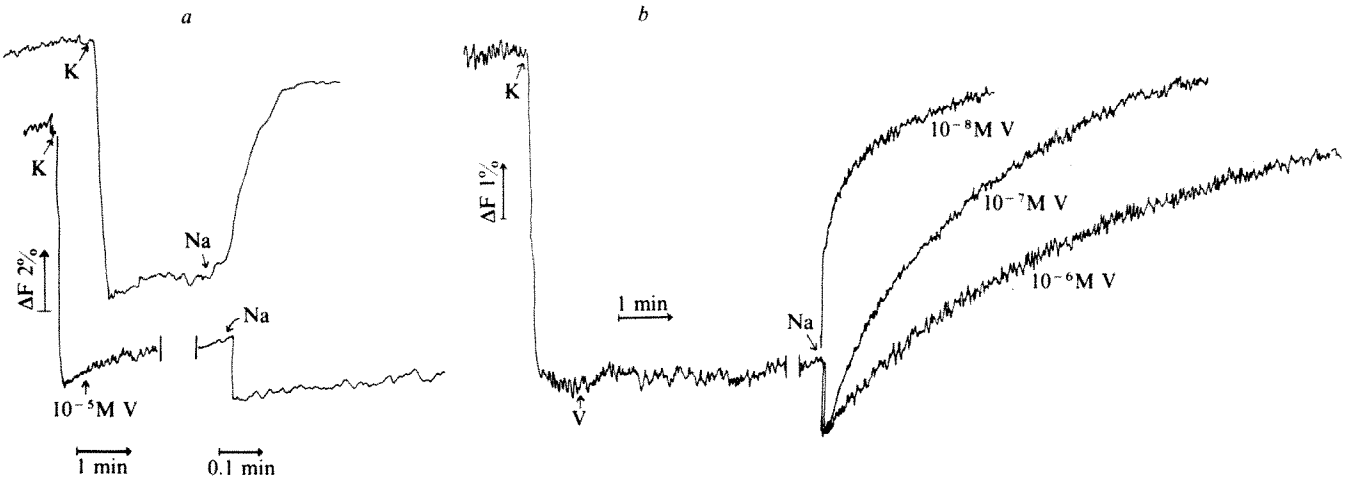

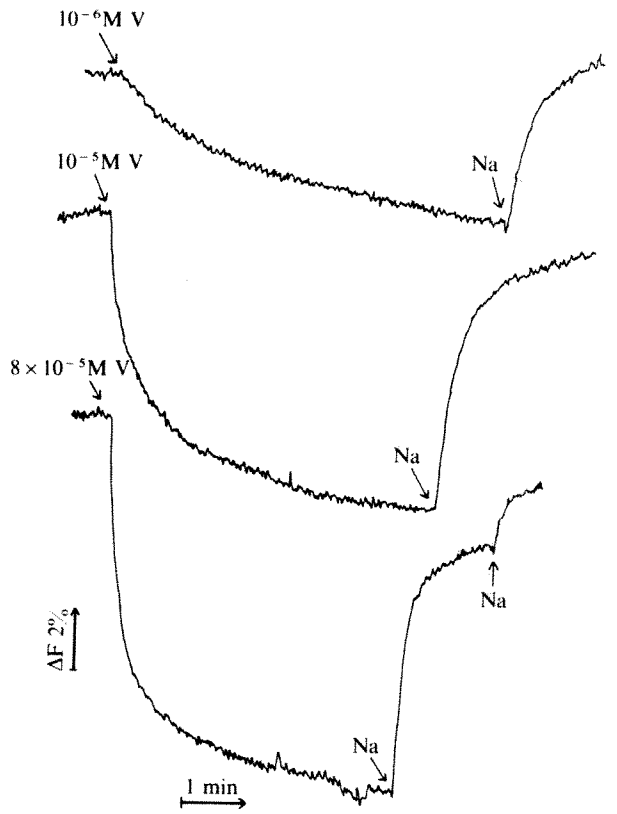

Fig. 1 Ten mg of enzyme (specific activity 20 μmol mg^{-1} min^{-1}) was incubated in 3.7 ml of a solution containing 100 mM NaCl, 50 mM Tris/Tris-Cl (*p*H 9.2 at 20 °C) and 5 mM 1,2-diaminocyclohexanetetraacetic acid. Fluorescein was added as a 150 μM solution in dried dimethyl formamide to give a final concentration of 7 μM. The suspension was allowed to stand for 30 min at 24 °C and was then dialysed at 0 °C against several changes of 150 mM Tris/Tris-Cl (*p*H 7.5 at 20 °C) containing bovine serum albumin (1 mg ml^{-1}) over a period of 48 h. For measurements of fluorescence, 60 μg of labelled enzyme was suspended in 2.5 ml of a solution containing 40 mM Tris/Tris-Cl (*p*H 8.0 at 20 °C) and 1 mM $MgCl_2$. Excitation was at 495 nm; emission was measured at 520 nm; the slit width was 10 nm, and the time constant of the machine was set at 0.3 s. The temperature was 20 ± 2 °C. *a*, Upper trace shows quenching of fluorescence by KCl (final concentration 16 mM) and the reversal of that quenching by NaCl (final concentration 80 mM). The lower trace shows that ammonium vanadate (10^{-5} M final concentration), added after the KCl, blocked the reversal by NaCl. Note (1) the gap in the lower trace represents a period of 5 min, designed to give the vanadate time to act; (2) the time scale was expanded 10-fold just before Na was added; (3) the apparent incompleteness of the reversal by NaCl is due to dilution of the enzyme; this also accounts for the sudden drop in fluorescence following the addition of NaCl in the lower trace. The drop due to dilution is not seen in the upper trace because it is masked by the rapid rise in fluorescence. *b*, Traces showing the effects of three different concentrations of vanadate on the rate of rise in fluorescence following the addition of NaCl. For 10^{-6} M vanadate, the complete curve is shown; for the other two vanadate concentrations only the part of the curves following the addition of NaCl is shown. Note (1) the gap in the trace represents a period of 5 min, designed to give the vanadate time to act; (2) the time scale was kept constant in these experiments; (3) with 10^{-8} M vanadate, the concentration of vanadate was much lower than the concentration of enzyme ($\sim 10^{-7}$ M), and the large amount of uninhibited enzyme accounts for the rapid initial rise in fluorescence, and the masking of the expected drop due to dilution.

incorporation of fluorescein groups into the large polypeptide chains of the enzyme, probably near the ATP binding sites. The labelled enzyme is unable to bind or to hydrolyse ATP, but it can still undergo the normal interconversion between E_1 and E_2 forms in response to changes in the concentrations of Na and K[12,15].) The fluorescein-labelled enzyme was suspended in a buffered medium, containing Mg but lacking both Na and K, in a fluorimeter cell fitted with a device that allowed additions to be made, and the suspension to be stirred, while the fluorescence was being recorded. In the Na-free, K-free medium, the enzyme was in the E_1 form and the fluorescence was high. When KCl was added to give a final concentration of 16 mM, there was a rapid fall in fluorescence as the enzyme was converted into the E_2K form (Fig. 1). (In the Mg-containing medium the K^+-induced fall in fluorescence is about 30% smaller than that observed in Mg-free media[15].) Vanadate was then added to give final concentrations in the range 0–10^{-5} M, and was allowed 5 min to act; no significant change in fluorescence occurred during this period. Finally, NaCl was added to give a final concentration of 80 mM. In the absence of vanadate, the fluorescence rose to its original level (allowing for dilution) within 5 s (Fig. 1*a*). With increasing concentrations of vanadate, the rise in fluorescence was progressively slower (Fig. 1*b*), until, with 10^{-5} M vanadate (Fig. 1*a*), the addition of Na had very little effect. The inhibition

Fig. 2 The reduction in the fluorescence of fluorescein-labelled enzyme by ammonium vanadate in the absence of KCl, and its reversal by NaCl (80 mM final concentration). The preparation of the enzyme, and the incubation conditions, were identical with those described in the legend to Fig. 1. Note (i) that the range of vanadate concentrations used in these experiments is higher than that in the experiments of Fig. 1; (ii) that ammonium ions were present in much too low a concentration to account for the fluorescence change; (iii) control experiments with Tris/Tris Cl showed that the effect of adding NaCl was not due to the increase in ionic strength.

by vanadate probably reflects the formation of a stable enzyme–K–Mg–vanadate complex[7].

In a second experiment, ammonium vanadate, in the concentration range 10^{-6} M–8×10^{-5} M, was added to enzyme suspended in the same Mg-Tris medium in the absence of both Na and K. As shown in Fig. 2, the addition of vanadate, in these conditions, itself caused a drop in fluorescence—faster at higher vanadate concentrations—which could be rapidly reversed by the addition of NaCl. The drop in fluorescence presumably reflected the net conversion of the enzyme to the E_2 form. This must have been caused by the vanadate ions, for, even at the highest concentration of ammonium vanadate, the ammonium ions alone could not have accounted for more than about 5% of the observed change. Furthermore, essentially similar results were obtained when Na vanadate was used. Addition of 80 mM NaCl before the addition of vanadate prevented the fluorescence change.

Inhibition of $(Na^+ + K)$ATPase by vanadate occurs only in the presence of Mg ions[1], which act at the intracellular surface[5,17]. It is therefore significant that the inhibition of the $E_2 \rightarrow E_1$ conformational change by vanadate could be detected only when Mg ions were present (not shown).

Taken together, the experiments reported here provide strong evidence that vanadate inhibits $(Na^+ + K^+)$ATPase activity by blocking the $E_2K \rightarrow E_1K$ conformational change that is thought to follow hydrolysis of the phosphoenzyme. When $(Na^+ + K^+)$ATPase preparations catalyse the hydrolysis of ATP in the absence of K, the rate limiting step is thought to be the hydrolytic step and not the subsequent conformational change. In the absence of K, therefore, we should expect the hydrolytic activity of the enzyme to be very much less sensitive to vanadate. Such a decrease in sensitivity is, in fact, observed, but the relation between K concentration and the effects of vanadate[7,8,18] cannot be wholly explained in this way.

We thank Mrs. R. Goldshlegger for technical assistance, and the Medical Research Council for financial support.

Vanadium compounds have been reported to inhibit the $(Na^+ + K^+)$ATPase activity of several cell membrane preparations[1–3], to have a positive inotropic effect on ventricular cardiac muscle[4], slightly increase myocardial cyclic AMP levels[5], stimulate fat cell adenylate cyclase[6], and cause natriuresis in rats[7]. Recently we have reported that vanadate produces a transient, initial stimulation of $(Na^+ + K^+)$ATPase activity in a cat heart cell membrane preparation, in addition to its well known inhibitory action on this enzyme system[8]. The transient stimulation occurred at the same concentration range as did the inotropic effects. There was, however, a serious discrepancy between the time courses of the two events. The former lasted only a few minutes, whereas the latter remained virtually stable for at least 30 min. The supposed stimulatory action of vanadate on $(Na^+ + K^+)$ATPase was deduced from an initial rapid loss of NADH in the ATPase assay used (optical coupled assay with an ATP regenerating system[9]). The oxidation of NADH was followed photometrically by continuous recording[8]. We now report that the rapid loss of NADH and hence the claimed transient stimulatory action of high concentrations of vanadate on the $(Na^+ + K^+)$ATPase activity is caused rather by an oxidation of NADH as a result of a NADH-dependent reduction of vanadate.

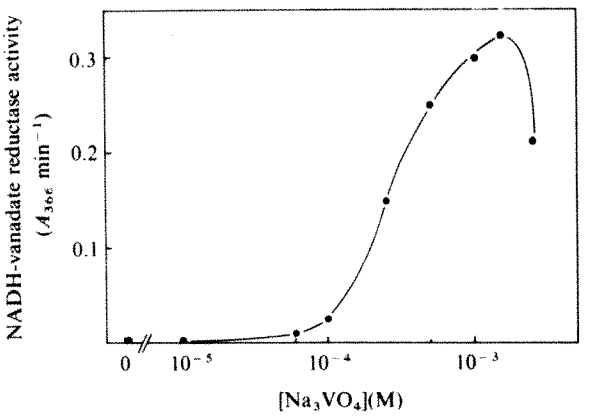

Fig. 1 Effect of vanadate on NADH-reductase activity in a calf ventricular cardiac cell membrane preparation. Calf cardiac cell membranes[10] (0.15 mg protein, 98% of total ATPase activity could be inhibited by 100 μm ouabain; $(Na^+ + K^+)$ATPase activity was 1.15 U per mg membrane protein) were incubated at 37 °C in 10 mM imidazole/HCl buffer, *p*H 7.25, 1.5 mM NADH (Boehringer Mannheim) and the stated concentrations of Na_3VO_4 (freshly prepared). Similar results were obtained with NH_4VO_3. Total volume 1.6 ml. The oxidation of NADH was followed photometrically at A_{366} by continuous recording. Similar results have been obtained with cell membranes from cat ventricles, human heart and human erythrocytes (not shown). Heating the cardiac cell membranes for 30 min at 60 °C completely destroyed enzyme activity. This curve exhibiting the oxidation of NADH (and reduction of vanadate) has the same concentration dependence as the formerly[8] reported rapid initial stimulation of NADH oxidation. This demonstrates that the coupled optical assay with NADH often used to measure ATPase activity is seriously influenced by NADH-vanadate reductase activity. The inhibition of enzyme activity at higher vanadate concentrations ($>10^{-3}$ M) might be due to the fact that NADH is oxidised very quickly.

The cardiac cell membrane preparation used in these and the former[8] experiments was isolated by the method of Pitts and Schwartz[10] but without the glycerol treatment. $(Na^+ + K^+)$ATPase activity was determined as 0.32 U per mg

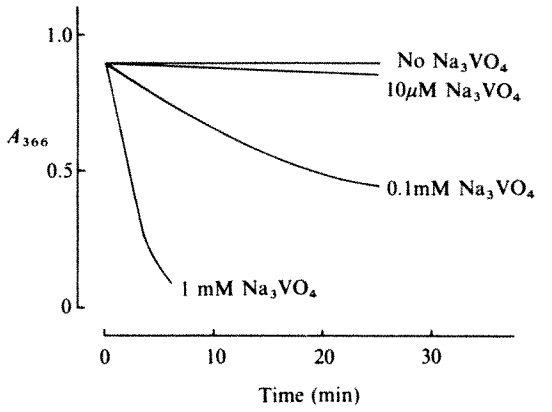

Fig. 2 Time and concentration dependence of NADH oxidation by NADH-vanadate reductase. Calf cardiac cell membranes[10] (0.02 mg protein) were incubated in 10 mM imidazole/HCl buffer, *p*H 6.75, 1.5 mH NADH and the indicated concentrations of Na_3VO_4; total volume 1.6 ml. The experiment was carried out in the same way as in Fig. 1. The curve shows that the oxidation of NADH is linear with time for several minutes.

membrane protein; 97% of total ATPase activity could be inhibited by ouabain (100 μM) and thus was defined as $(Na^+ + K^+)$ATPase. One enzyme unit is defined as 1 μmol ATP hydrolysed per min at 37 °C. Protein was measured as described by Lowry *et al.*[11].

When purified cardiac membranes[10] are incubated with NADH and different concentrations of vanadate but without ATP, a rapid oxidation of NADH, probably due to a reduction of $H_2VO_4^-$ (or $V_4O_{12}^{4-}$ or $V_3O_9^{3-}$)[12] to VO^{2+} is measured (Fig. 1). Thus, our previous interpretation of a stimulatory action of vanadate on $(Na^+ + K^+)$ATPase activity no longer seems justified.

A further analysis shows that the rate of NADH oxidation does depend on the concentration of vanadate (Fig. 2). Furthermore, increasing the amount of membrane protein in the test tubes results in an appropriately increased NADH oxidation (Fig. 3). As there is no NADH oxidation either in the presence of vanadate without membrane protein or in the presence of heat-denatured membranes, the isolated cell membranes must contain a NADH-vanadate reductase. The activity of this enzyme was stable for 4 d when kept at 4 °C and lost ~20% activity within 7 d (not shown). The vanadate concentration activating this enzyme half maximally (0.25 mM, Fig. 1) was rather high compared with the concentration of vanadium in serum or tissue (0.1–1 μM)[1,13]. Thus, unless higher vanadate concentrations at active sites are assumed, the enzyme does not

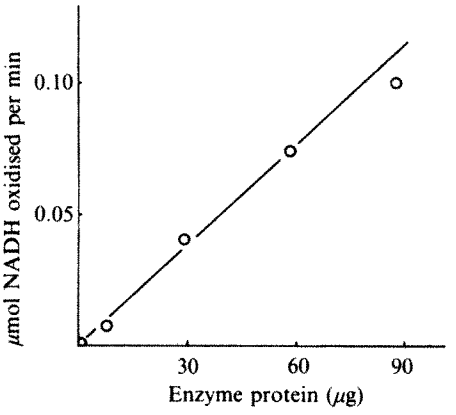

Fig. 3 The oxidation of NADH is increased linearly when the amount of enzyme protein is increased. The experiment was carried out as in Fig. 2 but with increasing amounts of calf cardiac cell membranes[10]. There was no NADH oxidation without enzyme.

function at optimal activity in physiological conditions. However, for most enzymes the Michaelis constant (K_m) has been found to be in this range (10–0.01 mH)[14].

As oxidation–reduction mechanisms are widespread in biological systems and have been found in high activities in the plasma membrane, cytoplasma and mitochondrial membrane of a variety of tissues, we think that this NADH-vanadate reductase activity is probably part of the well known plasma membrane NADH–oxidoreductase complex[15]. The exact significance of this enzyme for the action of vanadate at the molecular level requires further examination.

It is well known that vanadium compounds exhibit various valence states (II–V) and can be oxidised or reduced easily[15,16]. It is surprising, however, that purified cardiac cell membranes as used in these experiments contain such high amounts of vanadate reductase activity (about 1.1 U per mg protein). In the light of the results of Cantley *et al.*[1], suggesting that vanadate "may be an ideal specific regulator of $(Na^+ + K^+)$ATPase", this NADH-vanadate reductase in cardiac membranes might have physiological significance. Recently, it has been reported that most of the vanadate in red cells is reduced to vanadyl (VO^{2+}) and bound to haemoglobin[17].

Alamethicin-induced single channel conductance fluctuations in biological membranes

B. Sakmann* & G. Boheim†

* Max-Planck-Institut für biophysikalische Chemic, D-3400 Göttingen, FRG
† Ruhr-Universität Bochum, Lehrstuhl für Zellphysiologie, D-4630 Bochum, FRG

Alamethicin, a polypeptide of molecular weight ~2,000, induces voltage-dependent conductance phenomena in artificial lipid bilayer membranes that are in some ways similar to those found in excitable membranes[1]. Alamethicin-induced conductance is probably a consequence of the formation of predominantly cation-selective channels which span the bilayer, and single open channels fluctuate at random between several well defined conductance states[2–5]. Statistical analysis of single channel conductance fluctuations in planar lipid bilayers of various compositions has revealed that, whereas the conductance values are relatively constant in a variety of membranes, the average lifetime of the individual conductance states depends strongly on the lipid used to form the bilayer. This variability has tentatively been attributed to differences in lipid fluidity[6,7]. Alamethicin is therefore a probe of some aspects of membrane composition. The study of single alamethicin channels in various natural membranes would allow comparison with

the well defined bilayer systems and might yield information on lipid properties of natural membranes that could be important for the functioning of natural membrane channels and receptors. The experiments reported here show that alamethicin channels have similar conductances in the sarcolemmal (surface) membrane of frog and rat muscle and in lipid bilayers formed from synthetic lecithin. The average lifetime of the conductance states is, however, one order of magnitude larger in the biological membranes.

Experiments were carried out on frog (*Rana temporaria*) cutaneous pectoris and rat (Sprague–Dawley) omohyoid muscles bathed in their respective Ringer solutions (for ionic composition see Figs 1 and 3 legends). Alamethicin was applied to a small patch of the extracellular surface of the sarcolemma from a pipette containing alamethicin at nominal concentrations of 9–50 $\mu g\ ml^{-1}$. Alamethicin-induced membrane currents were measured by the extracellular patch clamp method[8,9]. The membrane potential of the muscle fibre was controlled locally by means of a two-microelectrode voltage-clamp circuit.

Figure 1*a* shows membrane current fluctuations as a function of time, recorded from a patch of frog muscle membrane in the presence of alamethicin at a membrane potential of −110 mV. The tip of the pipette had been in contact with the muscle membrane for ~20 s during which the membrane remained in the resting state. At point A (Fig. 1*a*), an inward current step is recorded indicating a sudden spontaneous conductance increase of the membrane patch under investigation. The membrane current then fluctuates between six discrete levels of amplitude, some of which occur with a greater probability than others. At point B the current returns to the resting level. This type of current fluctuation closely resembles the pattern seen in lipid bilayer experiments in the presence of low alamethicin concentrations and has been ascribed to the formation of a single pore structure, undergoing transitions between different conductance states and then disappearing[4,5,10,11]. Current bursts like that shown in Fig. 1*a* occur at irregular intervals. The times between single bursts vary between a few seconds and about 1 min. It is difficult to investigate interval durations systematically because in most experiments after a few minutes, two or more alamethicin channels become active. This could be due to a continuous increase in alamethicin concentration at the membrane surface. It precludes single channel measurements from the same membrane patch over long periods.

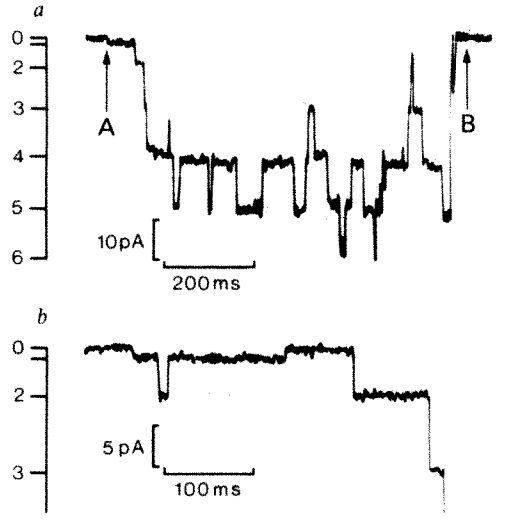

Fig. 1 Alamethicin-induced current fluctuations as a function of time. Frog sarcolemmal membrane at 18 °C. Inward current is downwards. The muscle was bathed in frog Ringer solution of the following composition (in mM): Na^+ 118; K^+ 2.5; Ca^{2+} 1.8; Cl^- 121; HPO_4^{2-} 2.15; $H_2PO_4^-$ 0.5; *p*H 7.2. Alamethicin (9 $\mu g\ ml^{-1}$) dissolved in frog Ringer was applied to the extracellular side of the surface membrane through a patch-pipette with a tip diameter of approximately 2 μm. The pipette had a d.c. resistance of 2.5 MΩ. The seal resistances when the pipette was in contact with the muscle were 12–20 MΩ. This results in a slight underestimation (≤15%) of the true current amplitudes[9]. *a*, Oscilloscope traces of a current 'burst' at −110 mV membrane potential. At the time indicated by the arrow labelled A, an inward membrane current turns on, fluctuates for about 1 s between different amplitude levels and at the time indicated by the arrow labelled B, returns to the resting level. Six discrete levels of current amplitude are discernible. The different levels are indicated by the numbered scale on the left side. The level marked 0 corresponds to the resting membrane. *b*, Oscilloscope traces of the initial part of another current burst shown at a faster time base, and higher gain so as to illustrate more clearly the size of the first, second and third current levels. The membrane potential was clamped to −110 mV. The different levels are indicated by the numbered scale on the left side. Resting membrane corresponds to level 0. Both records were low pass filtered at 200 Hz with Bessel characteristics. For analysis of current step sizes and durations, records were stored on magnetic tape. They were replayed on a pen writer at reduced speed. Step sizes and durations were measured by hand and then analysed on a PDP 11/34 computer.

Table 1 Relative distribution probabilities, P_ν (%) and mean lifetimes, τ_ν (ms) of alamethicin conductance states in natural and synthetic membranes

Conductance state	Frog sarcolemma (−70 mV/18 °C)		Rat sarcolemma (−65 mV/20 °C)		Rat sarcolemma (−60 mV/30 °C)		Dioleyllecithin bilayer (−90 mV/18 °C)	
	P_ν	τ_ν	P_ν	τ_ν	P_ν	τ_ν	P_ν	τ_ν
1					39	50	9	1.5
2	10	40	74	130	27	35	20	2.8
3	26	35	19	70	16	35	37	2.4
4	41	40	5	45	12	30	21	2.7
5	19	25	2	40	5	25	6	2.5
6	3	20	—	—	1	10	—	—
7	1	20	—	—	—	—	—	—

In experiments on muscle fibres the pipette contained 9 $\mu g\ ml^{-1}$ alamethicin. Numbers in parentheses refer to membrane potential and temperature. The relative distribution probability was calculated by dividing the sum of durations of each current level by the total duration of the current bursts. The mean lifetime was obtained from the decay constant of the distribution of durations at each level fitted by a single exponential. P_ν and τ_ν values represent means obtained from at least 50 individual events obtained from bursts at the same membrane patch. The beginning of a single burst was defined by the appearance of a spontaneous current jump from the resting level as shown in Fig. 1*a*. The end of a burst was given either by the return of membrane current to the resting level or by the appearance of a second pore. At membrane potentials of −60 to −70 mV burst durations are longer than at higher membrane potentials and up to 1,500 amplitude transitions occur during a single burst. However, the resting and the first conductance states are not always unambiguously discernible at these potentials. We therefore had to start the statistical analysis with the second conductance level. In experiments with artificial membranes, synthetic dioleylphosphatidylcholine was used to form the bilayer according to the Montal–Mueller technique[17]. The ionic composition of the solutions in the two compartments on both sides of the bilayer was chosen so as to mimic the ionic composition of the extra- and intracellular fluid in frog muscle experiments. The two compartments contained the following ions (in mM): compartment *A*: Na^+ 119.8; K^+ 2.5; Ca^{2+} 1.8; Cl^- 121.1; HEPES 4.8 (comparable to the extracellular bathing solution in muscle experiments). Compartment *B*: Na^+ 10.2; K^+ 140; Cl^- 2.2; HEPES 148 (comparable in its main cation composition to the intracellular composition of frog muscle[18]). HEPES was chosen to account for the large impermeable intracellular anions of muscle fibres. Compartment *B* was voltage clamped to −90 mV relative to compartment *A*. Alamethicin was added to compartment *A* at 0.5 $\mu g\ ml^{-1}$. The reversal potential for alamethicin-induced currents in this system was −38 mV, comparable to the experiments with frog muscle. The sequence of conductance states in this system is (in pS): $\Lambda_1 = 20$; $\Lambda_2 = 110$; $\Lambda_3 = 250$; $\Lambda_4 = 430$; $\Lambda_5 = 620$. (Recently, it has been found[19] that the lowest conductance state of the alamethicin pore in 1 M KCl at 21 °C is found at 19 pS. This would correspond to ~1.5 pS in the experimental conditions given in this study and is not resolvable by the present methods.)

Experiments with artificial bilayers have shown that the discrete current levels occurring during a burst are not integral multiples of a unit current step[2–4]. Figure 1*b* shows clearly that this is also the case in the muscle membrane, as the difference in amplitude between neighbouring current levels increases with the higher levels. Each current level is thought to reflect a discrete conductance state, ν, of the alamethicin channel. The different conductances, Λ_ν, of the channel in muscle sarcolemma were obtained by measuring current bursts at various membrane potentials and plotting the current–voltage relationship for the different states (Fig. 2). The relationship is approximately linear for all pore states in the range of membrane potentials measured. Extrapolation yields a reversal potential around −40 mV. The pore states vary over nearly two orders of magnitude in their conductance. In frog sarcolemma the Λ_ν values are in consecutive order (in pS): $\Lambda_1 = 20$, $\Lambda_2 = 100$, $\Lambda_3 = 260$, $\Lambda_4 = 460$, $\Lambda_5 = 660$, $\Lambda_6 = 860$. For comparison between channels in

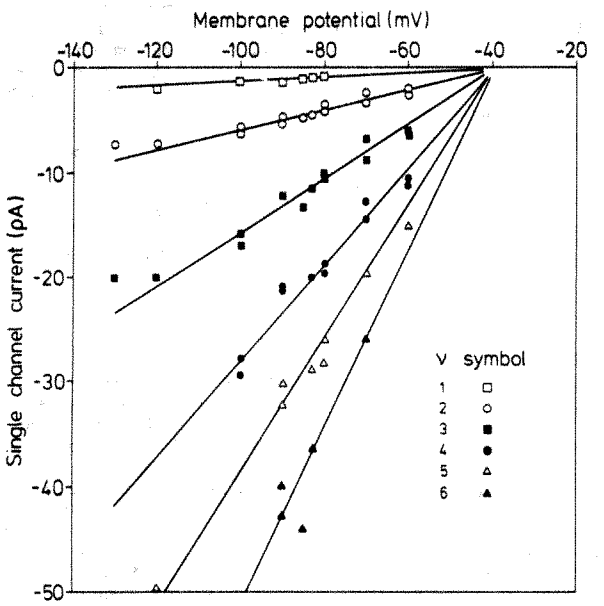

Fig. 2 Current–voltage relationships of the various conductance states, ν, of a single alamethicin channel in frog sarcolemma. The ordinate plots the average size of the inward membrane current during the individual conductance states (indicated by different symbols) as a function of membrane potential. Same experimental conditions as described in Fig. 1 legend with data pooled from two patches. The membrane potential was initially clamped to −130 mV until a current burst occurred. The potential was then shifted down stepwise to −60 mV. At each membrane potential the average size of the different discrete current levels occurring during a burst was determined from the amplitude distribution of the current burst. At each potential except at −60 mV, the level with the smallest average size was attributed to conductance state $\nu = 1$, the next larger level to state $\nu = 2$ and so on. At −60 mV membrane potential the average amplitude of the lowest level could not be measured accurately enough, therefore amplitude analysis was restricted to the higher states. The reversal potential of the alamethicin-mediated current obtained by linear extrapolation is near −40 mV. The conductance values, Λ_ν, of individual states ν obtained from the current–voltage relationships are (in pS): $\Lambda_1 = 20$; $\Lambda_2 = 100$; $\Lambda_3 = 260$; $\Lambda_4 = 460$; $\Lambda_5 = 660$, $\Lambda_6 = 860$. Similar experiments in rat muscle also gave a linear current-voltage relationship extrapolating to a reversal potential near −35 mV. The sequence of conductance values in rat (at 20 °C) is (in pS): $\Lambda_1 = 27$; $\Lambda_2 = 125$; $\Lambda_3 = 340$; $\Lambda_4 = 590$; $\Lambda_5 = 840$; $\Lambda_6 = 1{,}090$.

synthetic and muscle membrane, we have measured, in comparable experimental conditions (see Table 1 legend), alamethicin channel conductances in black lipid films made from synthetic lecithin. The Λ_ν values in this membrane are (in pS): $\Lambda_1 = 20$, $\Lambda_2 = 110$, $\Lambda_3 = 250$, $\Lambda_4 = 430$, $\Lambda_5 = 620$. The conductance sequences of alamethicin channels in the lipid bilayer and in muscle sarcolemma agree quite well. This similarity suggests that bursts like that shown in Fig. 1*a* are due to conductance fluctuations of a single alamethicin pore, as has previously been established in bilayer experiments[2–4].

The relative stability of the conductance states and the rates of transition between different states were evaluated by measuring relative distribution probabilities, P_ν, of each conductance state and their respective mean lifetimes, τ_ν, according to Boheim[4]. Table 1 shows the P_ν and τ_ν values of alamethicin pore states in frog muscle at 18 °C and −70 mV membrane potential. The channel adopts the three most probable states during ≈80% of the burst duration, the most stable state being the fourth one with a mean lifetime of 40 ms. For comparison, corresponding values of P_ν and τ_ν are given for the alamethicin channel in the lecithin bilayer. The distribution probabilities of the different pore states are comparable in both frog sarcolemma and lecithin bilayer, although the width of pore state distributions is somewhat narrower in the bilayer. However, there is a large difference in the average lifetimes of the pore states in the two membranes, the means of the τ_ν values of the three most probable states differing by more than one order of magnitude.

The difference in the open–close kinetics of the sodium channel[12] reported for frog and rat muscle prompted us to compare alamethicin channel state kinetics in both types of muscle. Figure 3*a* shows a recording of current through a patch of rat sarcolemmal membrane in the presence of a single conducting alamethicin pore. The conductances of corresponding pore states are somewhat larger in rat than in frog muscle, as would be expected from the different Ringer solutions (see Fig. 2 legend). The average lifetimes of the lower pore states in rat are much longer than in frog muscle (Table 1).

As indicated in Fig. 3*b*, pore state lifetimes are strongly temperature dependent. At 30 °C, the lifetimes of all conductance states are shorter than at 20 °C and are comparable to the values found in frog muscle at 18 °C (Table 1). The activation energies for channel closing were calculated from Arrhenius plots of the means of τ_ν values of the three most probable states. In frog (range 12–21 °C) the activation energy is ~40 kcal mol^{-1}, and in rat (range 15°–30 °C), ~20 kcal mol^{-1}. These values are larger by a factor of 4 and 2, respectively, than those reported for artificial membranes[11,13].

Thus, the above experiments show that alamethicin induces ion-conducting channels in muscle sarcolemmal membrane which show many properties that are qualitatively similar to those described for alamethicin channels in synthetic lipid bilayers. This suggests that the molecular mechanisms underlying channel formation are similar in both types of membrane. The main difference between the lecithin bilayer and the sarcolemmal membranes lies in the rates of transitions between the different conductance states. The major lipid components of sarcolemmal membrane are lecithins and cholesterol[14], and in lipid bilayer experiments, pore state lifetimes can increase with cholesterol content of the bilayer[6]. Therefore, the long lifetimes in sarcolemmal membrane may be due to the high cholesterol content. The lower rates of conductance state transitions in rat are in agreement with a similar (approximately two- to threefold) difference in sodium channel kinetics between frog and rat muscle fibres[12,15,16]. This could indicate that some difference between frog and rat sarcolemma, such as membrane viscosity, is responsible for the difference in channel kinetics. By measuring alamethicin channel kinetics in natural membranes in various conditions it might be possible to gain some insight into how membrane lipids can affect the kinetics of naturally occurring ionic channels.

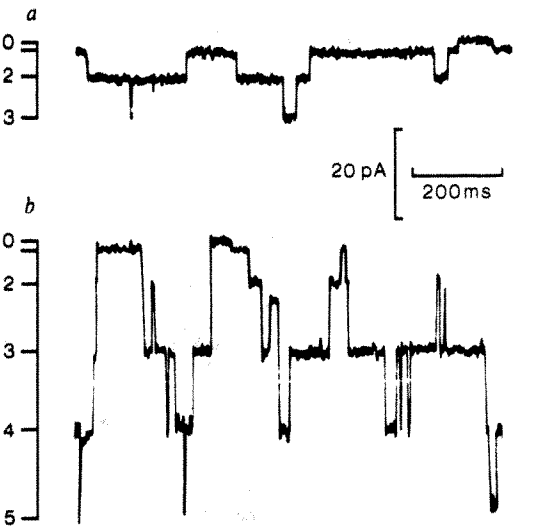

Fig. 3 Current fluctuations induced by alamethicin in rat sarcolemmal membrane at −95 mV membrane potential. Pipette contained 9 μg ml^{-1} alamethicin. Inward current is downwards. Muscle is bathed in rat Ringer solution of the following composition (in mM): Na^+ 156.4; K^+ 2.8; Ca^{2+} 1.0; Mg^{2+} 2.0; Cl^- 147.4; HPO_4^{2-} 8.2; $H_2PO_4^-$ 1.4; *p*H 7.2. *a*, Oscilloscope record of current fluctuations at 20 °C. Numbered scale on the left side indicates discrete current levels. Resting membrane level is indicated by 0. Note longer durations of individual current amplitude levels as compared with those observed in frog muscle at comparable temperature. *b*, Oscilloscope record of fluctuations at 30 °C. Calibrations are the same for both *a* and *b*.

This work was financially supported by the Deutsche Forschungsgemeinschaft (S.F.B. 114). Alamethicin was provided by Dr G. B. Whitfield (Upjohn) and dioleyllecithin was a gift of K. Janko and Professor P. Laüger.

Endogenous viral genes are non-essential in the chicken

Susan M. Astrin*†, Edward G. Buss‡ & William S. Hayward§

* Institute for Cancer Research, Fox Chase Cancer Center, 7701 Burholme Avenue, Philadelphia, Pennsylvania 19111

§ The Rockefeller University, New York, New York 10021

DNA sequences homologous to the genomes of type C retroviruses are widespread among vertebrates[1]. Ten genetic loci containing endogenous viral DNA sequences have been documented in the white Leghorn chicken alone[2,3]. Six of these genetic loci are associated with the production of virus or of viral proteins in embryonic fibroblasts (refs 2–4, and S.M.A., L. B. Crittenden and E.G.B., in preparation) and one of the loci may be expressed in the erythroblasts of 5-day-old embryos[5]. The ubiquitous presence of endogenous viral genes among vertebrate species and the association of their expression with development of the haematopoietic system in the mouse[6] have led to the proposal that these genes are involved in ontogeny. In addition, the genes may be implicated in oncogenesis as in the case of the AKR mouse in which a high incidence of spontaneous leukaemia is associated with the expression of endogenous murine leukaemia virus genomes[7,8]. We report here the production of a fertile rooster which lacks avian leukosis virus-related endogenous viral genes and which seems to be completely normal and healthy. Thus, endogenous viral genes are apparently not essential for the normal development of the chicken. An endogenous virus-free state has also been reported for three species of jungle fowl[9] and for the *B*-type viral genes of the mouse[10].

The DNA of individual chickens was assayed for the presence of endogenous viral sequences by cleavage of embryo or erythrocyte DNA with restriction endonuclease *Sac*I, electrophoretic separation of the resulting fragments, transfer of the fragments, after denaturation, to nitrocellulose filters[11], and detection of viral sequences by hybridisation with ^{32}P-labelled 70S RAV-2 RNA. Endonuclease *Sac*I (an isoschizomer of *Sst*I (ref. 12)) was chosen because it gives a single major band for each site of residence of viral genes in the chicken genome[2]. Most chickens analysed were homozygous for an endogenous viral locus previously designated as *ev* 1 (ref. 2). However, during a mating experiment involving chickens of defined genotype, we identified two matings which gave rise to a small fraction of embryonic progeny in which no endogenous proviruses could be detected. Twenty-one progeny from these matings were hatched, and DNA was extracted from erythrocytes and assayed for viral sequences. The fragment patterns for the dams, sires and 21 progeny of the two matings are shown in Fig. 1. The bands corresponding to molecular weights of 5.8, 3.7 and 12×10^6 each represent an individual site of residence of endogenous viral genes and have been designated *ev* 1, *ev* 2 and *ev* 5 in accordance with previous nomenclature[2]. As can be seen in Fig. 1, the dams each carried *ev* 1 and *ev* 5 (lane *a*) whereas the sires carried *ev* 1 and *ev* 2 (lane *b*). Of the 21 progeny, 16 inherited *ev* 1, 12 inherited *ev* 2, and 11 inherited *ev* 5. One of the progeny (no. 15) apparently inherited no endogenous viral loci. These data are consistent with the sires being heterozygous for both *ev* 1 and *ev* 2 and the dams being heterozygous for both *ev* 1 and *ev* 5. In this case, half the progeny (on average) would be expected to inherit *ev* 2, half would inherit *ev* 5, three-quarters would inherit *ev* 1 and one-sixteenth would be expected to inherit no endogenous viral loci. These figures are very close to the actual frequencies of inheritance observed in the progeny.

To test further the DNA of rooster no. 15 for endogenous viral genes, radiolabelled DNA probes complementary to RAV-0 RNA, the *src* gene, and total cellular DNA were prepared and annealed to the DNAs of chicken 15 and chicken 17. As shown in Fig. 2, the probe to total cellular DNA, the *src* gene probe and the RAV-0 probe extensively to the DNA of chicken 17. The differences in the final percentage of each probe that anneals are most probably due to differences in the sizes of the cDNA probes (see Fig. 2 legend). The DNA of chicken 15 shows normal annealing to the cellular DNA probe and to the *src* gene probe, but shows little or no annealing to the RAV-0 probe. This result is consistent with the DNA of chicken 15 containing less than 2% of the sequences of RAV-0. The presence of *src*-related sequences in the absence of RAV-0 sequences is consistent with the observation that the endogenous *sarc* gene segregates independently of endogenous viral structural genes[13].

As a more sensitive test for the presence of RAV-0 sequences in the DNA of chicken 15, cDNA probes corresponding to the *gag*, *pol* and *env* genes of ALV and to the 5′ 101 nucleotides and the 3′ 600 nucleotides ('c' region) of RAV-0 were prepared and annealed to the DNAs of chicken 15 and chicken 17. As shown in Table 1, the DNA of chicken 17 anneals extensively to the five

Table 1 Per cent cDNA hybridised in chickens 15 and 17

Probe*	No. 15	No. 17
$cDNA_{5'}$	2	66
$cDNA_{gag}$	0	61
$cDNA_{pol}$	1	57
$cDNA_{env}$	1	51
$cDNA_{c}$	1	67

Hybridisation was carried out to a C_0t of 3.5×10^4 mol s l^{-1} as described in Fig. 2 legend. All values were corrected for a background of 1–2% with heterologous (salmon sperm) DNA.

* cDNA probes, corresponding to the *gag*, *pol* and *env* genes, were prepared from RAV-2 cDNA. Isolation and characterisation of these probes have been described previously[19]. ^{32}P-labelled $cDNA_{5'}$ (specific activity 4×10^8 c.p.m. per μg) contains sequences complementary to the 101 nucleotides at the 5′ terminus of RAV-0 RNA. The DNA was prepared as described by Haseltine *et al.*[20]. $cDNA_{5'}$ was purified on 10% acrylamide gels, first with the primer tRNA attached, and then after removal of the primer by alkaline hydrolysis. $cDNA_c$ was prepared from RAV-0 cDNA by two cycles of selection against short (9–11S) poly(A)-containing fragments of RAV-0 RNA[19], and thus corresponds to the 500–600 nucleotides adjacent to the poly(A) tract at the 3′ end of the RAV-0 genome.

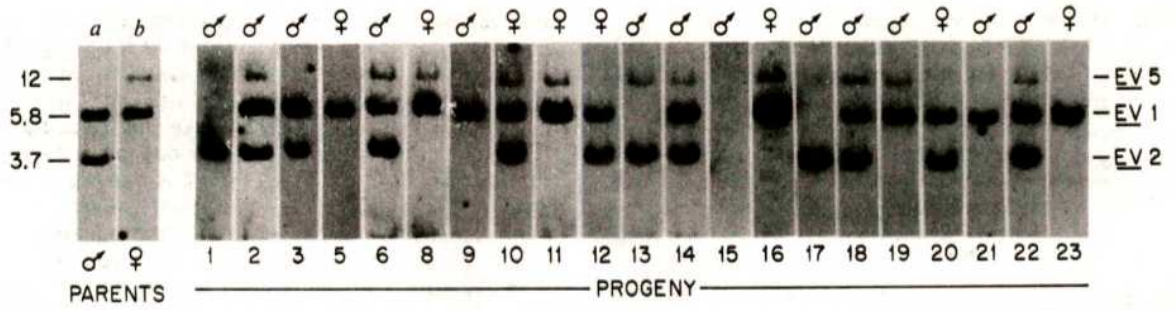

Fig. 1 *Sac*I digestion of chicken DNAs and identification of endogenous viral sequences. A marker of *Eco*RI digested λ ^{32}P-DNA was used to determine MWs, which are shown × 10^{-6}. Chicken DNAs were prepared[2] from erythrocytes and digested with *Sac*I. The resulting fragments were separated by electrophoresis on 1% agarose gels[2] and denatured and transferred to nitrocellulose filters by the method of Southern[11]. Viral sequences were detected by hybridisation with 70S ^{32}P-RAV-2 RNA as previously described[2]. The dams used in these matings were *gs*$^-$*chf*$^-$ hens from SPAFAS line 11. The sires used in the mating were F_1 progeny from a cross between a line 7_2 rooster and *gs*$^-$*chf*$^-$ hens from SPAFAS line 11.

probes, whereas the DNA of chicken 15 shows little or no annealing to any of the probes. From these results we conclude that chicken 15 definitely lacks avian leukosis virus-related endogenous viral genes.

We are now breeding rooster 15 to his female siblings and to the original dams to obtain stock to be used as the basis of a line of white Leghorns lacking endogenous viral genes. Twenty-one progeny have been hatched and are being tested for endogenous viral loci. One-quarter (on average) of the female siblings of rooster 15 should be homozygous for *ev* 1 because both the dam and sire of these chickens carried *ev* 1 in the heterozygous state. Matings with these homozygous females will produce no progeny lacking endogenous virus; the remainder of the matings should produce some of this type of progeny. Individuals lacking viral genes should be extremely useful in future studies on the possible involvement of these genes in ontogeny and oncogenesis. In addition, such chickens would provide a host for studying exogenous virus infection in the absence of endogenous proviral information.

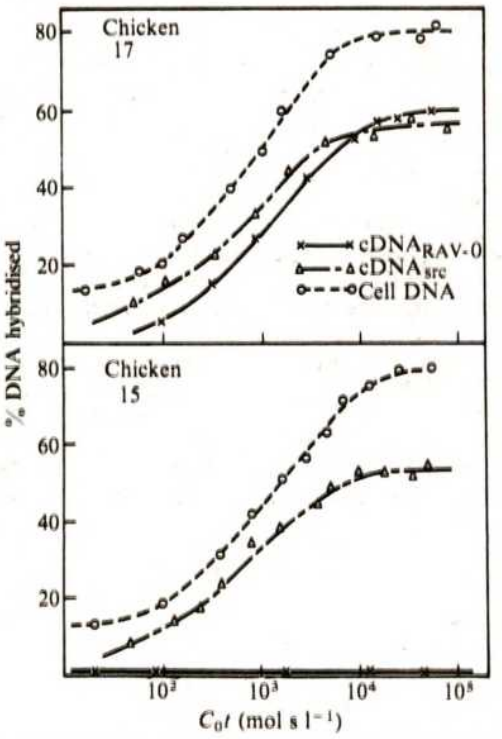

Fig. 2 Hybridisation of DNA of chicken no. 15 and chicken no. 17 to probes for total cell DNA, total RAV-0 sequences, and the cellular *sarc* genes (*src*). Probes were prepared as described by Hayward[19]. Re-association of cell DNA was monitored by addition of small amounts of ^{32}P-labelled cell DNA. Hybridisations were carried out in 4 × SSC using fragmented cell DNA at a concentration of 10 mg ml^{-1} and viral ^{3}H-labelled cDNA at 1 ng ml^{-1} (400 c.p.m. per reaction) in a total volume of 15–30 μl. Samples in sealed capillaries were heated to 100 °C for 3 min and incubated at 68 °C for various periods of time. Hybridisation was monitored by treatment with S_1 nuclease as described by Hayward and Hanafusa[21]. C_0t with values have been corrected to standard conditions of annealing as described by Britten and Kohne[22]. No corrections have been made for the differences in lengths of cell and probe DNAs. DNA lengths were approximately 150–200 nucleotides for unlabelled cell DNA, 150–200 nucleotides for ^{32}P-labelled cell DNA and 100–150 nucleotides for cDNAs.

The existence of an individual lacking endogenous viral genes implies that these genes are not essential in the chicken. How, then, does one account for their ubiquitous presence? The fact that domestic chickens lacking these genes have not been previously identified is probably a consequence of three aspects of the problem which we have observed in analyses of endogenous viral loci in over 500 individual chickens of more than 30 breeds (ref. 3 and J. Wyban, J. Fang and S.M.A., in preparation). First, there is a large multiplicity of loci in the total population of chickens; second, individual chickens usually possess several loci (J. Wyban, J. Fang and S.M.A., in preparation); third, the laboratory flocks of white Leghorns all contain locus *ev* 1 (ref. 2), an observation which may reflect the derivation of this breed from a limited gene pool. Given these three factors, the production, from random matings, of a chicken free of endogenous virus would be a rare event. If endogenous viral genes are indeed non-essential, why are they so prevalent in the population? It has been proposed that endogenous viral genes have arisen as a result of evolution of cellular genes[14]. Alternatively, they may have arisen as a consequence of retrovirus infection of germ-line cells[15]. The large multiplicity of endogenous viral loci observed in the chicken population and the heterogeneity observed among individual chickens are consistent with the theory that the viral loci arose through independent germ-line infections. Integration of the proviral genome at random or at any one of a large number of sites[16,17] would acccount for the observed large multiplicity of sites of residence of endogenous viral genes. In addition, differences in the genomes of the infecting virus and/or the occurrence of deletions, insertions or rearrangements in proviral DNA before integration would account for the heterogeneity observed among the endogenous viral genes themselves[18].

Structural similarities between Thy-1 antigen from rat brain and immunoglobulin

David G. Campbell*, Alan F. Williams*, Peter M. Bayley† & Kenneth B. M. Reid‡

The molecular basis of cellular interactions is poorly understood but it is commonly believed that direct interactions between membrane-borne ligands and receptors are important. Membrane molecules whose expression is regulated in differentiation are candidates for these roles. Functional assays for cellular interactions are of such complexity that the traditional biochemical methods of purifying a molecule by following a functional assay are not applicable. It can be argued that the best approach is first to identify cell-surface molecules and then to attempt to identify functions on the basis of their molecular characteristics or by using the molecules or antibodies to them to perturb functional systems[1]. The Thy-1 (theta) antigen has been much studied because it is expressed in large amounts on some cell types but is absent from others. Thy-1 is probably the most abundant cell surface glycoprotein of rodent brain and thymus, yet its function is unknown (reviewed in ref. 2). On the basis of structural studies it was suggested that Thy-1 would be a candidate for displaying ligands for cell interactions and that the specific determinants involved might be carbohydrate[3]. We present here a preliminary report of further structural work dealing with the amino acid sequence and circular dichroism (CD) spectrum of rat brain Thy-1. The results suggest that this molecule has a structure resembling an Ig domain, which would not be consistent with an enzymatic function. The molecule probably exists to be recognised and the determinants involved could be protein or carbohydrate.

Thy-1 antigen has been purified from rat and mouse lymphoid cells[4,5] and brain[6–8]. In all cases the molecule is a glycoprotein with an apparent molecular weight of about 25,000 determined by SDS-polyacrylamide electrophoresis. The correct molecular weight as determined by sedimentation equilibrium is 17,500 for rat brain Thy-1 and 18,700 for thymocyte Thy-1 (ref. 9). In both cases the polypeptide has a molecular weight of 12,500, the rest of the molecule being carbohydrate[3,9].

Thy-1 glycoprotein seems to have a hydrophobic portion because it binds one micelle of deoxycholate and forms a regular oligomer in the absence of detergent[9]. Also the molecule is heavily labelled when mouse thymocyte membranes are affinity labelled with a photoactivatable reagent which partitions into the lipid bilayer (M. J. Owen and M. J. Crumpton, personal communication).

Extensive amino acid sequence data for rat brain Thy-1 have been obtained by sequencing the peptides isolated after tryptic cleavage of succinylated Thy-1 (D.G.C., A.F. W. and K.B.M.R., manuscript in preparation). Overlaps were defined by sequencing peptides cleaved at Glu residues by means of staphylococcal V8 protease. The sequence begins with pyroglutamic acid (PCA) and contains 3 Cys and 1 Met as shown in Fig. 1. There is a disulphide bond from Cys 85 to Cys 9 or Cys 19 because reduction is required to release the two peptides obtained after CNBr cleavage at Met 84 (ref. 9). The disulphide bond thus includes 75 or 65 amino acid residues and this is similar to the residue number within intra-chain disulphide bonds of immunoglobulin (Ig) domains (55 to 75 residues[10]).

Fig. 1 Cys and Met amino acids in the sequence of Thy-1 glycoprotein.

The sequence of 105 amino acids contains no obvious hydrophobic sequences of the type found in glycophorin[11] and the only extended stretch of amino acids without charged groups is from residue 3 to 15 (Fig. 3). Thus the mechanism by which Thy-1 interacts with the membrane remains unknown. It could be that a small hydrophobic peptide is missing from the C-terminus because Arg 105 has only been identified from a tryptic peptide. However, the known molecular weight and amino acid composition are quite consistent with the sequence already obtained, and it is thus unlikely that a large number of extra residues will be found.

When the Thy-1 sequence was compared with sequences of the domains of Eu myeloma IgG, homologies were apparent. These were particularly evident at the sequences around the Cys residues which form the intra-chain disulphide bond of the Ig domains. This is shown in Fig. 2, where sequences around

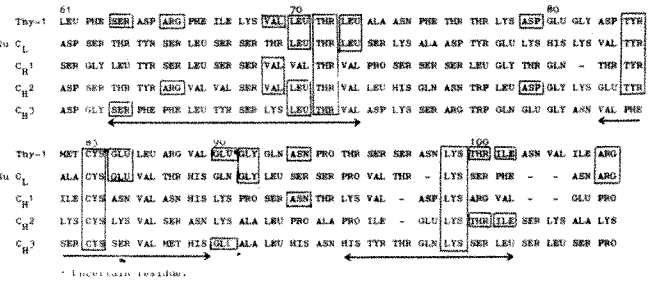

Fig. 2 Sequence comparisons between regions around Cys 85 of Thy-1 and the C-terminal Cys of the disulphide bridge in Ig domains. The sequences for the domains of Eu IgG are aligned as in ref. 12 for comparison of Ig domains with β_2-microglobulin. Thy-1 Cys 85 is aligned with Cys 81 in the β_2-microglobulin numbering. Positions are boxed where any Eu residue is identical to the appropriate Thy-1 residue. The arrows beneath the EuC_H3 sequences indicate the regions expected to be involved in β-sheet structures on the basis of the analysis of Beale and Feinstein[14].

the C-terminal Cys of the Ig domain are compared with those around Cys 85 of Thy-1. The alignment of the Ig domain is that used by Peterson *et al.*[12] for comparison of β_2-microglobulin with Ig and the Thy-1 sequence matches this alignment on both the N-terminal and C-terminal side of Thy-1 Cys 85 (the alignment with Thy-1 could be improved by altering the gaps in the Ig sequences in the region aligned with Thy-1 Lys 99). Most of the homologies occur where the Ig sequences are conserved, notably at residues in the regions aligned with Thr 71, Tyr 83 and Lys 99 of Thy-1. These sequences are in the regions which form the antiparallel β-sheet structure which is conserved in all Ig domains[13,14] (arrows in Fig. 2). In comparison with the Eu IgG domains the direct homology is best with the C_L and C_H2 domain sequences where identity with Thy-1 occurs at 9 and 10 positions respectively out of 42 and 44. For β_2-microglobulin compared over the same region as shown in Fig. 2 there is identity at 15 positions with C_L, 11 with C_H1 and C_H2 and 9 with C_H3 domain sequences[12].

A preliminary statistical analysis of the alignments shown in Fig. 2 has been done using the method of Moore and Goodman[15] which is based on the number of residues aligned and the minimum number of mutations needed to make the sequences identical. Given these values the probability that the alignment is due to a random occurrence can be read from a published table[15]. For the alignments shown in Fig. 2 the probability of a

0028/0836/79/460341—02$01.00
© 1979 Macmillan Journals Ltd.

random relationship for Thy-1 versus respectively C_L; C_H1; C_H2 and C_H3 is: >0.01 <0.1%; 1%; >0.01 <0.1%; 1%. As controls for these values the Thy-1 sequence as in Fig. 2 was aligned with the N terminal Cys of the Eu IgG domains and in the four alignments the probability of a random association was >10%. In another set of controls the Thy-1 sequence as in Fig. 2 was aligned with C_H2 but with the Thy-1 sequences displaced forward or back 1 or 2 residues (2 residues would be more relevant because this would lead to alignment of structurally similar residues in regions of alternating hydrophobic amino acids in β-sheets[14]). Regardless of whether the misalignment was one or two residues the probability of a random association was always >10%. The scores for the alignments of Thy-1 with C_L and C_H2 are of the magnitude considered by Moore and Goodman[15] to indicate a high probability of an evolutionary relationship.

The sequences around the N-terminal Cys residues of Thy-1 were also compared with sequences around the N-terminal Cys of the Ig domains. In Fig. 3 it can be seen that there appears to be homology between the sequences around Thy-1 Cys 9 or Cys 19 and those around the N-terminal Cys of the Eu domains. It was also interesting to note that when Cys 9 and Cys 19 of Thy-1 were aligned (Fig. 3) four homologies were seen within the 13 residues C-terminal to each Cys. This may be a trivial observation but could indicate an internal duplication although this possibility is confused by the fact that Cys 19 is within the region of possible homology.

The size of the Thy-1 polypeptide, the disposition of the disulphide bond and the sequence homologies suggest that Thy-1 may have a structure similar to that of an Ig domain. This view is further supported by the fact that Thy-1 is highly resistant to proteolysis[2,3] as are Ig domains[10]. A more striking feature of Ig domains is their high content of antiparallel β-sheet structure and an absence of α-helical structure[13]. This gives rise to a characteristic spectrum for CD measured in the far UV region (190–230 nm). This spectrum shows a negative peak at 217 nm and an absence of the intense negative peaks at 208 and 222 nm which are characteristic of α-helix[16]. In Fig. 4 the CD spectrum for rat brain Thy-1 antigen is shown in comparison with a typical native Ig spectrum, namely, that of human myeloma IgD-Ha (ref. 17). Both spectra show the negative peak at 217 nm. The magnitude is greater for Thy-1 than for the IgD spectrum shown but is not markedly outside the range seen with different Ig molecules or their proteolytic fragments[16,17]. The Thy-1 spectrum shows no sign of intense optical activity at the wavelengths characteristic of α-helical structure. This further confirms the absence of a hydrophobic sequence like that in glycophorin which forms an α-helix which is readily detectable by CD[18].

Taken together these data present a reasonable case for suggesting that Thy-1 antigen has structural similarities to Ig domains. Further, it seems likely that Thy-1 and Ig share a distant evolutionary relationship, as is believed to be the case for β_2-microglobulin and Ig[19]. In comparing β_2-microglobulin and Thy-1 the similarities are the size of the polypeptides, the sequence homologies with Ig, the CD spectra and the cell surface location of the molecules. Differences are that β_2-microglobulin is found on most cell types in combination with the heavy chain of histocompatibility antigens and that it lacks carbohydrate[19]. Thy-1 has never been shown to associate with another polypeptide but appears to bind directly to the membrane. The functions of both Thy-1 and β_2-microglobulin are unknown, but it could be that these molecules exist to mediate cell–cell interactions and that a structure like the Ig domain is particularly suited to this role. The versatility of the domain structure is already proven by the large number of effector functions mediated by Ig constant region domains[14].

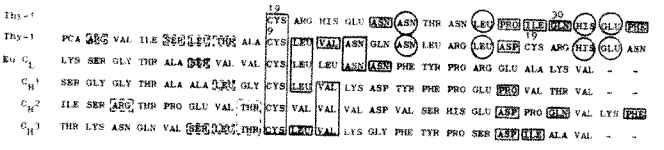

Fig. 3 Sequence comparisons between regions around the N-terminal Cys residues of Thy-1 and the N-terminal Cys of the disulphide bridge of Ig domains. Thy-1 sequences around Cys 9 and Cys 19 are aligned with sequences for the domains of Eu IgG aligned as in ref. 12 with Cys 9 or Cys 19 being aligned with Cys 25 in the β_2-microglobulin numbering. Residues are boxed where the residue of either Thy-1 sequence is the same as a residue in the Ig sequences. The residues boxed with dotted lines show homologies which would occur if a one residue gap was inserted in the Eu sequences at the N-terminal side of the Cys. The circled residues show homologies obtained on alignment of the sequences around Cys 9 and Cys 19 of Thy-1. At these internal homology regions there are no identical Eu Ig residues.

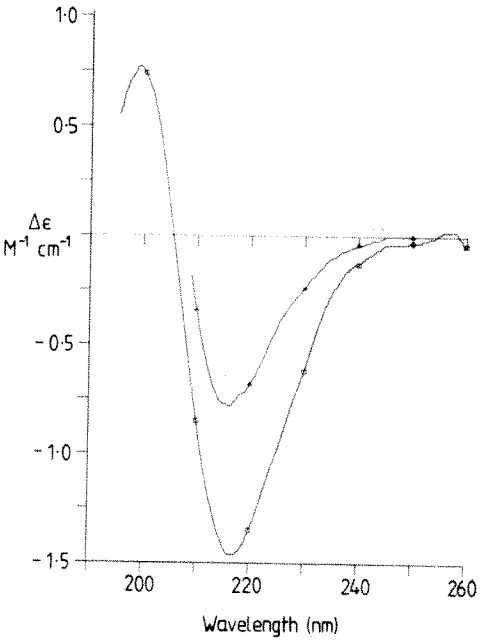

Fig. 4 CD spectrum of Thy-1 glycoprotein (○) and IgD(△). Thy-1 glycoprotein was purified from rat brains as previously described[6], with modifications involving the removal of lipid with chloroform:methanol extraction and the use of a monoclonal anti-Thy-1.1 antibody column for affinity chromatography (D.G.C., A.F.W. and K.B.M.R., in preparation). Deoxycholate was removed by ethanol precipitation of the glycoprotein[10] which was then solubilised in water. The CD spectrum was measured at 20 °C on a Jasco J41 CD spectrometer using a cell of 0.1-mm pathlength with glycoprotein at a concentration of 1.6 mg ml^{-1} (1.15 mg protein per ml). The CD spectrum of IgD-Ha[16] is shown for comparison. The CD spectra of brain Thy-1 in deoxycholate, or thymocyte Thy-1, were not distinguishable from that shown. For Thy-1 the mean residue ellipticity $[\theta_M]_{217} = 3{,}300 \times \Delta\varepsilon_{217} = -4.8 \times 10^3$ degrees cm^2 dmol^{-1}.

Circle No. 10 on Reader Enquiry

As easy as 1·2·5

If you've been wishing you could get rid of the inconvenience and difficulties of iodinating proteins, here is an easy way to do it. Get our simple, reliable Radioiodination System [^{125}I] – everything you need, ready for your protein.

We've selected a mild reaction method (enzymatic lactoperoxidase) to preserve your protein specificity. We've made sure that there are no contaminants to interfere with proper iodination. And we've tested each lot in a complete iodination procedure.

The ingredients are: Sodium iodide [^{125}I], iodination reagent, sodium phosphate buffer, 1% β-D-glucose to activate the system, and a volatile radioiodine trap.

This system is the new way to make iodination straightforward and reliable. Send for the protocol to start saving time and trouble.

Not for use in humans or clinical diagnosis.

AMBIO A JOURNAL OF THE HUMAN ENVIRONMENT

Now distributed for the Royal Swedish Academy of Sciences by Pergamon Press

Launched in 1972, AMBIO is already recognized by many as the leading interdisciplinary periodical in the environmental sciences.

Now, with the aim of broadening an already international coverage and readership, AMBIO will be published and distributed through a joint arrangement between the Royal Swedish Academy of Sciences and Pergamon Press.

Regular issues contain general articles on current environmental problems and challenges and reports on original research in the field. Special issues give a more comprehensive treatment of some topical subjects, e.g. issues are planned on the Baltic and threatened ecosystems.

" . . . The most authoritative journal of its kind on international environmental problems."
GILBERT F WHITE, *President, Scientific Committee on Problems of the Environment, I C S U*
" . . . AMBIO is the best magazine of its kind."
IGNACY SACHS, *Centre Nationale de Recherche sur L'Environnement*
"It conveys the message on crucial environment issues in the most accurate and well-presented way."

J. D. North

Science in the Middle Ages. Edited by D.C. Lindberg. Pp. 544. (Chicago University Press: Chicago and London, 1979.) £28; $40.

JULIET'S opinion notwithstanding, there is a great deal in a name, and "science" means something very different now from what it meant even a century ago (when, for instance, Lockyer chose to call his journal *Nature*). It is not necessary, on the other hand, to pay too much attention to those paradoxes who would have us believe that there was *no* science (in the current sense of the word) in the middle ages. Even putting aside Aristotelian and other natural philosophy ("great mother of the sciences", as Francis Bacon called it), there is an abundance of material in works on astronomy, optics, medicine, biology, technology, statics and the science of motion, which would be classed as essentially scientific by the modern scientist. The temptation to focus on this positive achievement of the middle ages has in the past been too great for many scholars. The pendulum has recently swung perhaps a little too far in the other direction, and we are growing accustomed to oh-so-scholarly articles uniting the most disparate of themes, so that no-one would now raise an eyebrow, for instance, at "The influence of judicial combat on the theory of refraction", or "Monastic poverty and the law of free fall". The most conspicuous merit of the collection of essays edited by Professor Lindberg is that their authors, despite an occasional attempt to tack, usually steer a sensible middle course between the two extremes.

There is little doubt that much scientific work of originality and worth remains hidden in manuscript, and that some is lost for ever. Of all the historian's main tasks, the one which tends to suffer least from these difficulties is that of tracing mediaeval influences in later periods. Many important studies have been opened up in this retrospective way; and here the study of mediaeval theories of motion, leading to Galileo and the successes of the seventeenth century, deserves pride of place. The chapters by William Wallace (on the philosophical setting) and John Murdoch and Edith Sylla (specifically on the science of motion) make excellent use of writings by such as Duhem, Maier and Clagett. The chapter by Murdoch and Sylla is notable for its mastery of the material, evidence of long and painstaking study. It is perhaps the best short introduction to the subject in any language. They stress the importance and pervasiveness of doctrines of motion to *all* mediaeval natural philosophy. Within their terms of reference, optics and statics were not considered as being strictly a part of natural philosophy, while astronomy is a difficult case, with one foot inside and the other outside the subjects. They discuss the mathematics of free fall, which managed to leave Aristotle on the sidelines, and the theory of impetus, which was hardly compatible with Aristotle; but they show how at every turn the books of Aristotle were, so to say, the intellectual driving force behind it all. The mathematical rules of the Mertonian (Oxford) and Parisian philosophers are remarkable enough, but moderately well known to scholars. What will perhaps come as a surprise to many readers is the importance they ascribe to the influence of the Church's doctrine of transubstantiation on the general theory of motion, so that "one of the two most prominent later mediaeval explanations of alteration, the so-called succession of forms theory, was originally taken seriously and worked out carefully as an explanation of the alteration and augmentation or diminution of the Eucharist". Another mediaeval tradition which might have been thought liable to lead to sterility but which is deemed influential, is that of the invention of sophisms within the context of logic. But all this activity was *secundum imaginationem:* it followed the creative imagination, and there was no question of any appeal to experiment.

The same was largely true of the science of optics, expertly discussed by the editor himself in a survey running from the ancient atomists to Descartes. Again the attack was on a broad front, making use of mathematical techniques (as of ray optics), but also taking in the physiology of the eye, the psychology of vision, and even theology. Here the key western texts were inspired not only by Aristotle, Euclid and Ptolemy, but by Islamic precursors such as Ibn al-Haitham and Avicenna. The editor is again himself responsible for a chapter on the transmission of Greek and Arabic learning. One can hardly complain about the brevity of the remarks on (for example) the work done in Castile under Alfonso X, as the chapter is so very full, tailing off only towards the end, where we might have had more about the *dissemination* of the translations done in Sicily, the Spanish peninsula, and elsewhere. The bibliographical references in this chapter are invaluable.

The mediaeval science of weights, discussed in a chapter by Joseph Brown, shared with optics and theories of motion an uncertainty of aim and content. Broadly speaking, two paths were followed: there was the quasi-dynamical approach of an early follower of Aristotle, and there was the Euclidean and Archimedean tradition. The mediaeval synthesis of the two was hesitant and imperfect. If we look to a later chapter by James Weisheipl on the "nature, scope, and classification of the sciences", I think we can detect one of the contributory causes, namely the sheer eclecticism of the mediaeval scholar. He wanted to combine an encyclopaedic coverage of his subject matter with that dangerous kind of confidence that comes from recording all conceivable points of view. In his more pragmatically orientated thinking, he was in many ways more successful than when he chopped logic and philosophy in the schools. (Divinity poses an unresolvable problem.) As John of Salisbury said somewhat impatiently, more time had been spent on Porphyry's questions than the House of Caesar spent in winning and in ruling the Empire of the World. Chapters on technology and economic progress (Brian Stock), science and magic, that is, a pragmatics of desire (Bert Hansen), astrology (touched upon by several authors in passing), and medicine (Charles Talbot), all show that when the chips were down the mediaeval scholar could dispense with the dialectical skills he had learned at his university — or at least that he could hold them in reserve to explain his failures.

Mathematics (Michael Mahoney), the science of matter (Robert Multhauf), and the universities as an institutional setting (Pearl Kibre and Nancy Siraisi), are all covered in ways which help the book to achieve a remarkable degree of comprehensiveness. Jerry Stannard's is a short but entertaining sketch of natural history, "a complex amalgam of fact and fancy". The two remaining chapters are by Edward Grant (cosmology) and Olaf Pedersen (astronomy), and are largely complementary. The first gives an outline of the Aristotelian cosmology with which the extraordinarily sophisticated picture arrived at by the mathematical astronomers had to be reconciled, if only for the sake of good form. The astronomy chapter provides an important reminder —

with many well chosen illustrations of instruments — that the astronomer at least was not averse to making observations of the real world. But to what extent he and other mediaeval scholars were doing real science is a question best answered by reading the collection as a whole. □

Formal theory of ecosystems

Theoretical Systems Ecology. Edited by E. Halfon. Pp. 516. (Academic: New York and London, 1979.) £43; £27.95.

THE opening sentence of the preface to this book claims that systems ecology is having a large impact upon all aspects of environmental research, and that the systems approach, with its body of concepts and techniques, has broadened the ecologists' perspectives and attracted students into ecology from other disciplines. The preface goes on to suggest, however, that there has been a lack of communication between theoreticians and modellers and field ecologists, and that the purpose of this book is to try to bridge the gap in communication.

Is it true that systems ecology, or the application of systems theory to ecology, is having an impact on environmental research? Many ecologists would disagree with the statement, and there are as yet relatively few examples of practical action on environmental problems having been taken as a result of studies of systems ecology. There is certainly much understanding of the ways in which organisms respond to changes in their environment, and some of this modelling is based on concepts derived from studies of control systems. I suspect, however, that one of the reasons for the lack of communication between theoreticians and field ecologists is that the dependence of ecological models on systems theory is less than is believed by the theoreticians. Much of the modelling still based on statistical concepts developed even earlier than those of the systems analysts.

This volume contains 20 chapters written by 28 contributors, and divided into four main sections. Part I discusses some fundamental system problems, particularly the aggregation problem and its relation to sampling. Part II includes information on modelling approaches and philosophy, with emphasis on model structure and model properties. Part III introduces methodologies and computer techniques of system identification. Part IV contains studies on model analysis, principally of structural properties such as stability, flow analysis and general systems properties.

Undoubtedly, the book contains original contributions in theoretical systems ecology which may be important as a basis for future developments. As most of the chapters are almost unintelligible to anyone not already well versed in systems theory, however, the book does little, if anything to bridge the gap between theoreticians and practical ecologists. Indeed, until theoreticians can learn to state their conclusions in simple and unambiguous plain language, it is doubtful if systems ecology will really have the impact that systems analysts claim for it. At present, those of us who are attracted by this approach to ecology too often mistake our models for the real world, and are content to leave our description of these systems in the mathematical terms for which they were derived. Those who have to use our research find it difficult to translate from the mathematics to the plain statements of every-day usage.

One of the problems that need to be solved is terminology. The terms used in this book are claimed to be as uniform as possible, but different names are frequently used for the same concept or the same name for different concepts. The problem is said to be typical not only of systems ecology but also of general systems theory. This confusion seems to derive from the fact that the contributors follow the terminology of quite different theories of general systems, and the concepts of these theories do not often overlap. An early priority for theoreticians, therefore, would seem to be the resolution of these inconsistencies, and the development of a formal theory of ecosystems as a working definition for ecological research.

J.N.R. Jeffers

J.N.R. Jeffers is Director of the Institute of Terrestrial Ecology, Natural Environment Research Council, Grange-over-Sands, Cumbria, UK.

Primary energy supply prospects

World Energy: Looking Ahead to 2020. Report by the Conservation Commission of the World Energy Conference. (IPC Science and Technology Press: Guildford, UK, 1978.) £12.50; $32.50.

THE objectives of the Conservation Commission were to evaluate, for the period 1985-2020, future primary energy supply prospects and to identify possible courses of action to overcome potential shortfalls in energy availability, particularly the impending decline of oil and gas supplies. The report is based on the work of a series of specialist study groups, dominated by OECD-centred experts.

The Commission notes that for industrialised nations there seems to be a decreasing requirement for additional energy supplies with increasing economic growth; by 2020, it seems that the energy coefficient might decline to one half its current average level in these countries (but it is unclear whether measurements are made in primary, delivered or final useful energy terms). In the case of developing countries, however, the incremental ratio of energy demand to economic growth will continue to increase.

Somewhat surprisingly, given the upsurge in public opposition to virtually any major energy siting decision (for example, refineries, coal mines and nuclear stations) and evidence of rising real capital costs, the Commission argues that "the energy supply which could be attained in the next few decades is easier to predict than is the demand for energy, because it is determined primarily by technology". The Commission forecasts that the share of conventional crude oil in total world primary energy supplies will decline from 40% at present to about 10% by 2020, with natural gas then contributing 20%, non-conventional petroleum (for example, tar sands, shales, geopressure zone gas) about 5%, coal 25%, and renewable sources 10%, with the balance, 30%, being provided by nuclear energy from fission.

Total primary energy demand is estimated to reach three times today's level of 9×10^9 metric tons of coal equivalent by 2020, involving major efforts in all energy resource areas. In particular, it implies tripling coal production, "doubling nuclear power plant capacity every six years" and substantial growth in solar energy.

The report envisages that about 30% of the energy that would otherwise have been needed by 2020 could be saved through technological improvements in conversion and utilisation. Further conservation, about 17%, is considered feasible through structural changes in the more mature economies, including saturation in car transportation and domestic energy demand and reduced utilisation by the energy-intensive industries.

The study is a valuable contribution to the literature, even though it omits sufficient discussion of issues such as public opposition, potential climatic impacts of increased energy consumption, geopolitical stresses likely to be prompted by international disparities in energy resource endowments, criteria for allocation of R and D expenditure, and more speculative and normative assessments of alternative world futures.

John Chesshire

John Chesshire is a Fellow of the Science Policy Research Unit, University of Sussex, Brighton, UK, and a member of the Unit's Energy Programme Group.

Speech Retarded and Deaf Children

Their Psychological Development

T. Fundudis, I. Kolvin and R. F. Garside

December 1979/January 1980, xviii+252pp., £15.80/$36.50 0.12.270150.X

In this book the authors describe a study in which outcome was investigated by examining a total population of speech delayed and of deaf children and an appropriate control group. Particular emphasis was paid to subsequent performance in speech and language development and behavioural functioning up to the age of eight. The authors also attempted to classify the disorders which share the symptom of speech delay. This is one of the few studies which have examined the later development of speech retarded and deaf children in depth and therefore contains much valuable and stimulating information, for psychologists, paediatricians, speech therapists, psychiatrists and neurologists.

Advances in Microbial Physiology Vol. 19

edited by A. H. Rose and J. Gareth Morris

November/December 1979, x+357pp., £17.80/$41.00 0.12.027719.0

This series presents critical review articles on all aspects of the physiological and biochemical activities of micro-organisms. *Advances in Microbial Physiology*, spanning the area between microbiology and biochemistry, is able to deal with subjects of interest in both fields which previously have received little attention from reviewers.

Contents:

H. J. Rogers: Biogenesis of the Wall in Bacterial Morphogenesis. **L. Stevens and M. D. Winther:** Spermine, Spermidine and putrescine in fungal development. **L. G. Ljungdahl:** Physiology of thermophilic bacteria.

Fast Neutrons in the Treatment of Cancer

Mary Catterall and David Bewley

November 1979, x+388p., £22.40/$47.50 0.12.790820.X

The first part of the book discusses the physical and radiobiological properties of fast neutrons. This is followed by a description of the clinical investigation undertaken on the MRC cyclotron at Hammersmith Hospital since 1970. A wide range of tumours were investigated including soft tissue Sarcomas, Adenocarcinoma, salivary gland tumours, locally advanced breast cancer and enlarged glands from Melanoma. This is the first full report of this method of treatment for cancer and it will be of interest to radiotherapists, surgical and medical oncologists, radiobiologists, hospital physicists and radiographers. Since the method involved new machines, it will also be of value to hospital administrators and engineers concerned with neutron generators and accelerators of heavy particles.

The Systematics Association Special Volume No. 13

Advances in Bryozoology

edited by G. P. Larwood and M. B. Abbott

November/December 1979, xvi+638pp., £24.00/$55.50 0.12.437450.6

The fourth conference of the IBA, held at Woods Hole, Massachusetts in September 1977, makes up this Systematics Association Special Volume. In scope it ranges from Phanerozoic forms to Recent faunas and documents the results of much new bryozoan research, combining in one forum neontological and palaeontological approaches. The contents range from introductory topics and reviews of the current state of knowledge to the results of very specialized studies. Such a variety of papers will be invaluable to marine ecologists and all environmentalists with an appreciation of the significance of bryozoan study. As a unique collection of papers containing much that is new and still controversial, this book will be indispensable for university and research workers and students in geology, biology and zoology, and is an important reference work for scientific libraries.

Geochemistry in Mineral Exploration 2nd edition

A. W. Rose, H. E. Hawkes and J. S. Webb

November/December 1979, xviii+658pp.

Clothbound: £28.00/$64.50 0.12.596250.9

Paperbound: £12.40/$29.00 0.12.596252.5

The book presents the three main aspects of geochemical exploration: the basic principles underlying geochemical methods; practical surveying techniques; and the characteristics of anomalies in rocks, soil, transported overburden, stream and lake sediments, surface and ground water, vegetation and air. The comprehensive coverage of existing knowledge (including over 1,000 references to significant publications), together with new insights and conclusions on many topics, ensure that this edition will have the same wide appeal as the first. For students it is an ideal introductory textbook; for practising exploration geochemists it is a necessary practical handbook and summary of the literature; for researchers in allied fields, such as environmental and agricultural geochemistry, and for nonspecialized earth scientists it is a valuable source of general information on geochemical exploration.

Essays in Biochemistry

Volume 15

edited by P. N. Campbell and R. D. Marshall

November/December 1979, x+130pp., £4.80/$11.50 0.12.158115.2

This well-established and highly praised series is intended for senior students, lecturers and research workers in biochemistry. Each essay presents an overall view of one aspect of the subject, providing an ideal introduction to it for anyone who lacks specialist information in the area concerned.

Contents:

R. Jeffcoat: The biosynthesis of unsaturated fatty acids in mammalian liver. **R. M. Denton and A. P. Halestrap:** Regulation of pyruvate metabolism in mammalian tissues. **M. F. Greaves:** Cell surface characteristics of human leukemic cells. *Subject index.*

Research in Psychology and Medicine

Volumes 1 and 2

edited by D. J. Osborne, M. M. Gruneberg and J. R. Eiser

Volume 1: Physical Aspects: Pain, Stress, Diagnosis and Organic Damage

December 1979, xiv+486pp., £10.80/$25.00 0.12.529201.5

Volume 2: Social Aspects: Attitudes, Communication, Care and Training

December 1979, xvi+488pp., £10.80/$25.00 0.12.529202.3

These two volumes, which contain papers presented at the International Conference on Psychology and Medicine held in Swansea in July 1979, provide the first full coverage of the work done in this important and growing field of behavioural medicine. The volumes present a considerable spread of research by psychologists, clinicians and others from hospitals and universities all over the world, with emphasis on the physical and social aspects of the relationship between psychology and medicine.

The papers in each volume have been grouped around a common theme: those in Volume I dealing with the physical aspects, and those in Volume II with the social aspects. Altogether 115 papers provide a unique source of information that will be of great value to a wide range of practitioners. As well as appealing to academic and clinical psychologists and sociologists, the volumes have a great deal to offer to physicians, surgeons, teachers and auxiliaries in almost every area of medicine including general practice, neurology, renology, accident surgery, paediatrics, anaesthesia, nursing, psychiatry, dentistry, health administration and health care planning.

European Monographs in Social Psychology No. 16

Jokes

Form, Content, Use and Function

Christopher P. Wilson

November 1979, x+252pp., £14.60/$34.00 0.12.758150.2

The author's aim is to provide a general portrait of humour, using data drawn from psychology, sociology and anthropology. He provides a detailed analysis of the defining features of jokes, their specific content, the formal categories into which they fall, the way form and content combine to evoke amusement, and the social and psychological reasons for, and effects of, joking. In particular, the author stresses the underlying unity of form as distinct from the superficial differences in the content of jokes. The book is notable for its attempt to draw together the divergent strands of research in this area and will provide a useful source of reference, as well as presenting a more coherent, overall theory of humour than is possible in a multi-author work. It is intended principally for psychologists, sociologists, linguists and anthropologists interested in the role of humour in their discipline. Much will also be found to interest students with a basic grounding in the social sciences.

Renal Function in Anaesthesia and Surgery

David R. Bevan

November 1979, xii+240pp., £15.20/$32.00

0.12.790581.1 (Academic Press) 0.8089.1160.0 (Grune & Stratton)

This book aims to review the effects of anaesthesia and surgery upon the normal kidney. It also deals with the problems of anaesthesia in the post-operative period, and provides guidelines to prevent further deterioration. To this end the text is divided into three sections: the basic principles of applied renal physiology; the effects of anaesthesia and surgery; and renal failure. It is hoped that application of physiological principles will enable the normal behaviour of the kidney in the post-operative period to be predicted, so that fluid and electrolyte therapy will follow a rational basis and any abnormality will be recognized earlier. This book is directed towards both clinician and researcher.

Experimental Virology Series

Hepatitis Viruses of Man

Arie J. Zuckerman and Colin R. Howard

December 1979/January 1980, viii+270pp., £16.80/$39.00 0.12.083550.9

This second volume in the series deals with the hepatitis viruses of Man. The year 1968 saw the discovery of the association between Australian antigen and hepatitis type B: five years later hepatitis A virus was identified in faecal extracts. Evidence has recently emerged of a third form of hepatitis, which may be caused by more than one virus; also there are as yet unpublished reports on the insertion of hepatitis B virus DNA fragments into *Escherichia coli* plasmid with subsequent production of clones. This volume, which is not intended to be an encyclopaedic review of hepatitis virus, provides a comprehensive account of the more important published advances and exciting developments in the field of human viral hepatitis during the last decade.

Essentials of Postgraduate Psychiatry

edited by P. Hill, R. Murray and A. Thorley

November 1979, xviii+802pp., £21.50/$49.50

0.12.791983.X (Academic Press) 0.8089.1204.6 (Grune & Stratton)

The contributors, who were all until recently members of staff of the Maudsley Hospital, provide the trainee psychiatrist with a reasonably sized general text with a modern approach which contains all the information that is now essential for the competent practice of psychiatry. The contributors place great emphasis on research evidence rather than clinical wisdom, integrating the results of recent research into the main body of clinical knowledge. In the words of Dr Birley, Dean of the Institute of Psychiatry, writing in the foreword: "The result of their labours is a very readable volume which provides up-to-date reviews of most of the important fields of psychiatry, with a plentiful supply of references for further reading."

Social Insects

Volume 1

edited by Henry R. Hermann

September 1979, 456pp., £23.40/$36.00 0.12.342201.9

Subscription price: $31.50

This three-volume treatise on social insects is an endeavour to collate the works of modern researchers working in the field of insect sociobiology. The vastness of the subject insect sociality warrants at least the number of pages comprising these three volumes. In their totality, the inclusive chapters touch on all or almost all of the concepts studied to date. They discuss the major reports that have built our present store of knowledge on the subject; and they reveal gaps in our knowledge and lapses of continuity in our research and thinking. The contributors to these volumes have cumulated information not only on the work and theory already recorded in the literature but have often added new information and theory to what is already known.

Theoretical Systems Ecology

Advances and Case Studies

edited by Efraim Halfon

September 1979, 544pp., £27.95/$43.00 0.12.318750.8

Contents: Aggregation and Organization: B. P. Zeigler: Multilevel multiformalism modeling: an ecosystem example. **W. G. Gale, Jr. and P. L. Odell:** Concerning aggregation in ecosystem modeling. **Model Structures, Formalisms, and Theory of Modeling: R. E. Ulanowicz:** Prediction, chaos, and ecological perspective. **J. R. Webster:** Hierarchial organization of ecosystems. **System Identification: C. Cobelli et al:** Structural identifiability of linear compartmental models. **M. B. Beck:** Model structure identification from experimental data. **G. J. Klir:** Computer-aided systems modeling.

Advances in Inorganic Chemistry and Radiochemistry

Volume 22

edited by J. J. Emeleus and A. G. Sharpe

December 1979, 480pp., £28.00/$48.00 0.12.023622.2

Chapter headings: H. D. B. Jenkins and K. F. Pratt: Lattice energies and thermochemistry of hexahalometallate (IV) complexes, A_2MX_6, which possess the antifluorite structure. **G. Stedman:** Reaction mechanisms of inorganic nitrogen compounds. **M. J. Atherton and J. H. Holloway:** Thio-, seleno-, and tellurohalides of the transition metals. **J. Mason:** Correlations in nuclear magnetic shielding, part II. **H. W. Roesky:** Cyclic sulfur-nitrogen compounds. **R. P. Burns and C. A. McAuliffe:** 1, 2-Dithiolene complexes of transition metals. **R. H. Prince:** Some aspects of the bioinorganic chemistry of zinc.

Boreham:** The pathogenesis of African and American trypanosomiasis.

Marine Mycology: The Higher Fungi

Jan Kohlmeyer and Erika Kohlmeyer

November 1979, 704pp., £38.65/$59.50 0.12.418350.6

An authoritative, up-to-date sourcebook on all aspects of the higher marine fungi, describing in detail all 209 filamentous species through the authors' own original investigations. The text includes 482 microphotographs and nine other illustrations, most of them never published before. Many of the species are depicted for the first time. The first, general part of the text deals with ecological groups and includes chapters on collection, culture, ontogeny, physiology, and phylogeny. The second, taxonomic-descriptive part contains illustrated keys, complete descriptions of each genus and species, together with substrates, geographical range, etymology of names, and literature. The authors advance a new theory positing two distinct groups of fungi in marine habitats.

Protein phosphorylation

Protein Phosphorylation. By M. Weller. Pp. 557. (Academic/Pion: London, 1979.) £29.

ALTHOUGH proteins such as casein and phosvitin have been known for many years to contain covalently bound phosphorus, it is only since the discovery of enzyme regulation by phosphorylation-dephosphorylation in 1956 by Krebs and Fischer, and the discovery of cyclic AMP-dependent protein kinase in 1968 by Walsh, Perkins and Krebs that interest in protein phosphorylation has increased dramatically. The number of enzymes known to be regulated by phosphorylation-dephosphorylation has increased from 4 in 1969 to about 25 today, and the number of phosphoproteins (as opposed to enzymes) that have been identified exceeds 100. These include such familiar proteins as fibrinogen, ovalbumin and pepsin, in which the role of phosphorylation is still unknown.

The past five years have established protein phosphorylation as the major general mechanism by which intracellular events in mammalian tissues are controlled by external physiological stimuli and research in this area may well account for 5–10% of current biochemical and pharmacological research. Protein phosphorylation is not only implicated in enzyme regulation, but in the control of secretion, ion transport, protein turnover, chromosome condensation and viral transformation. Protein-bound phosphate also plays an important role in the binding of divalent cations such as iron and calcium, and in bone formation. Furthermore, many enzymes form phosphorylated reaction intermediates as part of their catalytic mechanism. Six different amino acid side-chains (serine, threonine, histidine, lysine, glutamic acid and aspartic acid) are known to be phosphorylated.

Dr Weller is to be congratulated on being the first person to attempt the monumental task of writing a comprehensive book on all these different aspects of protein phosphorylation. The book is readable, very comprehensive in its subject matter and remarkably free of gross factual errors and printing mistakes. It comprises 13 chapters and covers work published up to about the beginning of 1977. Nearly 3,600 references are listed at the end of the book.

As always the major problem of writing a book on a topic that is progressing rapidly, is that large sections are already out of date on the day of publication. Indeed, after reading this book one can see how much progress has taken place in some areas over the past two or three years. The chapters dealing with cyclic AMP- and cyclic GMP-dependent protein kinases and the molecular specificity of these enzymes is already well out of date. The sections on enzymes such as pyruvate kinase, pyruvate dehydrogenase, acetyl-CoA carboxylase and initiation factors of protein synthesis which merit only a few lines in the book, would have to be expanded considerably today. Unfortunately the calcium dependent regulator protein story, which has revolutionised our understanding of the role of calcium in cellular control, and the interrelationship between cyclic AMP and calcium ions, broke just too late to get included. Naturally, enzyme systems discovered since this book was written, such as those involved in triglyceride, steroid, neurotransmitter and hormone synthesis are not included. Perhaps the major criticism that could be levelled at the book is that it is too much a catalogue of facts, and more could have been done to relate protein phosphorylation to the integrated metabolism of the whole cell. On the other hand, chapters dealing with topics that are no longer such active research areas, such as the caseins and phosvitins, will remain complete and accurate accounts of work in these areas for many years.

However, there is no doubt in my mind that this book is a remarkable achievement and that it is an extremely valuable background reference book for all people engaged in research in this area.

Philip Cohen

Philip Cohen is Reader in Biochemistry at the University of Dundee, UK.

Sensory mechanisms of the spinal cord

Sensory Mechanisms of the Spinal Cord. By W.D. Willis and R.E. Coggeshall. Pp. 485. (Plenum: New York, 1978.) $35. Available in the UK, Africa and the Middle East from Wiley (Chichester, UK) at £20.

THIS book will bring some coherence and stability to a confused subject. The confusion is partly inherent in the subject itself: inevitably the details of physiological mechanism, and, for the most part, micro-anatomical structure, come from experiments on a variety of higher animals, and any relevance to sensory mechanisms in man has to be established with the greatest caution. This kind of experimental evidence has appeared explosively in the past 15 years or so and the degree of caution has left much to be desired. So, although this is a detailed and wide-ranging monograph, it is a pleasure to find that it begins with a cautionary list of the types of general theory which have been advanced at various stages to bridge this gap and points out where these have been flawed by experimental error, unjustified assumptions, or plain mental confusion. The various 'dual' theories about somatic sensation are examined in this way and all found wanting. And an elementary but important semantic point is made that the word "modality" in sensation is a subjective and not objective term — one which defines quality in what we feel, and not, as many continue to treat it to the great confusion of others, a term describing an instrumentally measurable attribute of a stimulus. Similarly the book ends with a serious attempt to define, where evidence allows it, the sense-organs, tracts and nuclei which form the various channels on which the brain depends for its information in different kinds (or modalities) of sensory experience.

The main bulk of the book is concerned with categorising and summarising recent evidence. Enough is said about sense-organs to form a sound basis for what follows; but the main detailed subject-matter is the anatomy and physiology of the sensory mechanisms of the spinal cord and medulla, that is, in general terms, the early stages of synaptic processing of incoming information and its channelling into a variety of new specialised paths. This is a field in which the authors and their close colleagues have a large personal experience and have made important contributions. The terminology and specialised techniques are sufficiently explained to make this quite easy reading. A good test of a comprehensive text like this is to use it. I used it to answer a variety of fairly esoteric questions to which I did not have a definitive answer and found its layout conducive to doing this quickly. The chapter titles and subheadings are reliable. The summaries are particularly helpful: each section has a short italicised summary and each chapter a set of concise conclusions. The bibliography is excellent.

The subject is advancing in full spate. This book is undoubtedly the best available text, indeed the only one of the present period, and it covers material published up to and including 1977. The form of the book is such as to allow updating and it is very much to be hoped that this will be done in due course. It is an expensive book for students, who would find the first and last chapters by themselves an excellent introduction to a subject which is potentially confusing and usually poorly dealt with in the general run of textbooks. The bulk of the book, however, is for reference or for the worker in the field. As such it is very much to be welcomed and not overpriced.

George Gordon is Reader in Sensory Physiology at the University of Oxford, and Research Fellow, Brasenose College, Oxford, UK.

Nature Vol. 282 15 November 1979

Assessment of pesticides

The Use and Significance of Pesticides in the Environment. By F. McEwen and G. Stephenson. Pp.538. (Wiley: New York and Chichester, UK, 1979.) £16.75.

THIS book is based on lectures for a course that the authors have run for several years at the University of Guelph, and it is intended to give senior undergraduates a broad assessment of pesticides. The authors have achieved a high degree of detached assessment, based on the premise that although pesticides are virtually essential they also can and do present serious problems. On occasion this detachment almost becomes a fault, as both sides of some issues are presented in such a way that the authors' opinion is not immediately obvious. Students are unlikely to have the background of knowledge and experience to decide for themselves what reasonable assumptions can be drawn from a series of disjointed facts unless there is a fairly clear critical assessment of the issues involved.

The introductory chapter outlines the development of modern synthetic insecticides during and since the Second World War, the consequent problems of resistance to insecticides, the contamination of the environment by persistent insecticides, the effects on wildlife, possible hazards to human beings, and the possible role of integrated control. Several brief chapters then describe the types of issue raised by the use of pesticides, their use in public health, agriculture, forestry and 'rights-of-way', and for domestic purposes. No mention is made of industrial uses, particularly the treatment of wool and timber, which is causing much discussion in some parts of the world. A brief elementary but good chapter describes current testing procedures for the development of new pesticides: it should perhaps have referred to the current pressure for increasingly extensive and expensive toxicity tests, with the possible repercussions on the ability and willingness of chemical companies to develop new pesticides.

The major part of the book falls into two sections. The first gives brief accounts of the chemical, physical and biological properties of many individual pesticides, and the second describes the occurrence, movement and effects of pesticides in various parts of the environment — soil, water, air, food, birds, mammals and the biosphere.

This is a book that requires intelligent skimming, which would be helped if each chapter started with a list of its subdivisions. There is much material that may be useful for reference, but surely not all to be considered in detail. Examples are taken principally from North America, but this does not altogether detract from the book's value for a British or European readership. For instance, the accounts of spraying against spruce budworm in the forests of New Brunswick, the consequent effects on salmon in the Miramichi River, and the effects of parathion on agricultural workers in California are all of general interest.

I would fault the book on details. The section that describes individual pesticides, despite its extensive coverage, is not too well integrated with the section on pesticides in the environment: residues of dichlobenil and BHC are mentioned, but the student will find no account of their chemistry and properties. The decline of peregrine falcons (*Falco peregrinus*) in Great Britain is attributed to eggshell thinning, instead of the acute toxicity of dieldrin poisoning. The authors do state that pesticides in water can be associated with particulate matter, but quote LC_{50} values for DDT of up to 2,400 p.p.10^9, whereas the best estimates for the maximum solubility of DDT in water are a little over 1 p.p. 10^9. Similarly no comment is made on this aspect of Wurster's work on the effects of DDT on phytoplankton at concentrations of 10–100 p.p. 10^9.

On occasion too one would like the authors' opinions. The Delaney amendment in the USA, which prohibits the use on food of any pesticide that has been shown to be carcinogenic, is mentioned without any comment, although eighty pages later two and a half pages are devoted to testing for carcinogens. Again we are told, without comment, that "environmentalists" have criticised severely the use of dieldrin against fire ants. This is a programme of which those outside of North America may have heard but may lack detailed knowledge.

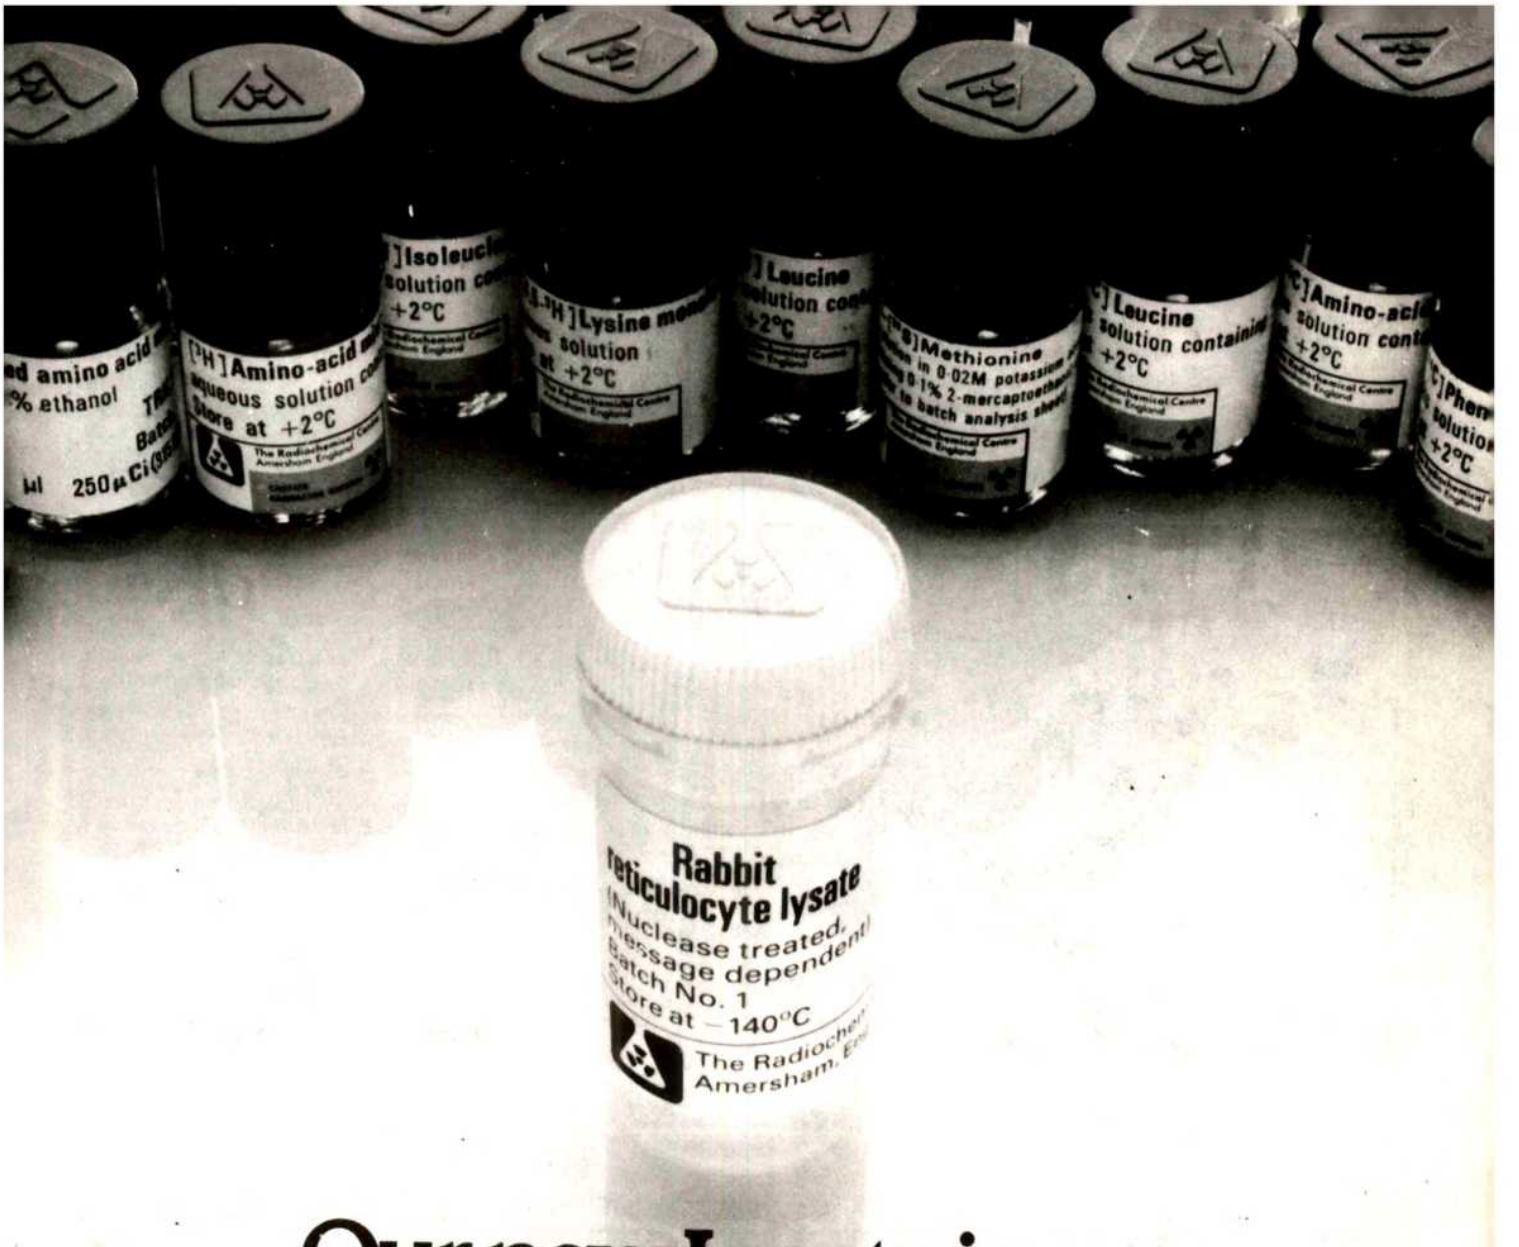
There is remarkably little about resistance — it is not listed in the index at all — nor about the wider ecological implications of pesticide use. To conclude, this is a book worth dipping into, although it will not suffice on its own for a broad assessment of pesticides. **F. Moriarty**

F. Moriarty is a Principal Scientific Officer at Monks Wood Experimental Station, Institute of Terrestrial Ecology, Abbots Ripton, UK.

Crystal structure determinations

Inorganic Molecular Dissymmetry. By Y. Saito. Pp. 167. (Springer: Berlin, Heidelberg and New York, 1979.) $42.90; DM78.

PROFESSOR Yoshihiko Saito pioneered in 1955 the determination of the absolute stereochemical configuration of chiral transition metal coordination compounds by the anomalous X-ray scattering method, following the application of the technique by Bijvoet in 1951 to (+)-tartaric acid. The latter study showed that the arbitrary stereochemical convention of Emil Fischer, proposed in 1891, is in fact correct, while the former demonstrated that Werner's prototype dissymmetric complex, (+)-tris(ethylenediamine)cobalt(III),(+)-$[Co(en)_3]^{3+}$, has the morphology of a left-handed three-bladed propeller, later termed the *Λ*-configuration.



More recently Professor Saito has measured the electron-density distribution around the metal ion in transition metal complexes from the difference synthesis maps obtained through the use of automated X-ray diffractometers. In the case of $[Co(en)_3]^{3+}$, for example, it is found that the cobalt(III) ion is almost uncharged, in agreement with Pauling's electroneutrality principle, and that the 3d-electron density distribution is aspheric, with lobes located at the corners of a cube centred on the metal ion, while the electron density of the nitrogen non-bonding electron-pairs forming the coordinate bonds are somewhat displaced from the line joining the nitrogen atom to the metal ion.

His book, *Inorganic Molecular Dissymmetry*, provides a concise account of the principles underlying these studies and of their application in selected crystal-structure determinations, together with the theoretical basis and the practical articulation of conformational analysis applied to metal chelates, and of the investigation of d-electron optical activity in chiral transition metal complexes. The introduction to the book covers the types of isomerism encountered in metal complexes, and used by Werner in his structure theory, symmetry notation, and the specification of absolute configuration. The illustrations are clear and instructive, as are the mathematical appendices.

The book is directed towards a general and synthetic understanding of chiral molecules, and their unique property of optical activity, in the field of transition metal chemistry. The level of treatment is suited to graduate or advanced undergraduate teaching. For these roles, and for library reference, the book is strongly recommended.

S.F. Mason

S.F. Mason is Professor of Chemistry at King's College, University of London, UK.

Our new Lysate is out on its own–but is backed by 80 labelled amino-acids

With Amersham's new reticulocyte lysate you just add the labelled amino-acid of your choice and mRNA and incubate. The lysate has been nuclease treated* to remove endogenous mRNA and has been optimised for immediate and convenient use. Each batch is tested for high protein synthesis activity with low background and is available from stock.

Our new lysate is backed by a comprehensive range of about 80 amino-acids labelled with ^{3}H, ^{35}S and ^{14}C, including our very widely used L-[^{35}S]methionine. All are produced to the same high standards of purity.

On its own our new lysate gives you quality, convenience and flexibility.

Together with our range of labelled amino-acids it gives you a complete, high quality translation package you can rely on for protein synthesis.

*based on the method of Pelham, H.R.B. and Jackson, R.S. *Eur. J. Biochem.*, **67,** 247-257, 1976.

Endorphins in Mental Health Research

Edited by Earl Usdin, William E. Bunney Jr. and Nathan S. Kline
This collection of papers provides an invaluable account of the current state of research in this new field of neuroscience. The vital issues covered are bound to stimulate a renewed controversy and further research activity – both from those already directly involved and from those who feel that they cannot ignore the increasing relevance of endorphins to their own work.

APPOINTMENTS VACANT

THE UNIVERSITY OF MANCHESTER
Oxford Road, M13 9PL
DEPARTMENT OF ZOOLOGY

TECHNICIAN (Grade 5)

or the Genetics section to assist with esearch on mosquitoes and other tropical nsects. Applicants should have a degree, HNC or equivalent and several years' elevant experience.

Salary on the scale £3,770 to £4,320 pa under review).

Applications together with the names of wo referees, should be sent to Dr R J Wood, Department of Zoology. 3734(A)

UNIVERSITY OF MANCHESTER

LECTURESHIP IN PHYSICS

pplications are invited for the above post. he Lecturer will be expected to take part in aching in the Physics Department and to rry out research on Experimental lementary Particle Physics, in either the ADE Collaboration on the PETRA e+e- orage ring at Hamburg or the Photon llaboration on the OMEGA detector at e SPS at CERN, Geneva. Further formation can be obtained from ofessor P G Murphy. Salary within the nge £4,333 to £8,992. Superannuation. tial salary will depend on age and perience but is unlikely to be above ,199.

Applicants with appropriate experience experimental particle physics should ply to the Registrar, The University, anchester M13 9PL, from whom further rticulars and application forms are tainable. Completed forms should be urned by December 15th. Quote ref: 4/79/N. 3730(A)

ROTHAMSTED XPERIMENTAL STATION
Harpenden, Herts AL5 2JQ

ADDITIONAL ORGANIC CHEMIST

h good practical ability required to work eam synthesizing powerful insecticides ted to the pyrethrins. Excellent instru- ntal facilities available. This temporary t (2 years) is provided by the National earch Development Corporation to loit promising previous work. The ointment should start as soon as sible. Minimum qualifications: HNC, s degree or equivalent, with five years' vant post-qualifying experience.

ppointment in grade of Higher ntific Officer, £4727 to £6211 (£5097 to 37 from 1.1.80). Starting salary accord- to qualifications and experience. Non tributory superannuation.

pply in writing to the Secretary giving es and addresses of two referees and ting Ref 415 by 30th November, 1979. her particulars on request. 3757(A)

STANFORD UNIVERSITY

GEOCHEMIST —PETROLOGIST

The Department of Geology in the School of Earth Sciences invites applications for a faculty position beginning September, 1980. Areas of interest include (but are not limited to) geochemical processes in the crust and mantle of the earth including isotope geochemistry, thermodynamics, kinetics, element distribution and phase equilibria studies. Teaching responsibilities might include graduate and undergraduate courses in geochemistry and igneous petrology. Level of appointment is open, but we are particularly interested in a creative young person, with a well-established record in research.

Applications should include (1) a resume of education, professional experience, and published research; (2) a brief statement of plans for future research, and (3) the names of 4 referees. Send to: Prof. J.G. Liou, Department of Geology, Stanford University, Stanford, CA 94305, by December 1st, 1979. Stanford University is an equal-opportunity/affirmative-action employer. W329(A)

POST-DOCTORAL POSITION
Cambridge

For either an experienced electron microscopist or a biophysicist with interests in laser and fluorescence work. From 1st January 1980 for 3 years with a mammalian experimental embryology group. Applications to Dr M Johnson, Department of Anatomy, Downing Street, Cambridge. 3758(A)

KING'S COLLEGE HOSPITAL MEDICAL SCHOOL
(University of London)
Denmark Hill,
London SE5 8RX

JUNIOR MEDICAL LABORATORY SCIENTIFIC OFFICER 'B'

required for the Chest Unit in this Medical School. Work will involve contact with patients and assisting doctors with research into diseases of the lung.

Minimum requirements, 5 'O' levels, 4 in Science subjects including maths, day release available. Post suitable for school leaver.

Salary according to age, qualifications and experience.

Applications, in writing, giving full details should be sent to the Secretary of the Medical School at the above address. Closing date 29th November, 1979. 3732(A)

SCOTTISH SOCIETY FOR RESEARCH IN PLANT BREEDING
PRINCIPAL SCIENTIFIC OFFICER

A vacancy exists in the staff of the Potato Breeding Department at the Scottish Plant Breeding Station for a Potato Breeder in the grade of Principal Scientific Officer.

The person appointed to fill this post will be responsible to the Head of Department for a wide range of potato breeding and associated work carried out by the Department, and will be expected to collaborate with other senior staff members in the up-dating and development of the department's breeding programme. The appointee will be required to lead teams engaged in field work, which will involve travel to trial sites in various parts of the United Kingdom, and to liaise with collaborators in the potato processing industry and in other breeding organisations.

Applicants should be experienced plant breeders with a flair for planning, analysis and interpretation of field trials data, and a facility for collaboration.

Qualifications: 1st or upper 2nd class Honours degree in a biological subject, with considerable relevant post-graduate research experience.

Salary: In the range £7,534 to £9,646 per annum.
The post is superannuable.

Application forms may be obtained from The Secretary, Scottish Plant Breeding Station, Pentlandfield, Roslin, Midlothian, EH25 9RF, to whom completed forms should be returned not later than 7th December 1979. 3727(A)

SYDNEY HOSPITAL

Director of Medical Research

Kanematsu Memorial Institute

Applications are invited from medical graduates with senior degrees and substantial research experience for the position of Director of Medical Research.

Sydney Hospital, the oldest Hospital in Australia, was founded 191 years ago. It is situated in the centre of the City of Sydney and is a Teaching Hospital of the University of Sydney. During the year 1978/79, 18,828 inpatients were admitted to its 476 beds and 250,000 persons attended as outpatients.

The Kanematsu Memorial Institute, an integral part of Sydney Hospital, was established in 1933 and provides a clinical service as well as both clinical and applied research.

The Director will be in charge of the Medical Research Department which has well equipped laboratories, a workshop, an animal house and its own associated wards. The Director may develop fundamental and/or clinical research along any line appropriate to the work of the Hospital.

The salary will be that of a Senior Medical Specialist (at present up to A$39,061). There is also an administrative allowance and a right of limited private practice.

A supporting statement giving information about the Department, the Institute, and the Hospital, as well as details of the conditions of employment and instructions to applicants is available from the undersigned.

Applications close on 1st January, 1980, and should be forwarded to the undersigned in an envelope marked "Director of Medical Research". Further enquiries should be addressed to Chief Executive Officer, Sydney Hospital, Macquarie Street, Sydney, NSW 2000, Australia. 3723(A)

Entomologist

Fisons Limited, Agrochemical Division is a major UK producer of chemicals for agriculture, public health and industrial applications.

The Research and Development Centre for these rapidly growing operations is based at Chesterford Park, a renovated country house set in its own gardens near Saffron Walden, Essex, providing an attractive location for a secure career.

We are currently looking for an Entomologist (male or female) to join a team of scientists engaged in assessing the value of pesticides as new compounds, new formulations or new uses, under laboratory, greenhouse or field conditions both in the UK and abroad.

You should have a post graduate qualification in applied entomology, but graduates with a good honours degree in a related subject and experience should not be deterred from applying.

We offer a competitive salary supported by a substantial range of fringe benefits normally associated with a major industrial company including assistance with relocation expenses where appropriate.

For full details and an application form please write to or telephone: Peter England, Personnel Officer, Fisons Limited,
Agrochemical Division,
Chesterford Park Research Station,
Saffron Walden, Essex CB10 1XL.
Telephone: Saffron Walden 23542.

FISONS

3772(A)

REGIONAL NMR FACILITY

The University of Illinois has recently been designated as an NSF Regional Instrumentation Facility for NMR Spectroscopy. Systems operating at 500, 360(2), 250, 220 and 150 MHz will be featured in the Facility and the following positions are now available:

SPECTROSCOPIST

We are seeking a highly motivated and talented individual who will assist in the design and construction of state-of-the-art Fourier transform NMR instrumentation. This work will initially involve development of a new 500MHz high-sensitivity spectrometer for NMR of solids and liquids. Previous experience in one or more of the following areas is essential: probe design for high-field FT NMR; spectrometer construction; mini/micro-computer programming and interfacing.

The primary job responsibility is to help establish and maintain a state-of-the-art NSF Regional NMR Instrumentation Facility for the Midwest in the School of Chemical Sciences. The successful candidate will typically possess a PhD in Chemistry or Physics, or an MS in Electrical Engineering. The starting salary will be not less than $22,000, depending upon experience and qualifications. The position is a continuing one and offers a month's vacation per year. The starting date is negotiable but an early date is preferred. The appointment will be academic/professional.

RESEARCH ASSOCIATE

We have an additional vacancy, for a Research Associate (about $12-13,000, with one month's vacation), to participate in the development of high-field NMR spectrometer and probe instrumentation, together with demonstration of improved performance on systems of chemical and biological interest. This position is available immediately, would be renewable for a second year, and would be suitable for a PhD chemist wishing to gain additional experience with NMR instrumentation and new applications.

Applications for either position should include a *curriculum vitae* and three letters of recommendation and should be submitted as soon as possible, preferably by January 1, to Professor Eric Oldfield, School of Chemical Sciences, University of Illinois, Urbana, Illinois 61801, Phone: (217/333-3374). The University of Illinois is an Affirmative Action/Equal Opportunity Employer.

W526(A)

THE AUSTRALIAN NATIONAL UNIVERSITY

RESEARCH SCHOOL OF PHYSICAL SCIENCES

RESEARCH FELLOW IN ULTRAVIOLET PHYSICS

Applications are invited from suitably qualified persons for appointment as Research Fellow, to work with the Director, Professor J H Carver, in the Ultraviolet Physics Unit. The Unit investigates laboratory problems of astrophysical and atmospheric significance and collaborates with members of the Mount Stromlo and Siding Spring Observatories and the Plasma Research Laboratory of the Research School of Physical Sciences. Applicants should have research experience in one or more of the following fields: photoionization and photoabsorption in atmospheric gases, VUV spectroscopy, plasma spectroscopy, laboratory astrophysics, evolution of the atmosphere, space astronomy, computer control of atomic and molecular physics experiments.

Salary on appointment will be in accordance with qualifications and experience within the range: $A16,291 to $21,265 per annum. Present exchange rate: $A1 = £0.51p.

Appointment is for three years with possible extension to five years.

Reasonable appointment expenses are paid. Superannuation benefits are available for applicants who are eligible to contribute. Assistance with finding accommodation is provided for an appointee from outside Canberra. The University reserves the right not to make an appointment or to make an appointment by invitation at any time.

Prospective applicants should first obtain further particulars from the Association of Commonwealth Universities (Appts), 36 Gordon Square, London WC1H 0PF. Applications close on 31 January 1980. 3760(A)

MEDICAL RESEARCH COUNCIL

INSTITUTE OF HEARING RESEARCH

2 RESEARCH SCIENTISTS (Nottingham and Cardiff)

In collaboration with DHSS and the Welsh Office, the Institute is establishing outstations for multi-centre applied research into hearing, of relevance to services for the hearing-impaired. The multi-centre research and development work is of three main types, all using the close links with the service activity of the otolaryngology departments of the respective University Hospitals — epidemiology, detailed clinical characterisation, and the trial of pharmacological and electronic plus rehabilitative regimes of management. Experienced scientists are required to oversee the scientific aspects of the activity of the support teams provided by the Health Departments and to make an original personal research contribution within the broad programme of the Institute. The pre- and post-doctoral backgrounds of applicants may be in any science basic to medicine and its application, but some consideration will be given to the relationship between applicants' suggested personal research and the specific facilities in and outlined programmes for the respective outstations.

The appointments will be from 1st January 1980 or other time to be agreed. Further particulars and forms are available from Dr. M.P. Haggard, Institute of Hearing Research, Medical School, Clifton Boulevard, Nottingham NG7 2UH, to whom applications should be sent by 30th November 1979. Salary will be on the MRC Grade II or 1 scientist scale (£4232 to £6627 or £6886 to £8452). For an appointee of appropriate experience the senior grade (£8182 to £10,097) may be used. 3742(A)

NEW HALL
Cambridge

Applications are invited from school teachers who are teaching chemistry to spend a term at New Hall during the academic year 1980/81 as the Salters' Fellow Commoner. Free board and lodging and a small allowance is available.

Particulars may be obtained from the President, New Hall, Cambridge, to whom applications should be sent by 31st March, 1980. 3756(A)

ATHROFA GOGLEDD-DD CYMRU
The North East Wales Institute of Higher Education

SCHOOL OF NATURAL SCIENCE (RESEARCH DIVISION)
Kelsterton College

RESEARCH ASSISTANTS

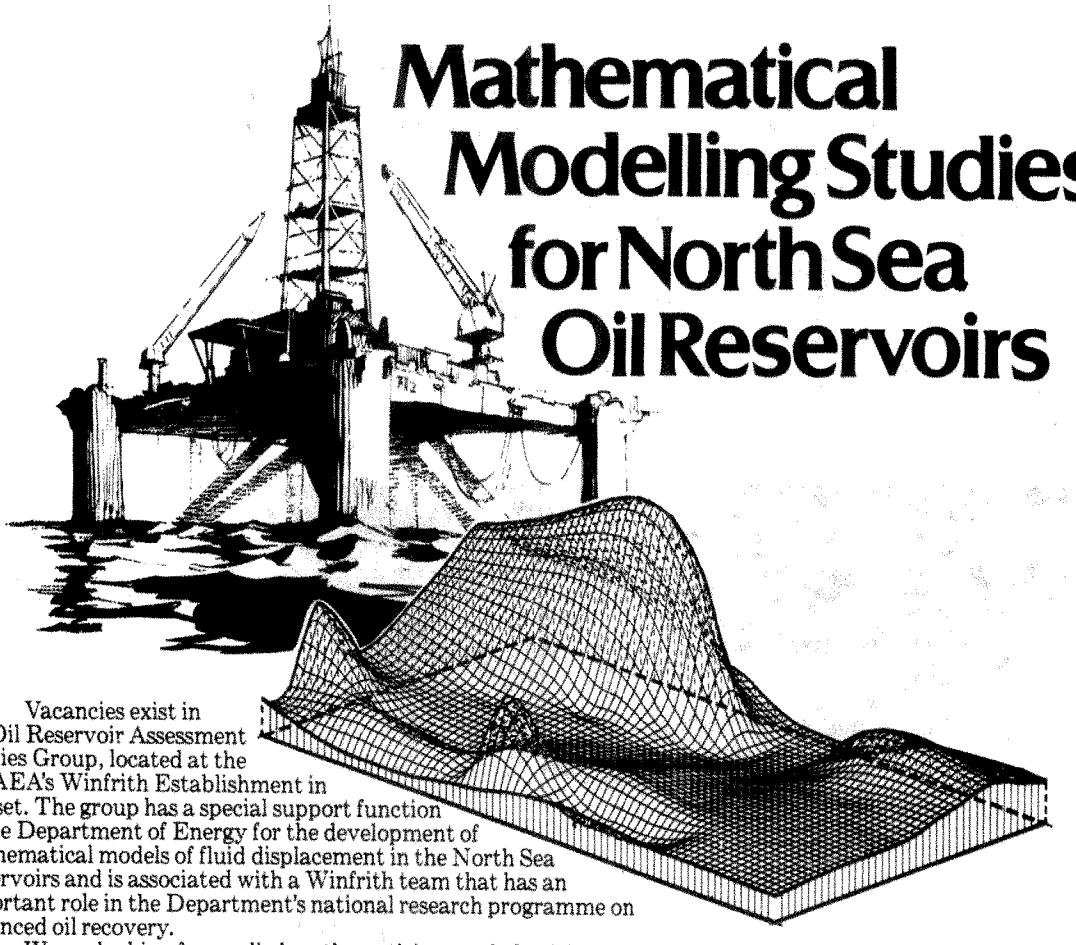
Two posts are available, initially for a 2 year period, for a suitably qualified:
1. Biochemist, with interests in cellular and intermediary metabolism.
2. Cell biologist, preferably with experience in tissue culture techniques.

Both posts are industrially-sponsored, and form part of the Institute's programme of drug research, under the general supervision of Dr J C Allen, the Head of the Research Division. The Division possesses well equipped animal and tissue culture facilities.

Appointment will be on the T3/4 Grade of the NJC scales, with salary between £4,080 and £5,067 pa. Applicants, who should be Honours Graduates, and who will have the opportunity to register for a higher degree, should apply to The Institute Registrar, Kelsterton College, Connah's Quay, Clwyd, before 30th November, 1979. 3695(A)

UNIVERSITY OF WAIKATO
Hamilton, New Zealand

LECTURER IN EARTH SCIENCES



The University of Waikato invit applications for the position of Lecturer Earth Sciences. The appointment may made for a limited term. The appoint should be able to undertake and supervi research in either engineering hydrology in the physics and hydraulics of water an sediment motion in fluvial, estuarine, coastal environments.

Some general teaching in hydrology undergraduate level will also be require The salary will be in the range f Lecturers: NZ$13,722 to $16,861 p annum.

Further information on the method application and general conditions appointment is available from t Registrar, University of Waikato, Priv Bag, Hamilton, New Zealand or from Association of Commonwea Universities (Appts), 36 Gordon Squa London WC1H 0PF. Enquiries of academic nature may be made to Profes J D McCraw, Head of Earth Sciences the University. Applications close on January 1980. 3759(A

Applied Mathematicians and Physicists

Mathematical Modelling Studies for North Sea Oil Reservoirs

Vacancies exist in the Oil Reservoir Assessment Studies Group, located at the UKAEA's Winfrith Establishment in Dorset. The group has a special support function to the Department of Energy for the development of mathematical models of fluid displacement in the North Sea Reservoirs and is associated with a Winfrith team that has an important role in the Department's national research programme on enhanced oil recovery.

We are looking for applied mathematicians and physicists in their 20s or early 30s with honours degrees, preferably with some background in computational methods. Candidates should be able to demonstrate high-level scientific attainment.

The work spans a broad range of technical interests, including an understanding of fluid flow phenomena in porous media, solution of coupled systems of partial differential equations, computer code organisation and refinement, and an appreciation of field characteristics and the problems of optimal selection of model details in matching predicted performance to field observations. Simulation studies are undertaken on an IBM 3033 computer which is data linked via an Interdata 732 work station with colour graphics and other input/output devices.

Scientific Officer, Higher Scientific Officer and Senior Scientific Officer posts are offered with the recently agreed salaries effective from 1 January 1980 in the range of £4,720-£9,315, depending upon experience. The Winfrith establishment which undertakes a wide range of nuclear and non-nuclear programmes of work, is situated in pleasant rural surroundings close to the Dorset coast. There are excellent recreational and residential amenities in the surrounding areas from Bournemouth to Dorchester and Weymouth. We also have generous leave allowances and a contributory superannuation scheme.

For further information and application forms, please contact Mr. P. J. A. Fysh, Personnel Manager, AEE Winfrith, Dorchester, Dorset. Telephone No. 0305 3111, Ext. 3455. (Reference WA 321).

3738(A)

AEE WINFRITH

Head of Astrophysics Group

A vacancy has arisen for a Senior Principal Scientific Officer to head the Astrophysics Group of the new Space and Astrophysics Division within the merged Rutherford and Appleton Laboratories.

The current and planned programmes of the Division include ultra-violet and X-ray solar studies, ultra-violet astronomy and an infra-red astronomy satellite and millimetre astronomy project. The majority of the programme is based upon the use of Space techniques.

The Astrophysics Group, which is broadly identifiable with the former Astrophysics Research Division at Culham in Oxfordshire, undertakes programmes in collaboration with university research groups. In the future, these will involve a closer integration of the Laboratory's research and support roles.

The successful candidate will take overall responsibility for the work of the Group whilst pursuing his/her own research within the approved programme of the Group. He/she will report direct to the Division Head and be expected to play a full part in the management of the Division which currently has about 120 staff.

The officer appointed is likely to be an active research scientist with substantial experience in one or more of the areas outlined above and should have the ability to co-ordinate project teams and manage large collaborative programmes.

Salary will be paid within the range of £14,250 to £15,748 on the SPSO scale, according to experience. These rates will be payable from 1.1.1980.

The post will be based initially at Culham, but will move to the Rutherford Laboratory site at Chilton in Oxfordshire within one or two years.

Applicants should request an application form from:

Jane Griffiths, Rutherford and Appleton Laboratories, Chilton, DIDCOT, Oxon OX11 0QX.

Tel: Abingdon (0235) 21900 Ext. 510. Please quote reference VN5012.

CLOSING DATE: 3 December 1979.

3728(A)

Rutherford and Appleton Laboratories

COMMONWEALTH AGRICULTURAL BUREAUX

COMMONWEALTH MYCOLOGICAL INSTITUTE

Kew, Surrey

SCIENTIFIC INFORMATION OFFICER

The Commonwealth Mycological Institute has a vacancy for a Scientific Information Officer. The main duties include preparing abstracts of the literature on plant pathology and mycology, information retrieval from the CAB computerised database, preparation of bibliographies, and editorial work.

Qualifications: A degree in biological science in which plant pathology has featured is required. Post-graduate experience in plant pathology would be desirable, as would knowledge of or willingness to learn European languages.

Salary: In the scale £3,289 to £6,211 per annum plus Outer London Weighting £325, plus a compensatory allowance (taxable but not superannuable) of 3.3% of basic salary to offset personal contribution to superannuation scheme. Starting salary according to qualifications, experience and age.

Applications by 14 December to the Executive Director, Commonwealth Agricultural Bureaux, Farnham House, Farnham Royal, Slough SL2 3BN, from whom application forms and particulars can be obtained. 3767(A)

LINCOLN COLLEGE (University College of Agriculture) New Zealand

LECTURER IN CROP PHYSIOLOGY

Applications are invited for the position of Lecturer in the Department of Plant Science. Applicants should have a postgraduate qualification and research experience in crop physiology, preferably combining a sound knowledge of physiological principles with personal experience of crop pasture production. Teaching at undergraduate and postgraduate levels will necessitate competence in such topics as photosynthesis, water relations, competition, etc.

Commencing salary according to qualifications and experience. Present salary scale for lecturing staff is: NZ$13,722 to NZ$16,861.

Travel and removal expenses are reimbursed up to specified limits. New Zealand Government Superannuation available.

Conditions of Appointment are obtainable from the Association of Commonwealth Universities (Appts), 36 Gordon Square, London WC1H 0PF, or from the Registrar of the University. Applications close on 15 January 1980. Please quote Vacancy No 78/50. 3720(A)

UNIVERSITY OF OXFORD

SOIL CHEMIST

preferably post-doctoral to work on an ARC project on the solubilization of soil phosphate in the rhizosphere. Salary in Grade 1A: £4333 to £7521.

Applications, mentioning two referees, to the Administrator, Department of Agricultural Science, Parks Road, Oxford OX1 3PF before 30 November 1979. 3750(A)

QUEEN ELIZABETH COLLEGE Kensington (University of London)

TECHNICIAN GRADE 5

NUTRITION DEPARTMENT

A vacancy exists for a technician to run the automatic analyser unit providing a service for the department and College. Applicants should have experience in the use of Technicon Autoanalyser systems, and some knowledge of amino acid analysis would be an advantage.

Salary in range £3,700 to £4,320 p.a. (under review) plus London weighting of £780 p.a. Application forms from the College Secretary, Queen Elizabeth College, Campden Hill Road, London W8 7AH. Tel: 01-937 5411 ext 209. 3763(A)

Southampton THE UNIVERSITY

DEPARTMENT OF PHYSICS MAGNETISM GROUP

Two posts are available to support investigations into the magnetic properties of rare earth ions in (a) two-dimensional systems and (b) inter-metallic compounds. A third post (c) is available to study a number of transition metal alloys in high magnetic fields.

Applicants should hold or expect to hold a PhD in Physics or Materials Science, or for post (a) in Physical Chemistry although applications for posts (b) and (c) will be considered from those with a good honours degree. Such applicants would be permitted to register for a higher degree.

Starting salary will depend on age and experience and the posts will be available for two years in the first instance.

Applications which should include the names of two referees should be addressed to Professor E W Lee, Department of Physics, The University of Southampton, SO9 5NH, from whom further particulars can be obtained. Please quote reference N. 3740(A)

MANCHESTER POLYTECHNIC

DEPARTMENT OF BIOLOGICAL SCIENCES

RESEARCH ASSISTANT

to work in one of the following areas:- Toxicological and physiological effects of organic nitrates; copper tolerance in algae; biochemistry of peptide hormones; ultra-structure and physiology of mammalian capillary growth.

Candidates should be well-qualified academically and have research experience up to PhD level.

Salary scale: £3,780 to £4,083.

For application form (returnable by 7 December 1979) please send a self-addressed envelope marked "T/525" to the Secretary, Manchester Polytechnic, All Saints, Manchester, M15 6BH. 3724(A)

VIROLOGIST: SEARCH REOPENED Applications are solicited for a nine month, tenure track faculty position. Th appointment will be at the Assista Professor level and will be availab immediately. Applicants must have a Ph and postdoctoral experience. Th successful candidate will be expected develop and direct a quality researc program and advise graduate student Preference will be given to candidat actively studying viral diseases and vir pathogenesis but applications from indi iduals working in other areas will considered. Responsibilities will inclu teaching at the introductory and advanc levels.

Send curriculum vitae and three letters reference to: Neil R. Baker, Chairma Search Committee, Department Microbiology, The Ohio State Universi 484 W 12th Avenue, Columbus, Oh 43210. Applications will be accepted un March 1, 1980. An Equal Opportunit Affirmative Action Employer. qualified persons, including wome members of minority groups, and handicapped are encouraged to apply. W527(A)

NIHE

National Institute for Higher Education Dublin
Foras Náisiúnta um Ardoideachas Baile Átha Cliath

The National Institute for Higher Education, the most recently established higher education institution in Ireland, is engaged in recruiting its first academic, academic support and administrative staff to participate in the development and implementation of its first academic programmes which will commence in Autumn 1980 with the enrolment of its first students. The Institute will conduct programmes within the five Faculty areas of Administration, Business & Professional Studies, Science and Paramedical Studies, Engineering & Design, Education Studies and Communication and Human Studies.
Initially six first degree programmes will be conducted including programmes in Electronics, Analytical Science, Business Studies, Accounting & Finance, Computer Applications, Media Studies, Staff Development and Languages.

The Institute is now seeking to recruit to the following positions:-

Faculty of Science

Head of School of Chemical Sciences
Head of School of Biological Sciences
Head of School of Mathematical Sciences
Head of School of Physical Sciences

Two at Principal Lecturer level and two at Senior Lecturer level, together with 8 lecturers within the Schools.

CHEMISTRY
- Inorganic, Organic, Physical, Analytical.

BIOLOGY
- Botany, Zoology, Microbiology, Biochemistry, Environmental Science.

PHYSICS
- Applied Physics, Molecular Spectroscopy, Experimental Physics.

MATHEMATICS
- Applied Mathematics, Computer Science.

Faculty of Engineering

Head of School of Electronic Engineering *(Principal Lecturer)*
Four lectureships in Electronics (including Digital Electronics) are also to be filled.

Similar ranges of positions are also available within the Faculties of Administration, Business & Professional Studies, Communications & Human Studies and Education Studies.

Academic Support Services

A number of professional support units are also being established. The following positions are, therefore, also being filled.

Librarian *(Principal Lecturer)*
Head of Computer Services *(Senior Lecturer)*
Head of Educational Technology *(Senior Lecturer)*

CURRENT SALARY SCALES (under review)

Principal Lecturer	£10,859 -	£12,461
Senior Lecturer	£9,020 -	£11,309

Qualifications
Candidates will normally be expected to be highly qualified academically, preferably holding a higher degree or professional qualification, with considerable industrial, business and academic or research experience at an advanced level. Considerable importance will be attached to the teaching and research abilities of candidates.

For further information, apply immediately to: National Institute for Higher Education, 1 Lower Grand Canal Street, Dublin 2. Ireland. Telephone: 765175.

3733(A)

Biologist

Immunology Project Indonesia

As part of Australia's aid programme which seeks to assist developing nations in promoting the economic and social advancement of their people, the Australian Development Assistance Bureau (ADAB) is undertaking in Indonesia, a project for research and training in immunology. The Royal North Shore Hospital, Sydney will be managing agent for this project and is seeking the services of a Biologist.

The laboratories for the project are situated in the Biomedical Research Centre, National Institute for Health Research and Development (Ministry of Health), Jakarta. The research work of the project includes studies on the immunology of filariasis, hookworm and tuberculosis. The laboratories have a wide range of equipment for studies of cellular and humoral immunity.

Duties
The successful applicant will be responsible for much of the laboratory immunology, under the direction of the Australian team leader, Dr D A Higgins.

Qualifications and Experience
Applicants should have a PhD or equivalent qualification or experience in immunology or a relevant branch of biology.

Salary and conditions
The salary range is that for a Senior Scientific Officer (NSW Public Hospital Scientists Award), at present $A17,955-21,965. (At current rate of exchange £1 = $A1.88). Conditions of appointment include:—

* Appointment for two years in the first instance
* Return air fares to Jakarta
* Accommodation at a reasonable rental will be arranged
* Certain allowances, e.g. post allowance, cost-of-living adjustments, settling-in allowances, conference allowances
* Leave fares within the region

Applications
Full details of qualifications and experience including publications, should be sent to: Dr D S Nelson, Director, Kolling Institute of Medical Research, Royal North Shore Hospital, St Leonards, NSW, Australia 2065. A copy should also be sent to: Dr D A Higgins, Team Leader, Immunology Project — Indonesia, Australian Embassy, Jalan Thamrin 15, Jakarta, Indonesia. Enquiries about the work of the project and facilities available should be directed to Dr Higgins.

Applications close on 7 December, 1979. 3755(A)

M.R.C. CLINICAL RESEARCH CENTRE
(Northwick Park Hospital) Watford Road, Harrow, Middx HA1 3UJ.

The division of Comparative Medicine requires a

VETERINARY GRADUATE

with an interest and experience in the health, welfare and management of experimental animals. The successful candidate will be expected to participate in collaborative projects and to carry out independent research to investigate animal models for the study of low birth-weight infants, particularly in relation to disturbances of carbohydrate metabolism.

This is a limited term post and the appointment will be for a period of 4 or 5 years depending on age and experience. Candidates should have a minimum of three years relevant experience since qualifying and salary will be within the range £6,066 to £8,992 plus £740 pa London allowance.

Potential applicants may discuss this appointment with Dr C R Coid (Tel: 01-864 5311 extn. 2510) before applying to Miss B. Shaw for an application form, quoting ref. 102/1/3896. Closing date 10th December, 1979. 3752(A)

AGRICULTURAL RESEARCH COUNCIL
INSTITUTE OF ANIMAL PHYSIOLOGY
Babraham, Cambridge, CB2 4AT

A vacancy, financed by the National Institutes of Health for three years from October 1st 1979, exists for a

POST DOCTORAL SCIENTIST

to assist with research on the mechanism of transport of steroids and other compounds into the seminiferous tubules of the testis.

Salary in Higher Scientific Officer (£4,727 to £6,211 p.a.) (£5,097 to £6,737 from 1.1.80) or Senior Scientific Officer (£5,876 to £7,864 p.a.) (£6,332 to £8,705 p.a. from 1.1.80) scale according to experience.

Candidates should have a first or upper second class honours degree in appropriate subject with at least 2 years for H.S.O. and 4 years for S.S.O. relevant post-qualifying experience and a PhD or equivalent training in cellular transport mechanisms, preferably in animals. Non-contributory superannuation schemes.

Application, quoting Ref. B.P.S.2. to the Secretary of the Institute by 30th November 1979. 3768(A)

UNIVERSITY OF NEWCASTLE UPON TYNE
CHAIR OF ORAL PHYSIOLOGY

Applications are invited for the Chair of Oral Physiology which will become vacant on the retirement of Professor G N Jenkins on the 30th September, 1980. The post is open to candidates, with or without dental qualifications, who have biochemical or physiological research interests. The appointment to the Chair will carry with it the Headship of the Department of Oral Physiology for an initial period of five years.

The salary will be in accordance with the professorial scale with membership of the appropriate superannuation scheme.

Further particulars may be obtained from the Senior Assistant Registrar, The Medical School, University of Newcastle upon Tyne, Queen Victoria Road, Newcastle upon Tyne, NE1 7RU, with whom applications (15 copies) giving the names of not more than three referees, must be lodged not later than 15th January, 1980.

(Applicants from outside the British Isles may submit one copy only.) 3726(A)

SUNDERLAND POLYTECHNIC
Faculty of Science
SCHOOL OF PHARMACY
RESEARCH OFFICER/ RESEARCH ASSISTANT IN PHARMACOLOGY

Applications are invited from interested persons for the above position, renewable annually for up to three years. The successful applicant will be expected to work on a programme, funded jointly by Fisons Limited, Pharmaceuticals Division and the Polytechnic, to study the pharmacology of chemical mediators of allergic disease in abdominal organs. There could be an opportunity for suitably qualified persons to register for a higher degree (MPhil/PhD, CNAA).

Research Officer: £3,480 to £3,780
Research Assistant: £3,030 to £3,330.

An application form and further particulars may be obtained from the Personnel Officer, Sunderland Polytechnic, Chester Road, Sunderland, SR1 3SD, and should be returned as soon as possible. 3722(A)

THE UNIVERSITY OF PAPUA NEW GUINEA

Applicatins are invited for the post of

LECTURER

in the Department of Biology. The appointee will be required to teach courses in Plant Physiology and Ecology and contribute to the general teaching of Botany especially with regard to the lower plants. Tropical experience is an asset but not essential. There is particular opportunity for applicants interested in the biology of aquatic plants.

Salary scale; Lecturer II K13725 pa Lecturer I K11875 pa (£1 sterling = K1.5) Family passages; baggage allowance; 3 yr contract; 24% gratuity of which 5% taxable; research support; rent free accommodation; overseas leave; educational allowances; medical scheme; secondment welcomed.

Detailed applications (2 copies) with curriculum vitae and naming 3 referees to be sent direct to Assistant Secretary, P.O. 4820, University PO, Papua New Guinea by 31 December 1979.

Applicants resident in the UK should also send one copy to Inter-University Council, 90/91 Tottenham Court Road, London, W1P 0DT.

Further details may be obtained from either address. 3771(A)

UNIVERSITY COLLEGE CARDIFF

DEPARTMENT OF BIOCHEMISTRY

RESEARCH OPPORTUNITIES

Applications are invited for the following positions which are available under the direction of Drs. J. Kay and A. Cryer.

RESEARCH ASSISTANT Grade 1B

to work with Dr Kay on chicken pepsin as a rennet substitute. Studies on its production, stability and activity. The project will involve techniques such as enzyme purification, affinity chromatography, milk clotting assays and protein structural investigations.

The appointment which will be for one year in the first instance, with the possibility of renewal for a further two years, is financed by a grant from the Agricultural Research Council. The salary will be in the range of £3,775 to £4,333 (under review).

Candidates should have a good Honours degree in biochemistry or a related subject and research experience in protein chemistry/enzymology would be an advantage.

POST-DOCTORAL RESEARCH ASSISTANT Grade 1A

o work with Drs Kay and Cryer in collaboration with Professor R F Mahler of the Clinical Research Centre on cellular studies of spontaneous atherosclerosis in White Carneau pigeons. The project will nvolve the characterization of both protein and glycosaminoglycan synthesis in pecific cell lines maintained in culture.

The appointment which is for two years with possible extension for a third, is inanced by a grant from the British Heart oundation. The salary will be £4,333 for he first year and £4,622 for the second. xperience of cell culture techniques and adioisotope methodology as applied to rotein and polysaccharide biosynthesis easurements would be an advantage.

POST-DOCTORAL RESEARCH ASSISTANT Grade 1A

o work with Dr Cryer on molecular and ellular aspects of the control of cardiac poprotein lipase activity. The project will volve studies of enzyme synthesis in olated cardiac muscle cells maintained in n already established incubation system.

The appointment which is for one year in e first instance with the possibility of enewal for a further two years, is financed y a grant from the Medical Research ouncil. The salary will be in the range 4,333 to £4,910 (under review).

Candidates should have a PhD or quivalent post-graduate research perience. Experience of work with olated cells, immunological techniques or neral metabolic studies would be an vantage.

Applications (2 copies), including a rriculum vitae together with the names d addresses of two referees and dicating clearly the post of interest, ould be sent to the Vice-Principal dministration) and Registrar, University llege, PO Box 78, Cardiff CF1 1XL. osing date 13th December, 1979. ference 1925. 3731(A)

Analytical Biochemist or Pharmacologist for quality control

The Radiochemical Centre Limited is a world leader in the production and marketing of radioactive isotopes for medical, scientific and industrial purposes. Although the main laboratories and head office of the Company are at Amersham, Buckinghamshire, a major new establishment is nearing completion in Cardiff.

We now require a versatile Life Scientist to be based at Cardiff and who will take responsibility for the development of new quality control testing procedures, including biological methods, for a wide variety of radioactive biochemicals including amino-acids, nucleotides, steroids and biochemicals used in receptor site studies. This is a new post offering an opportunity to employ some of the advanced techniques used in current academic biochemical research.

The position will appeal to Life Scientists – men or women who have had experience and/or research training in analytical biochemistry, pharmacology or biochemical research.

Conditions of service are excellent and include good holidays and a contributory pension scheme. Salaries which are **at present under review** currently start at around £5,000 - £6,000 pa dependent on the calibre of the successful applicant. They are increased with service in accordance with incremental scales. An initial period of training at our Amersham headquarters will be required.

Please write quoting reference number CR73 giving concise career details to: Mr. R. Hart-Jones, Personnel Department, The Radiochemical Centre Limited, Forest Farm, Whitchurch, Cardiff.

BIOLOGY TEACHING OVERSEAS

Research-Teaching positions in Biology starting Fall 1980 in such specialties as: Plant Physiology, Developmental Biology, Plant Taxonomy, Marine Biology (Invertebrate Zoology/Ecology) PhD required, rank and salary dependent on experience & qualifications. Normal contract 3 years with fringe benefits.

Air mail CV, resume & letters of recommendation to: Chairman, Biology Dept. American University of Beirut, Beirut, Lebanon. Review begins Feb. 1, 1980.

AUB is an equal opportunity affirmative action employer. W534(A)

The Department of Pathology at the University of Pittsburgh School of Medicine wishes to recruit a member for its Division of Experimental Pathology. The position will entail research and teaching to medical students and to graduate students. There are ample clinical opportunities for research programs needing them. The major areas of interest in the Division are immunology and tumor biology.

The level of academic appointment will be commensurate with the candidate's qualifications.

Reply with Curriculum vitae to: Thomas J. Gill, MD, University of Pittsburgh School of Medicine, Department of Pathology, Room 716, Scaife Hall, Pittsburgh, PA 15261.

An equal opportunity/affirmative action employer. W495(A)

UNIVERSITY OF EDINBURGH

Department of Molecular Biology

POSTDOCTORAL RESEARCH FELLOW

required as soon as possible to work on the molecular relationships of plasmids from strains of *Pseudomonas* and of enterobacteria. The methods currently being used include genetic manipulation *in vitro*, DNA-DNA hybridisation and electron microscopy of heteroduplexes. The position is for two years.

Further information from Dr P M A Broda (tel 031-667 1081, ext 2886) to whom applications should be sent with the names of referees and details of experience. Please quote reference 5063. 3725(A)

ELECTROPHYSIOLOGIST

Syntex Research Centre is the research division of Syntex Pharmaceuticals Limited, part of the multi-national Syntex Corporation.

Due to continued expansion we have a vacancy for an electrophysiologist within the Pharmacology Department. This position will involve the setting up of an electrophysiology laboratory to investigate the effects of cardiovascular and CNS active compounds. Ideally the suitable applicant will be recently qualified PhD with a keen interest in mode of action studies. Applicants about to attain PhD would be considered.

We offer salaries competitive with appropriate public service grades and attractive conditions of service which include non-contributory pension scheme, free life insurance, membership of BUPA, bonus opportunities and assistance with relocation expenses.

The Centre is in pleasant surroundings in the Research Park of Heriot-Watt University, 7 miles west of the centre of Edinburgh.

Please write or telephone for an application form to: Mr A B Cran, Director of Personnel at the address below.

Range Animal Nutritionist

Overseas Assignment

The Kuwait Institute for Scientific Research is a rapidly expanding institute for applied science and technology. We are currently seeking a Researcher who is interested in a challenging career in range animal nutrition.

You should have a Ph.D. and previous experience in range animal nutrition, preferably dealing with sheep. We also require a minimum of 2-4 years' experience in range animal studies and academic training in an arid region plus a thorough knowledge of laboratory and field techniques of range/sheep studies.

Kuwait Institute offers attractive salaries commensurate with qualifications and experience, furnished housing, liberal fringe benefits including round trip air tickets and free medical benefits.

Please airmail your complete resume by **January 1, 1980** to: **Mr. Habib Al-Sahhaf, Personnel Manager, Kuwait Institute for Scientific Research, P.O. Box 24885, Safat, Kuwait, State of Kuwait.**

TECHNICIAN/ RESEARCH OFFICER

required at the Imperial Cancer Research Fund Human Tumour Immunology Group, University College Hospital Medical School, London, WC1 to work on production and use of monoclonal antibodies to human tumour and differentiation antigens. Experience in tissue culture or cellular immunology an advantage, HNC/Degree.

Salary range £4714 to £5949. For further information and application form write or telephone Miss S.M. Hurley, Imperial Cancer Research Fund, Lincoln's Inn Fields, London, WC2 on 242 0200 ext 305. 3741(A)

DALHOUSIE UNIVERSITY
Halifax, Nova Scotia, Canada

PHYSICAL OCEANOGRAPHERS

Grant-supported positions available for two research associates for theoretical and experimental work on shelf processes. Both post-doctoral and senior applicants welcome. Submit applications with names of three referees before December 15.

Further details available. Dr. C. Garrett, Department of Oceanography, Dalhousie University, Halifax, N.S., Canada, B3H 4J1. W530(A)

FACULTY POSITIONS
DEPARTMENT OF GEOLOGY
UNIVERSITY OF WINDSOR

Applications are invited for two tenure-track positions at the Assistant Professor rank in the following fields: 1. Paleontology-Biostratigraphy, and 2. Engineering Geology — Geotechnical Engineering.

Applicants with expertise in closely related applied geological disciplines (e.g., paleoecology, petroleum geology, rock mechanics, clay mineralogy and oxygen isotope geology) are encouraged to apply. They should hold a doctoral degree or anticipate receiving it near the time of commencement of the positions on July 1, 1980. Both positions involve teaching at the undergraduate and graduate levels as well as conducting a research programme involving undergraduate and graduate thesis students. Salary will depend on the applicant's experience in teaching, research and industrial experience and will be in the range of $20,000 to $25,000. Send a curriculum vitae and the names and addresses of three referees to: Dr D T A Symons, Department of Geology, University of Windsor, Windsor, Ontario, Canada N9B 3P4. W533(A)

UNIVERSITY COLLEGE LONDON
DEPARTMENT OF PHYSIOLOGY

Applications invited for position of

POSTDOCTORAL RESEARCH ASSISTANT

in a Developmental Neurobiology Programme supported by the Wellcome Trust. Research is in progress to study the internal environment of the fetal brain in relation to brain development. Two year appointment to work in group headed by Dr N R Saunders. Starting date 1 December 1979 or by arrangement. Experience of morphological techniques essential, preferably including immunohisto-chemistry.

Salary range £4,910 to £5,199 plus £740 London Allowance.

Further details from and applications to: Dr N R Saunders, Dept. of Physiology, University College, London, Gower Stret, WC1E 6BT. 3770(A)

SCOTTISH SOCIETY FOR RESEARCH IN PLANT BREEDING
SCIENTIFIC OFFICER/ HIGHER SCIENTIFIC OFFICER

A Scientific Officer is required to join the Cereals Department at the Scottish Plant Breeding Station.

The appointee will be required to join a group working with spring barley and spring oats with the object of producing crop varieties adapted to local conditions. Training in genetics and/or pathology along with an interest in the practical aspects of plant breeding would be an advantage.

Qualifications: A pass degree or HNC with relevant experience or an honours degree in a biological science. At least five years relevant post-graduate experience is normally required for appointment as HSO.

Salary: Depending on qualifications and experience:
Scientific Officer: In the range £3,289 to £5,085 per annum.
Higher Scientific Officer: In the range £4,726 to £6,211 per annum.
The post is superannuable.

Application forms and further information may be obtained from the Secretary, Scottish Plant Breeding Station, Pentlandfield, Roslin, Midlothian, EH25 9RF, to whom completed application forms should be returned not later than 3rd January 1980. 3735(A)

QUEEN ELIZABETH COLLEGE
Kensington
(University of London)
DEPARTMENT OF PHYSICS

IMAGE ANALYSIS AND IMAGE PROCESSING

Applications are invited for the following posts which are tenable for periods of up to three years on funds provided by the Science Research Council. The appointments will date from 1 January, 1980, or as near as possible thereto and will be made at a salary commensurate with age and experience.

POST-DOCTORAL RESEARCH ASSISTANT

The work concerns the digital analysis and enhancement of images obtained by electron and optical microscopy or from earth satellite recordings. Appropriate experience in computing is required, in the context of image processing, to play a leading role in soft-ware development within a scientific programme to achieve the benefits of array processing — for example, in the simultaneous processing of multiple images. Digital processing facilities are available using a local dedicated GEC 4070 computer system with interactive graphics and remote access to an ICL Distributed Array Processor.

Salary in range £4,333 to £6,066 pa plus London allowance of £740 p.a.

COMPUTER PROGRAMMER/ COMPUTER SCIENTIST

A graduate with experience of programming is required to run a GEC 4070 computer system with interactive graphics for the image analysis group and to provide programming support for the work described above. Part-time registration for a higher degree may be arranged for a suitable candidate.

Salary in range £3,775 to £4,333 p.a. plus London allowance of £740 p.a.

Applications, giving two referees, to Professor R.E. Burge, Physics Department, Queen Elizabeth College, Campden Hill Road, London, W8 7AH.

3762(A)

Wellcome

Molecular Biologists

Scientists and Technicians

with relevant experience are invited to apply for positions at several levels within a young enthusiastic cell biology group with the objective of utilizing the potential of recombinant DNA techniques to contribute to problems of medical and veterinary interest.

Candidates should have a relaxed attitude to collaboration together with the motivation and ability to make a significant contribution to a major basic research programme studying the genetic properties of viruses, bacteria and parasites with a view to engineering microbial hybrids capable of expressing biological molecules of potential importance in immunoprophlaxis.

Excellent facilities are available, including containment laboratories from category II to category IV.

Salaries will be in the range £6,000 to £11,000 for scientists and £4,000 to £7,000 for technicians, depending on age and experience.

The Laboratories are situated in pleasant parkland surroundings close to open countryside yet within easy reach of Central London. Conditions of employment are excellent and include subsidised canteen, pension scheme, 4 weeks' holiday, relocation expenses where appropriate and wide-ranging sports and social facilities.

Please apply with full Curriculum Vitae including publication list, to:

Personnel Manager, Wellcome Research Laboratories, Langley Court, Beckenham, Kent BR3 3BS.

3748(A)

FACULTY POSITION IN THE DEPARTMENT OF ASTRONOMY, HARVARD UNIVERSITY

The Department of Astronomy at Harvard University plans to make one or two appointments to the position of Assistant Professor to begin in the Summer or Fall of 1980. The department invites applications for these positions, which will have a term of three to five years. The Department wishes to consider applications for highly qualified persons in any area of astronomy or astrophysics, and it particularly encourages applicants in the areas of theoretical astrophysics, high energy astrophysics, and optical astronomy. The successful applicants will be expected to participate actively in teaching activities within the Department of Astronomy, and it is also expected that they will spend a significant fraction of time in research activities at the Center for Astrophysics.

Letters of application should be accompanied by a résumé of experience in teaching and research, a statement of research interests and a bibliography. The applicant should request three astronomers or physicists to write directly to Professor A.G.W. Cameron, Chairman, giving their evaluation of the applicant's abilities. Applicants are expected to have received their PhD at least one year before taking up this post.

Harvard University is an Equal Opportunity Employer with an Affirmative Action Program, and it encourages applications from women and members of minority groups.

Send applications to the Department of Astronomy, Harvard University, 60 Garden Street, Cambridge, Massachusetts 02138 for receipt by February 1, 1980.

W532(A)

ODENSE UNIVERSITY
Denmark
PROFESSOR IN PHOTOSYNTHESIS

We again invite applications for the new position as professor in Photosynthesis at the Institute of Biochemistry. The position is available for occupation as soon as possible.

It is desired to appoint a person, whose research activities are experimental investigations of the functions of the photosynthetic membrane systems in eukaryotes and/or prokaryotes. A part of the current research in the Institute is concerned with electron transport in respiratory and photosynthetic systems, and the Institute is well equipped with special apparatus for this type of work.

The successful applicant will be expected to participate in the teaching programme of the Institute, which includes elementary courses common to science and medical students, advanced courses for science students and supervision of advanced project work.

Further information is obtainable from Institute of Biochemistry, Odense University, telephone (09) 15 86 00, ext. 2441.

The application should contain information about the candidate's teaching experience.

The employment field covers the Ministry of Education and the institutions under it. The wage frame is 37, and the salary amonts to Danish Kroner 230.520,24 a yer inclusive of bunusses as per the 1st October, 1978.

A professional selection committee will discuss the applications and the recommendations will be sent out to all applicants in its complete form.

Applications received until now will be taken into consideration if they are not withdrawn.

Application in 5 copies, marked "Position No. 745" enclosing curriculum vitae and documentation for professional and pedagogical activities must be made to the Queen and sent together with all enclosures also in 5 copies to: Journalkontoret, Odense University, Campusvej 55, DK 5230 Odense M, Denmark, so that we will receive it on the 2nd January, 1980 as the latest.

W522(A)

Research Scientist

Guinness Research Laboratory

If you have already gained your doctorate in Chemistry or Biochemistry, backed by two years' experience in protein or polyphenol chemistry, then Guinness have a career opportunity for you at their Park Royal Brewery.

Researching in the field of polyphenol, carbohydrates and lipid interaction, you will be responsible for planning the work involved in both fundamental research and in the development of projects to strict time schedules.

Your work will involve you in the Guinness brewing group activities in the UK, as well as the possibility of overseas travel on specific assignments for the Guinness brewing operation overseas.

Not only should you be an initiator, capable of highly creative thought, but you should have the ability to motivate others and exploit your basic and applied research.

Our conditions of employment are excellent, with a salary from £7,350, 5 weeks holiday, profit share, non-contributory pension scheme and first-class opportunities for career development within this diverse and expanding group.

Please write or telephone for an application form to:
Miss A. P. Lloyd, Assistant Personnel Manager, Arthur Guinness Son & Co. (Park Royal) Ltd., Park Royal Brewery, London NW10 7RR.
Tel: 01-965 7700.

3766(A)

THE UNIVERSITY OF LEEDS
DEPARTMENT OF GENETICS

Applications are invited for a post of

RESEARCH FELLOW

in the above Department. The successful candidate will work on a project, supported by the SRC, on the biosynthesis and mode of action of cytokinins in the moss, *Physcomitrella patens*. Applicants with research experience in either plant physiology or microbial genetics would be especially suitable. Candidates should possess a PhD degree. The appointment will be made for a fixed period of up to 22 months from 1 January 1980 or from a date to be arranged.

Salary at an appropriate point on the 1A scale for Research and Analogous Staff (£4333 to £7521) (under review).

Application forms and further particulars may be obtained from the Registrar, The University, Leeds LS2 9JT, quoting reference number 50/5/D. Closing date for applications 1 December 1979.

3744(A)

GUY'S HOSPITAL MEDICAL AND DENTAL SCHOOLS

Pre- or post-doctoral Research Assistant (Biochemist or Immunologist), with experience in biochemistry or immunochemistry of bacteria, required for one year to work on research project concerned with separation of specific components, especially proteins from Streptococci. Salary according to qualifications, with superannuation.

Apply in writing, with full curriculum vitae, to the Secretary, Guy's Hospital Medical School, London Bridge, SE1 9RT, quoting Ref IM7. 3729(A)

SECTION LEADER
Cardiovascular Research

A vacancy exists within the pharmacology department for an experienced scientist to lead a team of seven graduates and technicians engaged in research into drugs for use in hypertension and other cardiovascular disorders.

The ideal candidate will hold a PhD and have gained a minimum of 2 years post doctoral experience in cardiovascular physiology or pharmacology in either industry or an academic institution. After an initial induction period he/she will be expected to make a positive contribution to the work of the department and will be actively encouraged to publish scientific results.

The present salary range, £6,500 to £7,500, will be reviewed in January. Other benefits are commensurate with the level of appointment.

The company's modern research laboratories are situated in a pleasant part of the Thames Valley and have the added advantage of being within easy access of the M4.

For further details and an application form please contact:

Miss C. Bradshaw, Personnel Officer,
WYETH LABORATORIES, Huntercombe Lane, South, Taplow, Maidenhead, Berks SL6 0PH.

Wyeth Laboratories 3749(A)

DIRECTOR OF BIOLOGICAL RESEARCH (CANADA)

The Canadian affiliate of Merck & Co. Inc.'s world-wide research organization has a challenging senior research position available as Director of Biological Research in Canada. This position reports to the Canadian Executive Director of Research, and is responsible for the effort of a team of approximately 25 scientists involved in CNS and respiratory research.

The ideal candidate we are seeking will have a PhD degree in the biological sciences, 10-15 years industrial or university research experience and a proven record of scientific achievement and recognition. Additionally, the candidate will possess strong leadership and communication skills and a demonstrated ability for creative thinking.

This senior research position offers an exceptional opportunity for growth and development within one of the most progressive industrial research organizations in the health care field in Canada. Excellent salary and full range of employee benefits.

Our research laboratories are located in modern facilities in Kirkland, Quebec, a suburb 15 miles from downtown Montreal.

Please send a curriculum vitae, a list of publications and the names of three references to: The Employment Manager, Merck Frosst Laboratories, PO Box 1005, Pointe Claire-Dorval, Quebec, Canada, H9R 4P8. W531(A)

Recombinant DNA Research

GENENTECH, INC. is continuing to expand its research program and is inviting applications for several positions in recombinant DNA research. Positions are available for highly qualified individuals in the areas of molecular genetics, molecular and general virology, immunology, and Bacillus and yeast molecular biology at the following levels:

SENIOR POSITIONS: Highly motivated individuals with a PhD and extensive postdoctoral experience are sought for project-and/or group-leader positions. Candidates should have the drive and capability to set up and direct independent research programs.

POSTDOCTORAL POSITIONS: Under its postdoctoral program, Genentech offers two-year appointments at competitive salaries in a stimulating scientific environment. We strongly encourage our scientific staff to publish.

RESEARCH ASSOCIATES & TECHNICIANS: Candidates for these positions should have a BS or MS degree, significant laboratory experience and the ability to carry out a successful research program with minimal supervision.

Genentech is situated on the San Francisco peninsula and provides a stimulating working environment with competitive salaries and extensive fringe benefits. Please send a resume and list of three references to the attention of Mrs. Chris McKinley at:

GENENTECH, INC.
460 Pt. San Bruno Blvd.
So. San Francisco, CA 94080

Appointment in grade of Scientific Officer, £3,289 to £5,085. (Scale rises 1.1.80 to £3,591 to £5,486 pa). Placing on scale depends on qualification and experience. Non-contributory superannuation.

Apply in writing to the Secretary, giving names and addresses of two referees and quoting Ref. 413 by 30th November, 1979. 3736(A)

FACULTY POSITION
Organic Chemistry

Applications are invited for a tenured senior appointment which the Department of Chemistry at Stanford University expects to be able to make in the near future. Applicants must have outstanding research credentials in organic chemistry and a strong commitment to teaching undergraduates as well as graduates.

In applying, send curriculum vitae and bibliography to: Professor K.O. Hodgson, Department of Chemistry, Stanford University, Stanford, California 94305. Stanford is committed to Equal Opportunity through Affirmative Action in employment and we are especially eager to identify women and minority persons with appropriate qualifications.

Applications should be received by 15 December, 1979. W516(A)

GRANTS and SCHOLARSHIPS

THE ROYAL SOCIETY
BROWNE RESEARCH FUND
MAURICE HILL RESEARCH FUND
MARSHALL AND ORR BEQUEST
Grants 1980

The Council of the Royal Society invites applications from qualified research workers for personal grants:

(a) from the Browne Research Fund, for research in marine biology at a marine biological laboratory or elsewhere. Preference will be given to those who propose to work on purely scientific problems rather than to those whose work would be primarily directed towards an economic end.

(b) from the Maurice Hill Research Fund (established in memory of the late Dr M N Hill, FRS, for the encouragement of research in physical oceanography and marine geophysics) for research at sea and/or in the laboratory in physical and chemical oceanography, marine geophysics and geology.

(c) from the Marshall and Orr Bequest for the support of marine biological research.

Grants may be used for periods up to one year, and are made on the understanding that university or other posts held by applicants will meanwhile be kept open for them. Recipients are permitted to use grants while receiving salaries from regular appointments.

In 1980 the total amounts available to be shared among all successful applicants will be about £4,500 from the Browne Research Fund, £9,500 from the Maurice Hill Research Fund and £7,500 from the Marshall and Orr Bequest; individual grants will not ordinarily be more than £750.

Applications should be made on forms to be obtained from the Executive Secretary, The Royal Society, 6 Carlton House Terrace, London SW1Y 5AG, and returned by 15 December 1979. 3607(H)

COURSES

NATO ADVANCED STUDY INSTITUTE

"MOLECULAR ELECTRO-OPTICS. ELECTROOPTIC PROPERTIES OF MACROMOLECULES AND COLLOIDS IN SOLUTION — THEORETICAL STUDIES, EXPERIMENTAL METHODS, AND EXPERIMENTAL RESULTS"

July 14-24, 1980
at Rensselaer Polytechnic Institute, Troy, N.Y., USA

Closing date for applications: March 15, 1980

This NATO Advanced Study Institute will cover the theory of molecular electro-optics and rotational diffusion, the interaction of chemical and biological systems with electric fields, the instrumentation used in molecular electro-optics, applications of electro-optics to proteins, polypeptides, polynucleotides, nucleoproteins, polyelectrolytes, colloids and liquid crystals, and an introduction to electrophoretic light scattering and to magneto-optics. Lectures include O'Konski (Univ. of Calif, Berkeley), Jennings (Brunel Univ.), Buckingham (Cambridge Univ.), Neumann (Max-Planck Inst., Munich), Garcia de la Torre (Univ. Extremadura), Stoylov (Bulgarian Acad. Sci.), Charney (Natl. Inst. of Health, Bethesda), Weill (Strasbourg), Jernigan (Natl. Inst. of Health, Bethesda), Houssier (Univ. Liège), Greve (Vrije Univ., Amsterdam), Pörschke (Max-Planck Inst., Am Fassberg), and Uzgiris (General Electric).

A limited number of grants are available to participate from NATO countries. Except in extraordinary circumstances, they will cover only about 50% of living and travel expenses. Living expenses are $310.

Applications may be in the form of a letter including curriculum vitae and present scientific interest to: Professor Sonja Krause, Department of Chemistry, Rensselaer Polytechnic Institute, Troy, NY 12181, USA. W528(D)

ASSISTANTSHIPS

UNIVERSITY OF NOTTINGHAM
DEPARTMENT OF BIOCHEMISTRY
POSTGRADUATE RESEARCH ASSISTANTSHIP

Applications are invited for a Wellcome Trust funded post to investigate the synthesis and function of a multivalent receptor in *Escherichia coli*.

The grant is for a period of three years and the starting salary will be £3,775 on the Range 1B scale. The successful applicant will be expected to register for a PhD.

Applications, including a curriculum vitae and the names of two referees, should be sent to Dr Robert E Glass, Department of Biochemistry, Medical School, Queen's Medical Centre, Nottingham NG7 2UH. 3737(P)

FELLOWSHIPS and STUDENTSHIPS

Southampton THE UNIVERSITY

SOLAR CELL THEORY

Post-Doctoral SRC Fellowship

Applications are invited for the above post-doctoral post which is available from January 1980, and is suitable for appropriately interested mathematicians, physicists or engineers. Salary up to £4505 per annum.

Applications should be sent to Professor P T Landsberg, Department of Mathematics, University of Southampton, Highfield, Southampton SO9 5NH, before 20 December. Candidates are asked to request two referees to write directly to the same address. Please quote Ref: N. 3764(E)

THE ROYAL SOCIETY
JOHN MURRAY TRAVELLING STUDENTSHIP IN OCEANOGRAPHY AND LIMNOLOGY 1980

Applications are invited for the above Studentship, open to British graduates under the age of 35, for the encouragement of travel and work in oceanography or limnology. This award, which may be held for periods from three months to one year will in 1980 be up to £2,000, adjusted according to qualifications and place and duration of research. Applications are especially invited from workers in oceanography and limnology, as well as in zoology, botany, geology, mathematics and physics, and it will be permitted to hold the award while receiving a salary from a regular appointment. Applications receivable by 15 December 1979 should be made on forms obtainable from The Executive Secretary, The Royal Society, 6 Carlton House Terrace, London SW1Y 5AG. 3605(F)

ROBERT GORDON'S INSTITUTE OF TECHNOLOGY, ABERDEEN

SCHOOL OF MECHANICAL AND OFFSHORE ENGINEERING

POSTDOCTORAL RESEARCH FELLOWSHIP

Metallurgist or materials scientist for major research project on marine corrosion and fouling of North Sea oil and gas installations, financed by SRC Marine Technology Directorate. RGIT's marine corrosion research group will collaborate with University of Aberdeen marine biologists and zoologists and with offshore industry.

Salary range £4,910 to £5,777 with appropriate placing according to qualifications and experience.

Details from Secretary, Robert Gordon's Institute of Technology, Schoolhill, Aberdeen, AB9 1FR. 3745(E)

UNIVERSITY OF SUSSEX
School of Mathematical and Physical Sciences

RESEARCH FELLOWSHIPS IN THEORETICAL ASTRONOMY

Applications are invited for SRC-supported posts of Research Fellow in Theoretical Astronomy, for a period of one or two years, with possible extension to a third year. The posts are on the Research Fellow 1A scale (£4,333 to £7,521 pa, under review). Appointments are likely to be made no more than half way up the scale. All posts carry USS benefits. Appointments will normally commence on 1st October, 1980.

Candidates should propose an independent research programme. Further information can be obtained from Professor R J Tayler, Astronomy Centre, Physics Building, University of Sussex, Falmer, Brighton BN1 9QH, UK.

Applications should arrive by 12th January 1980. Applicants should ask up to three referees to send confidential reports, to reach the Astronomy Centre by the same date. 3721(E)

WORKSHOP

EMBO WORKSHOP

GENETICS AND IMMUNOBIOLOGY OF PATHOGENIC *NEISSERIA*

June 16-19, 1980, Hemavan, Sweden

Cosponsors: The Swedish Medical Research Council, Umeå university, Astra, Eli Lilly, FOA, Pharmacia

The objective of the workshop is to evaluate our current under-standing of the basic biology of pathogenic *Neisseria*, with special attention given to genetic aspects, cell surface organization and host-parasite interactions.

Main topics:

I ANTIGENIC AND BIOCHEMICAL CHARACTERIZATION OF THE *NEISSERIA* CELL SURFACE
II GONOCOCCAL AND MENINGOCOCCAL GENETICS
III HOST-PARASITE INTERACTIONS
IV PROSPECTS OF A GONOCOCCAL VACCINE

Invited speakers:

T. Buchanan (Seattle), S. Falkow (Seattle), C. Frasch (Bethesda), J. Heckels (Southampton), K. Holmes (Seattle), K. Johnston (Dallas), Z. McGee (Nashville), L. Mayer (Salt Lake City), S. Morse (Portland), R. Rosenthal (Indianapolis), F. Sparling (Chapel Hill), J. Swanson (Salt Lake City), D. R. Veale (Birmingham), F. Young (Rochester).

Organizers: D. Danielsson/S Normark

Applicants (actively engaged in the field) should submit a preliminary abstract of their poster and a brief description of their interest in the above topics. Participants will be accommodated in the congress hotel at Hemavan, situated in the northern Swedish mountains.

Total costs: including registration fee, travel from Umea to Hemavan, accommodation and meals 900 Swedish crowns. There are some possibilities for travelling support particularly for younger participants. It is suggested that all contributions should be published.

Applications, requests for further information and suggestion should arrive before **January 1, 1980** at:

Department of Microbiology
Unversity of Umea
S-901 87 Umea, Sweden.
Telephone: 090/10 1774.

FOR SALE and WANTED

AMBIO A JOURNAL OF THE HUMAN ENVIRONMENT ☙ RESEARCH AND MANAGEMENT

Now distributed for the Royal Swedish Academy of Sciences by Pergamon Press.

Launched in 1972 prior to the United Nations Conference on Human Environment, AMBIO is already recognized by many as the leading interdisciplinary periodical in the environmental sciences.

Now, with the aim of broadening an already international coverage and readership, AMBIO will be published and distributed through a joint arrangement between the Royal Swedish Academy of Sciences and Pergamon Press.

Regular issues contain general articles on current environmental problems and challenges and reports on original research in the field. Special issues give a more comprehensive treatment of some topical subjects.

"... The most authoritative journal of its kind on international environmental problems."
GILBERT F WHITE, *President, Scientific Committee on Problems of the Environment, The International Council of Scientific Unions*

"... AMBIO is the best magazine of its kind."
IGNACY SACHS, *Centre Nationale de Recherche sur L'Environnement*

FREE SPECIMEN COPY AVAILABLE ON REQUEST

Published 6 issues p.a.
Annual subscription (1980) **US$60.00** Two-year rate (1980/81) **US$114.00** Individual rate **US$25.00**

Prices include postage and insurance and are subject to change without notice.

ASSISTANTSHIPS

THE UNIVERSITY OF BRITISH COLUMBIA
DEPARTMENT OF CHEMISTRY
GRADUATE TEACHING ASSISTANTSHIPS 1980/81
Academic Year

Graduate Teaching Assistantships are available for candidates with high academic records who wish to pursue further studies towards the M.Sc. and PhD Degrees in Chemistry. Excellent research facilities are available in all areas of modern Chemical Science, ranging from Bio-Inorganic Chemistry to Chemical Physics. For first year students the minimum stipend, including the summer research assistantship, is anticipated to be $8,000 per annum.

Students entering the programme with a Master's degree will receive a higher minimum stipend of $8,500 per annum. In addition, many special merit awards are made to those graduate teaching assistants who show excellence in the performance of their duties. Numerous graduate scholarships are also available for students with outstanding academic records.

Application forms and further particulars may be obtained from the undersigned:

Professor C.A. McDowell, Department of Chemistry, The University of British Columbia, 2075 Wesbrook Mall, Vancouver, B.C. Canada, V6T 1W5 W525(P)

IMPERIAL COLLEGE
(University of London)
DEPARTMENT OF BIOCHEMISTRY
POSTDOCTORAL RESEARCH ASSISTANTSHIP

A postdoctoral research assistant is required for structural investigations of the erythrocyte membrane protein spectrin, using monoclonal antibodies to study functional sites and molecular interactions. A sound background in protein chemistry and/or immunology is required, preferably with experience in monoclonal antibody techniques. The successful applicant will join an active, well equipped research group, preferably starting on January 1st 1980.

The position, supported by the MRC, is for an initial period of one year, extendable up to three. The starting salary will be £6,228 p.a. including London allowance of £740 and U.S.S. benefits.

Applications including a curriculum vitae, a full statement of research interests and experience, and the names of two referees should be sent to Dr David Shotton, Department Biochemistry, Imperial College, London SW7 2AZ England. 3769(P)

COURSES

EMBO

Advanced Laboratory Course on "Molecular Biology of Membranes"

co-sponsored by FEBS & SKMB

14-27 September 1980
Bio-Center, Basel, Switzerland

The course will include review lectures, specialized lectures and laboratory experiments. Main topics to be covered will include the physical chemistry of membranes, membrane reconstitution and analysis of membranes by biochemical, genetic and immunological methods.

Laboratory space will be available for 24 students. The course fee will include Swiss Francs 100 for registration and approximately Swiss Francs 500 for accommodation and food. Fellowships will be available. Applicants will be selected on a world-wide basis.

Application forms can be obtained from the organizers. Deadline for application is April 1, 1980. Organizers: G. Schatz and J Seelig, Biocenter, University of Basel, Klingelbergstrasse 70, CH-4056 Basel, Switzerland. Tel. 061/25 38 80.

LEADING UK MANUFACTURERS OF

The SCORAH Automatic Electric all glass WATER STILL (patented)

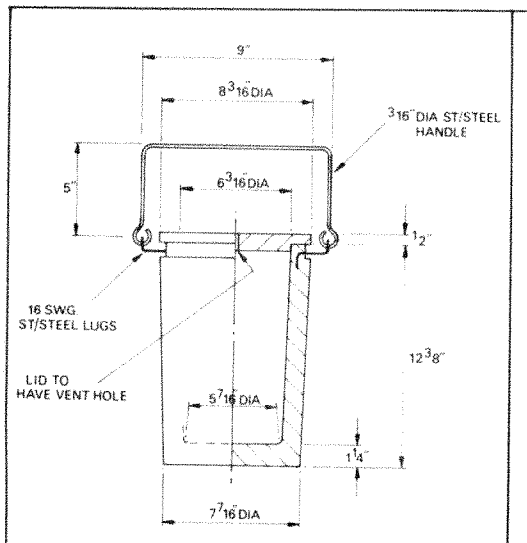
Automatic Can be left on without attention. Heater current cuts off if water supply is interrupted, or inadequate or forgotten. When receiver (5 litres capacity) is full, current cuts off. When distilled water is drawn from receiver, the still resumes operation until receiver is refilled.

Purity Electrostatically charged condenser droplets can pick up fumes, dust and air-borne organisms from the laboratory atmosphere. The design of the receiver vessel ensures absence of such contamination.

Efficiency Heater of Scorah design and manufacture, consumption 1,700 watts, output 2.4 litres per hour (the full theoretical yield). Cost less than 2p per gallon at ½p per unit.

Safety The heating element is out of contact with the feed water, thus eliminating danger from "live" water supply or electrolytic effects of "burn out".

Assembly No retort stands of clamps are required. The 2½-in. diameter ball joint gives a stainless set-up. Outlet cap on boiler for quick periodical drain-off of sediment. The still may be installed on a shelf or platform about 1 ft. above bench level near a sink and enclosed in a transparent plastic cover to keep out dust.



Heat-resisting glass. Interchangeable ground glass joints.

LIQUID SCINTILLATION CHEMICALS

We're at Your Service More Than Ever Before.

Our sales, service, and technical assistance have never been stronger in Europe. As a result you can expect immediate response from the NEN office in your country, and fast delivery of the products you need from the world's most widely referenced selection of liquid scintillation chemicals.

If you need technical assistance, you will find that our people are exceptionally well equipped to provide it. But if they don't have the answer, the director of our LSC Applications Laboratory, Dr. Yutaka Kobayashi, will help you.

In short, we're doing everything to meet the rapidly increasing demand for NEN liquid scintillation chemicals in Europe—with an expanded technical sales force, locally available products, and fast response to technical questions.

We look forward to your call.

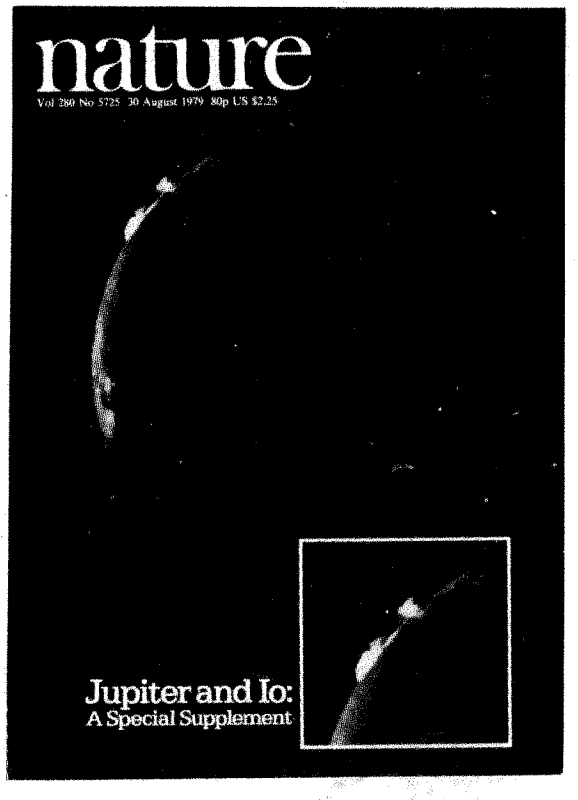
THE CHAIN STRAIGHTENERS
Fruitful Innovation – The Discovery of Linear and Stereoregular Polymers

FRANK M. McMILLAN



One of the most exciting stories in the history of Science – in the tradition of The Double Helix.

A narrative account of the remarkable burst of scientific discovery and technological innovation that gave science mastery over the 3-dimensional structure of high polymers and the world its most useful group of plastics and synthetic rubbers.
This book examines the personalities and the work of the key people involved and the controversies they aroused. Amongst these it pays particular attention to the seminal work of Karl Ziegler in Germany and Giulio Natta in Italy. This is a superb case study of the conditions under which fruitful innovation takes place; of the fortuity of many discoveries and their later rationalisation, of the continuity of science, the critical importance of alert observation, and the necessity of aggressive follow-up.
To be published in November by The Macmillan Press « £9.00 0 333 2529 7

Payment may be made in any currency at the prevailing rate of exchange. Cheques should be made payable to Nature.

Guide to authors

● Review articles should be aimed at a relatively wide readership. Many reviews are invited, but submitted articles may also be accepted; it is advisable to consult us before writing a review article.

● Articles may be up to 3,000 words long with at most six displayed items (figures and tables); they are reports of major research developments.

● Letters are brief reports of original research of unusual and wide interest, not in general longer than 1,000 words; they have at most three or four displayed items.

● 'Matters Arising' permits short discussion (up to 300 words) of papers that have recently appeared in *Nature*.

Articles should be accompanied by an abstract of not more than fifty words. Letters should begin with a paragraph giving the background and main conclusions in terms intelligible to as wide a readership as possible.

Manuscripts may be submitted either to London or New York. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the Système International. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible; exp (*a*) is preferred to e^a if '*a*' is more than one character.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) only one reference number need be used if the reference is to several papers by identical authors.

(ii) first and last pages of references should be cited.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth edn (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished' should be incorporated in text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings should be either photographic prints or in Indian ink on heavy cartridge paper, tracing paper or similar materials. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text, they should contain only essential material. Ideally, an unaltered original and three lettered copies should be provided; labelling on half-tones should, if possible, be avoided entirely. Magnifications quoted should be for the figures as submitted. We are always glad to see artwork for possible use on the cover, but cannot guarantee its return.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

Nature's publishing policy is outlined in **258**,1 (1975) and **264**, v, 11 Nov. (1976).

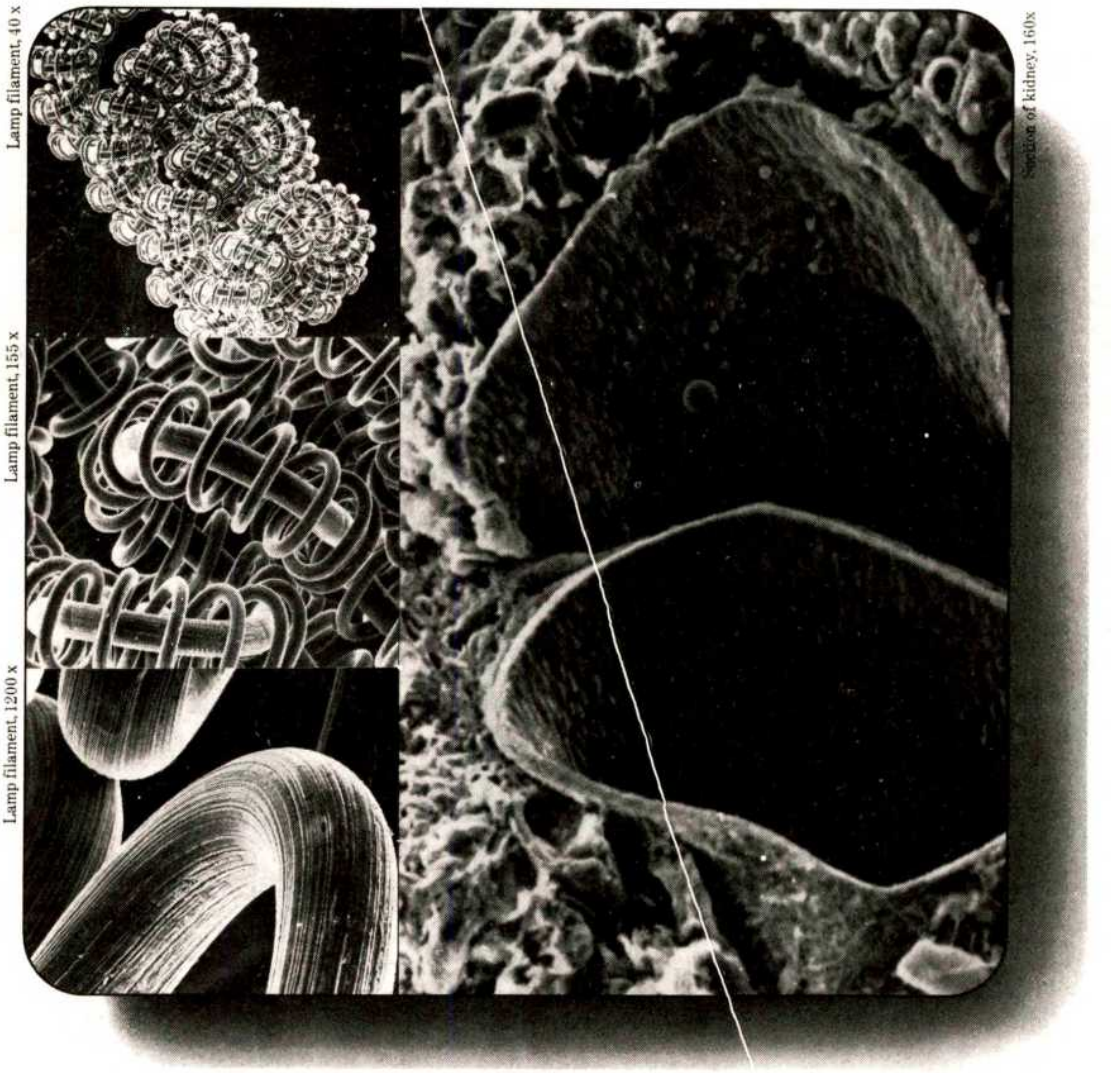
NEW PRODUCT REVIEW

This month's new product review features oscilloscopes, laboratory computers and calculators, and image analysis equipment. See page xvii.

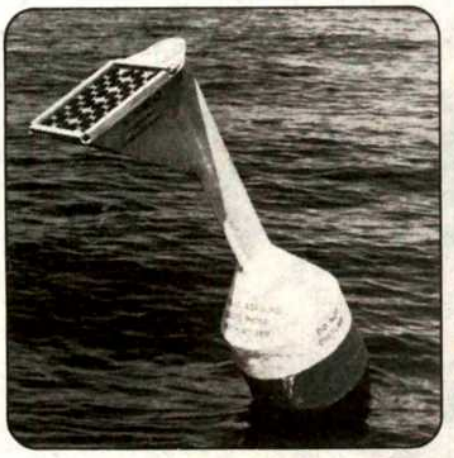


A Reader Enquiry Card is bound into each copy of *Nature* for enquiries regarding advertisements.

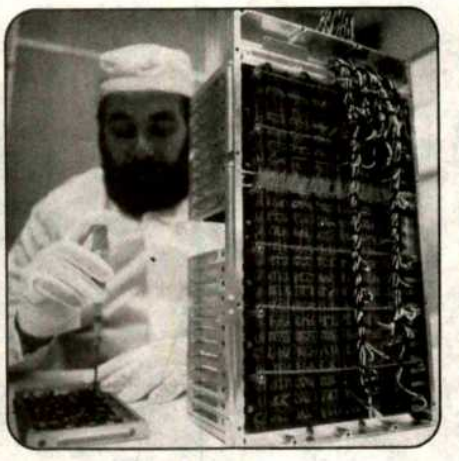
Seeing is believing

The striking realism of greatly magnified images is the key feature of the results obtained by means of the Scanning Electron Microscope (SEM) – the latest development in electron microscopy.

By scanning a three-dimensional surface area of a specimen, this microscope produces images with great depth of field. By increasing or decreasing the power used, it scans minute details or entire areas in much the same way as a zoom lens magnifies. And since almost all functions of the Scanning Electron Microscope are automated, even untrained operators obtain results which are easily interpretable and meaningful to the research worker. Fast.



The results of transmission electron microscopes, on the other hand, are derived from minute two-dimensional microscopically thin slices. The purpose



PHILIPS

of these research tools is to reveal the structure of materials and tissues to the last detail. Here, the optimum resolution of the instrument counts. It may be as high as 0.14 nm (1 nm being equivalent to 1/1 000 000 mm) as in the Philips EM 400, for example.

Though the SEM is capable of high resolution, its real strength lies in the production of three-dimensional looking images which show what it really looks like. The optional ability to visually display the elemental composition of the sample through analysis of X-rays really confirms that seeing is believing. This is only one way in which Philips advanced technology is being turned to practical use. Here are three more examples.

Solar energy was used to re-charge the storage battery aboard each of the forty survey buoys which performed a marine study in the Indian Ocean. Continuously monitored data was automatically transmitted from each buoy every hundred minutes via the Nimbus-Six satellite. The study was carried out by the Commonwealth Scientific and Industrial Research Organisation (CSIRO). Philips supplied the solar collector systems and technology.

IRAS – Infra-Red Astronomical Satellite – due to be launched into a 900 kilometre polar orbit in 1981, is the first scientific satellite designed to make a detailed inventory of infra-red sources in space. The on-board computer, which will process about 500 million bits of measured data per day was designed by us and will be supplied along with other Philips electronic systems.

Ultrasonic diagnosis. Philips Sono DIAGNOST systems let the mother see her baby before it's born - and they help her doctor. Obstetricians are aided in accurately calculating foetal age, locating placenta, detecting abnormalities and determining the exact position of the foetus. Ultrasound can also help in diagnoses of ailments of organs such as the heart, liver, kidneys and pancreas.

The Cambodian picture becomes clearer

In the past few weeks, the people of many countries have been exposed to the plight of Cambodia, or Kampuchea, through television programmes, through dramatic gestures, such as Mrs Carter's visit to Thailand, and through the widespread publicity of the relief agencies. The response has been generous; governments have pledged all manner of aid, and voluntary bodies are receiving a steady flow of funds. There is an evident need for the care of many thousands of Khmer refugees in Thailand. But as more is learnt about the situation within Cambodia, it is emerging that the need is not so much for immediate, massive emergency aid to relieve a national famine (for which there is little evidence), but for steady aid over the medium and long term to bring a once flourishing country back to health.

Observers who have recently been in Cambodia, or who have worked amongst the refugees in Thailand, are now beginning to bring back a more comprehensive picture, and this is augmented by satellite photographs of areas under cultivation. As far as food is concerned, it is likely that a substantial harvest was available at the end of 1978. Most of the country has one harvest per year, so food resources under normal circumstances should have been fairly adequate for most of 1979. Of course the circumstances are not normal and much of the stored rice could have been lost; possibly upwards of 200,000 tonnes of food aid has been shipped in this year at the request of the government but this should be put in the context of an annual consumption of about 1 million tonnes (assuming a population of 4.5 million). Where simple indicative tests such as the measurement of mid-upper arm circumference of children have been carried out, they equally suggest moderate under-nutrition rather than starvation.

The mid-term food supply in Cambodia depends very much on the 1979 harvest, which runs from October to December. Estimates of the amount of land under cultivation after the disruptions of the past year vary greatly, but the figures that are emerging suggest that less than a third of all arable land will be productive, and that the shortfall in food supplies for 1980 will be up to 50%; pledges through the World Food Programme and from individual countries will ensure that this deficit will be made up for the next six months at least, provided that movement through ports of entry can be expedited.

The problem on the medical side is, if anything, more serious. It is reported that malaria is killing widely, and that untreated gastro-enteritis, tuberculosis and anthrax are also taking a heavy toll, although figures are proving hard to come by. During the dry season (until April) the incidence of malaria will fall, but concern is being expressed about the degree of drug-resistance being shown. Medical supplies have poured in beyond the capacity of local staff to use them and the problem for the immediate future is the development of a proper medical infrastructure to provide health care. With the (literal) decimation of the professional classes in Cambodia, no real progress towards self-sufficiency is likely until new schools are built, new people are tained and self-confidence is re-established.

The real need for Cambodia is not to relieve a nationwide famine; it is to supply food, medical aid and transport steadily and intelligently over the coming months, and for a large scale investment both in rural and urban re-construction and in the rebuilding of the professions. This poses difficult questions for the more thoughful of those connected with relief. Film of starving children (and it cannot be denied that some children, particularly amongst the displaced, are starving), mention of widespread famine and hints of many further deaths in the coming weeks undoubtedly opens the floodgates of goodwill, but it also leaves relief agencies with strong political and emotional pressures to act on an emergency basis, even when it were better that investments were delayed until more information became available. There is a very serious dilemma here. Fund raisers know full well that tragic pictures bring in the money, but fund-spenders know equally well that the real needs are often elsewhere, or over a different time-frame, or for a different purpose. They know, for instance, that any money given now to alleviate the effects of the severe drought which has hit parts of India this year is ten times more valuable than cash that will flow in the summer of 1980 when the effects become all too visible.

The only resolution of this dilemma is slow, patient education of the public on the value of prevention. It is something that governments themselves should take on, if they see any merit at all in scientific assessments of disasters. The British government — now winding down its development education programme which had only been given a breath of life a year ago — could well make an imaginative step. □

Sociobiology critics claim fears come true

The National Front in England and the Club d'Horloge in France draw inspiration and support from human sociobiology, its critics said in Harvard last week. **David Dickson** reports.

National Front demonstration in Essex. NF literature has drawn on sociobiology texts.

HUMAN sociobiology came full circle last Thursday, when critics from Harvard University — the theory's principal *alma mater* — argued that its recent use by right-wing groups in Europe vindicated their earlier statements about its inherent political content.

A packed audience in the university's geology lecture hall was told that events in England and France supported warnings issued four years ago, when a biological interpretation of human social behaviour was suggested by Harvard zooloist E O Wilson in his book 'Sociobiology: The New Synthesis'.

The European experience "has realised some of our worst fears" said Dr Jonathan Beckwith, a geneticist at the Harvard Medical School. In England, for example, the extreme right-wing National Front party had used statements by Wilson and others in its literature to justify racism as a strategy for ensuring genetic survival. Similarly in Paris, right-wing intellectuals had used the writings of sociobiologists to defend claims about the inevitability of human hierarchies, said Beckwith.

In the US, sociobiology had appealed less to extremists than to those endeavouring to preserve the status quo against the claims of feminists or minority groups. But with the US entering "a new period of racial strife" extra caution was needed. "The European experience shows that groups who have used these ideas consider them to be powerful tools for rationalising their policies", said Dr Beckwith.

The Harvard meeting was organised by the sociobiology study group of Boston's Science for the People. Members of the group emphasised that they were not branding all those who wrote about sociobiology as extremists — but were drawing attention to the potentially dangerous connections between ideas expressed by scientists and the social and political climate in which they were propagated.

Thus two speakers warned that biological ideas about human nature had underpinned the practices of Nazis in Germany prior to and during the Second World War. Dr Stephen Chorover of the Massachusetts Institute of Technology said that the roots of Nazi extermination policies could be found in ideas about 'social biology and racial hygiene' which arose in Germany in 1904, when a concern for the health of the individual factory worker evolved into a generalised concern to protect the public health against external threats.

Ideas about the 'naturalness' of social roles also permitted the Nazis to extol the role of women as housewives subservient to men, said Freda Salzman, a physicist from the University of Massachusetts.

Dr Richard Lewontin, Professor of Biology at Harvard, defended the scientific attack on human sociobiology. There was no evidence, he said, of a single human behavioural characteristic caused by genetic variability, as sociobiologists claimed. Labelling all critics of sociobiology as 'reds' was a "last refuge" which ignored scientific critics holding a variety of political views.

"The problem for the ideologues in our society is that they are unable to offer a reasonable excuse for continued inequality in a society which is claimed to be democratic" he said. Hence the temptation to label social inequalities as inevitable.

Dr Beckwith produced an article 'sociobiology; the instinct in our genes', which appeared earlier this year in the National Front publication *Spearhead*. The article says that scientists from the early eugenicists to modern sociobiologists have demonstrated that social differences have a biological basis, thus showing up "the genetic basis or racial awareness, discrimination and solidarity".

Similarly in Paris, said Dr Beckwith, right-wing intellectuals had recently gained wide publicity for their statements that hereditary differences posed insurmountable barriers to social equality. Members of groups such as the Club de l'Horloge used sociobiological arguments to support their claim that people with superior genes should become the leaders of society.

In both countries, the rise of right-wing groups resulted from economic difficulties. So far in the US, the use of sociobiological ideas had focused primarily on sex roles. Newspaper articles said that men would always play a dominant role in politics because of their 'natural aggression'. Sociobiological influences were growing in school text books as an explanation of sex roles. "Exposing sociobiology for what it is is an important part of the battle against racism and sexism in our society" said Dr Beckwith.

No sociobiologist had been asked to respond. But speaking from the floor, Dr Irven Devore, Professor of Anthropology at Harvard, said that sociobiology was not being treated fairly by its critics — and that it was necessary to separate the scientific content from some of the claims being made for it.

Dr Devore agreed that the world-wide swing to the right was an "unhealthy movement", but denied that sociobiology should take any of the blame. "Historically it is unfortunate that this movement has taken place at a time when ideas about 'inclusive fitness' have emerged in biology that have revolutionised the study of animal behaviour. It is a question of whether these ideas are totally a product of that political/ideological shift or not. I do not think they are."

The critics remained firm. Dr Beckwith emphasised that the political uses of human sociobiology were inherent in its construction, not merely abuses of a neutral theory. Dr Lewontin said that the Chinese might refer to it in terms of the three vulgarities: "vulgar Darwinism, vulgar Mendelism, and vulgar reductionism." □

Oceanographers fear greater federal involvement

THE increasing activities of mission-oriented federal agencies in oceanographic research threatens to undermine a creative tension between government, industry and universities, according to a report published by a panel of the National Academy of Sciences.

The report also warns that a desire for "useful" research, coupled with possible research restrictions in foreign territorial waters, is shifting the emphasis from oceanography as a science searching for principles and understanding to oceanography as a tool with which to accomplish practical goals.

The report was prepared by an *ad hoc* committee established by the Academy's National Research Council to study the geological and geophysical research needs and problems of the continental margins. The chairman was Dr Alber W Bally of the Shell Oil Company.

Stating that a substantial increase in funding for research on domestic continental margins could produce considerable benefits in terms of both scientific knowledge and information about mineral resources, the committee says that it is disturbed by recent trends in the distribution of responsibilities between government, universities and industry.

"Overall federal money for oceanographic research has increased substantially in recent years, but most new funds have gone to mission-oriented government agencies. Funding for basic oceanographic research done by scientists in academic institutions has barely kept up with inflation", the report says.

It suggests that government should concentrate primarily on research related to its function of governing and regulating the use of public resources — and that a considerable amount of future research effort should be delegated to universities.

The report also expresses concern about the possible impact of restrictions emerging from the Law of the Sea Conference, now under negotiation by the United Nations, under which scientists would require permission to conduct research within 200 miles of a country's coastline.

Given these restrictions, as well as the importance of scientific knowledge as a basis for resource exploitation, the report argues that "the time is ripe" to concentrate more research on domestic continental margins.

"Science — and particularly oceanography — is international. However we believe that an effort with increased emphasis on national concerns is needed. We are recommending an increase in the momentum of solid-earth science research in our own back yard."

Commenting on the likely restrictions on international research, the report points out the irony that in recent years, pressure to demonstrate the social relevance of scientific research has caused university scientists to submit proposals containing rhetoric extolling the potential social impact of their work.

"Because of the emphasis placed on justifying research as having significance for resource evaluation, great strain may be placed on the credibility of the researcher if he proposes to do similar work on foreign margins, claiming it to be 'pure' scientific research" it says.

The report suggests that a strong academic domestic research programme on US continental margins might help to convince foreign sceptics that US academic institutions "are not implicitly interested in prospecting, that their interest is to contribute to the understanding of principles related to resources and to the environment." □

WHO looks at bacteria for vector control

THE potential of certain bacteria, notably strains of *Bacillus thuringensis*, for the control of insect vectors of tropical diseases is being actively examined by the World Health Organisation, in collaboration with a number of laboratories on both sides of the Atlantic. For many years, strains of *B. thuringensis* have been marketed by a number of pesticide manufacturers in commercial formulation for use against the larvae of various lepidopterous pests, but it is only recently that the potential of the serotype H.14 (also known as *B. thuringensis israeliensis*) has been fully appreciated. This strain is now known to be extremely lethal for the larvae of certain Diptera, including mosquitoes of the genera *Aedes* and *Culex* which are vectors of malaria and filariasis respectively (although somewhat less so, apparently, against *Anopheles*). Now WHO sees the possibility of using it to control the blackfly, *Simulium damnosum*, the vector of onchocerciasis (river blindness).

On the commercial side, development is already going ahead, notably on the part of the Franco-Belgian firm Bellon-Biochem. They are working in close collaboration with the Pasteur Institute, where Dr Huguette de Barjac leads a team in this field. The first results from serotype H.14 formulations were so encouraging that Biochem decided to go straight to field testing, thus leap-frogging the lengthy procedure in a way that WHO itself could never do. The results against blackfly larvae in the Ivory Coast have so far shown very high toxicity rates, with, a report states, "nearly total short-term innocuity against the associated non-target fauna".

The nature of the new material, however, has raised problems in its large-scale application that have yet to be resolved. The larvicidal action, it appears, is due to crystalline toxic compounds present on the outer coating of the bacterial spore. These operate in fact as a chemical insecticide. Unfortunately they have a high specific density, tending to sink to the bottom in water, and one problem is therefore to find a formulation that will keep the toxic materials afloat long enough for them to reach the target larvae downstream of the point of application. This in turn raises difficulties in attaining the concentration necessary to achieve the experimentally predicted results.

It is therefore necessary to put the maximum amount of crystal toxin into the primary powder used as a basis for the actual pesticide, and then to formulate the latter in such a way as to give the desired residual effect under normal field operating conditions. From the commercial point of veiw, the development of such a formulation could probably enable the manufacturer to patent his material, a matter of great importance in the highly competitive pesticide industry. Moreover, any such formulation must also pass the stringent requirements of most governments with regard to safety against mammals. This aspect is also being examined in a number of laboratories. However, with government support in several countries — notably France, the USSR and Switzerland — it looks as though the new materials may reach a stage in the quite near future where mass field trials can be undertaken under WHO auspices.

The current resurgence of malaria, with increased resistance to normal insecticides as well as to therapeutics, and the pressure to find alternatives to such materials as DDT, will certainly encourage research in this field. Quite apart from its enormous potential for use against the vectors of malaria and other mosquito-borne disease, the new material could provide a valuable stand-by alternative to the pesticide Abate. The huge onchocerciasis control programme in the Volta Basin in West Africa at present depends entirely on this one pesticide for blackfly control.

Peter Collins.

France seeks bioengineers

France this year needs 30-40 biotechnologists familiar with such things as the purification of proteins, fermentation, and cell cultures. Next year there will be a need for 60-80 and the year after 120-160, according to a report reviewed last week by *le Monde*. The report is part of a massive work 'Sciences de la vie et société' prepared by Francois Jacob and available for consultation in Paris. □

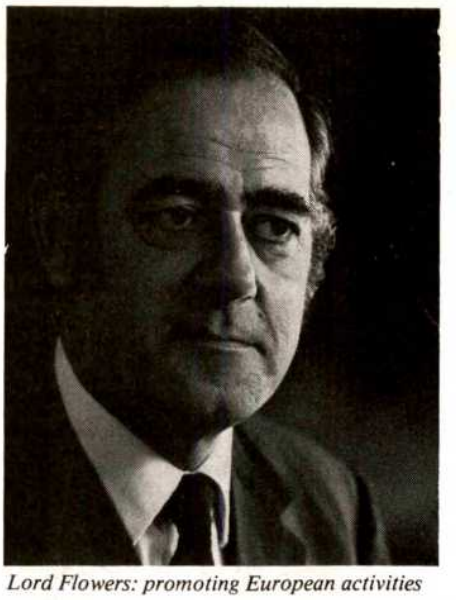
European Science Foundation expands 'additional' activities

THE European Science Foundation, which over five years has established the role of 'stimulant' for European cooperation in basic research, is increasing its emphasis on 'additional', directly funded research. Approximately half of ESF's 10 million FF expenditure is now devoted to such work, and the proportion is increasing.

One example is a proposal for work in taxonomy, which the ESF believes is neglected in Europe — to the extent that assessment of environmental impacts (of SO_2 for example) are hindered. A 'European Floristic, Taxonomic, and Biosystematic Documentation System' should thus be established, and the work required would become an 'additional activity' of the ESF. This means that the 46 national research councils which are members of the ESF will be asked if they would like to contribute to the activity as an addition to their membership subscription to the Foundation.



Lord Flowers, in his presidential introduction to the 1979 annual report (to be published shortly) says: "It is through the additional activities that our work as a foundation will stand or fall". But he adds "we are conscious that each new activity adds to the financial burden of those of our members who participate in them".

For some additional activities, however, funds have been made available from outside sources such as the Leverhulme Trust and the Commission of the European Communities (which is supporting a study on the mobility and employment of scientists).

"Participation in the additional activities represents on the part of our member organisations a conscious and deliberate intention to give a certain priority to research which is conducted at a European level" writes Flowers.

The increasing importance of additional activities, which was hardly foreseen when the ESF was set up, may however lead to some difficulties among its members. They will be increasingly invited to fund projects controlled not from their own offices but from the ESF, testing their commitment to Europe. Thus, says the report, "money from an organisation in country A can and will be used to pay a scientist coming from country B, and possibly working in country C". Some members have already set up a new category in their budgets for 'European cooperation' to allow for this, says the report.

Another indication for the future of the Foundation was the agreement at this year's annual general meeting, held in Strasbourg earlier this month, that tentative approaches should be made to Soviet and East European scientific bodies to enquire if they might participate in some of the ESF's activities — without becoming official members. Lord Flowers will visit Moscow next year with this in mind.

Lord Flowers: promoting European activities

Turkey's Scientific and Technical Research Council also joined the ESF this year, and Finland, announced it will become a full member. **Robert Walgate**

European synchrotron radiation facility brings governments together

IN AN unprecedented move, the European Science Foundation is to approach governments — albeit gingerly — to discuss the construction of a $120 million European Synchrotron Radiation Facility.

Officially, the ESF will have nothing to do with governments, and preserves its independence jealously. Unofficially, the retiring secretary-general of ESF, Dr F Schneider, will in his retirement be convening an intergovernmental committee with the object of making the ESRF a reality. Thus the committee will strictly not be a part of ESF activities, although it is ESF-inspired.

Dr Schneider, who is retiring this year to be succeeded as ESF secretary-general by Belgian lawyer John Goormagtigh, complains in an unsigned introduction to this year's annual report, that the lack of access to governments hampers the Foundation. The ESF's influence compared unfavourably with that of the National Academy of Sciences in the US, says the article. "A project proposed by the NAS is brought to the government for decision. The National Aeronautics and Space Administration's space science budget is decided in one place, not fifteen capital cities."

The report recommends a new role for the ESF: "In cases where concerted action is needed, a new machinery enabling the Foundation to approach governments in the name of all its members [national research councils] and to act for them ought to be developed".

The ESF has prepared the case for the facility in two booklets produced by Yves Farge, director of the Laboratoire pour l'Utilisation des Rayonnments Electromagnétique (LURE), Orsay, and collaborators. The booklets are titled "ESRF: the feasibility study" (pp67) and "ESRF: the scientific case" (pp173) (May 1979) available from H Schmied, European Science Foundation, 1 quai Lezay-Marnésia, F-67000 Strasbourg, France. □

European Space Agency "crippled space science in Europe" says ESF report

WHEN the European Space Agency was established, funds for scientific research were confined to no more than 12-15% of the whole budget, to make room for an applications programme and the development of Ariane (ESA's own launcher, due for test flight in December) and Spacelab. "It is now apparent that this was wrong" says an independent report just published by the European Science Foundation. The chosen level of funding "seriously crippled space science in Europe", leaving European space scientists with only one sixth of the resources available to US scientists.

"Launches of ESA satellites are so infrequent" claims the report "that each hardware-building institute in Europe has approximately two chances in ten years" of participating in an ESA payload. "This is utterly inadequate, because the programme is so small that new talent is not likely to be attracted". Some 1500-2000 scientists in the countries of ESF members are presently using the results of space investigations, the report estimates.

Financial pressures have also limited ESA's collaborations with the National Aeronautics and Space Administration; ESA's contribution to the space telescope, for example, is only 15%. Europe should aim to match the US and the USSR in space science, says the report. An annual ESA launch rate of one satellite fully instrumented by European groups, and "additional spacelab flight opportunities" will be required to keep European groups above "the critical threshold of efficiency".

The report recommends that ESA increase its mandatory scientific budget. But this requires unanimous approval by all ESA member states, and is therefore unlikely. Optional programmes could augment the mandatory budget, however, because they allow funding to be more flexible, says the report. "Space Science in Europe" (pp66) available from H Schmied, ESF, 1 quai Lezay-Marnésia, F-6700 Strasbourg, France. □

"Hidden cuts" will damage UK medical research

THE Medical Research Council, like other UK research councils, has had to face "unprecedented" and immediate cuts in its current budget, as a result of the present British government's policy of reducing public expenditure. But although these amounted, in the MRC's case, to a £500,000 reduction in direct funding from the Department of Education and Science, "hidden cuts" would hit the MRC harder, said its secretary Professor J L Gowans at a press conference last week.

These were losses through having to meet pay increases from within a falling budget, through having to pay higher value added tax (the rate has been increased from 8% to 15%). And the tropical disease research programme of the MRC has been badly hit by the reduction in budget of the Ministry of Overseas Development, when it was absorbed into the Foreign Office to become the Overseas Development Administration. The total cuts amounted to some £2.1 million, or 3.5% of the MRC budget, said Professor Gowans.

Furthermore there was no firm information available to the MRC on which it might make plans for 1980-1 and beyond (though Professor Gowans expected that it would sustain further cuts). This caused great difficulties "as the shortest period for which we have to plan funding is three years, the duration of a research grant".

"We need a stable budget both from the DES side, and from the universities." The dual support system, whereby the universities themselves provided the basic facilities for a laboratory — building, stores, technicians and so on — was creaking.

Universities were also sustaining cuts, and in endeavouring to maintain teaching were leaving more and more of the basics of laboratory funding to the research councils. The system was "creaking under the strain".

"If in addition to the cuts we took this year, there are cuts of any magnitude in successive years, then damage will be done to medical research in Britain . . . There is a danger that high class new applications for research will go unfunded."

However, despite the cuts the MRC managed to set up three new research units in the past year: a molecular haematology unit in Oxford, one for neuroendocrinology in Newcastle, and an environmental epidemiology unit in Southampton.

The council's annual report for 1978-9, just published, pays attention to the jobs problem facing medical researchers. The MRC, which employs 991 clinical and non-clinical research scientists, "is constantly aware of the need to keep under review its career structures in relation both to the interests of the individuals themselves and the advancement of science" says the report. The report offers no panaceas.

●The Advisory Board to the Research Councils, which coordinates the direct funding of the councils through the Department of Education and Science, is consulting with the Treasury and the National Research Development Corporation to see if there can be any financial return to the Councils from patents arising from research council funded work. At present all benefits from these are retained by the NRDC, a large fraction of whose income comes from patents on the 'cephalosporin' antibiotics discovered under MRC funding. The talks, however, are progressing very slowly.

Robert Walgate

Hubert Curien to head ESF in 1981

PROFESSOR Hubert Curien, 55-year-old President of the French Centre National d'Etudes Spatiale, is to succeed Lord Flowers as President of the European Science Foundation in 1981. Flowers, now Rector of the Imperial College of Science and Technology, London, was founder-President of the ESF and will have served two three-year terms when Curien takes over.

Professor Curien has played a prominent role in science politics since 1966, when he became scientific director of the Centre National de la Recherche Scientifique, the body which funds much of France's basic research. "A laboratory is not a laboratory in France without some CNRS staff" says Curien. In 1969 he became its Director-General. In 1973 he was délégué general to the Délégation Générale à la Recherche Scientifique et Technique, and since 1976 he has been President of the CNES. □

Commons debates animal experiments Bill

TWO separate bills to control the use of animals in scientific experiments are currently being considered by the UK Parliament: Lord Halsbury's Animal Protection Bill (Nature, 16 August page 534) which successfully received its second reading in the House of Lords last month, and Mr Peter Fry's Protection of Animals Bill which was read for a second time in the House of Commons last week.

Both bills are seeking to up-date existing legislation which is based on the 1876 Cruelty to Animals Act. "Whole new procedures have been developed, which I understand are totally outside the Act's jurisdiction", said Peter Fry during the opening speech to last week's commons debate. For example, the transplant of tumours from one animals to another and the implanting and developing of antibodies within animals, he said, were procedures now in use which were not covered by the Act. New legislation was needed which would incorporate these and other procedures developed over the past 103 years.

Peter Fry's Bill goes further than Lord Halsbury's in several respects. In particular, it lays greater emphasis on the need to reduce the number of animals in experiments by controlling the type of research that is done. Like Lord Halsbury's Bill, it recommends that alternatives to animal experiments should be used wherever they are available but it also emphasises the need to eliminate repetition of experiments.

One of the more controversial clauses of the Bill, however, states that "operative procedures" will only be allowed for "the advancement of biological science" in a way calculated to save or prolong human or animal life or relieve suffering. Is it possible to decide in advance what research will lead to such progress asked Tam Dalyell, who cited the discovery of enkephalin as an example of research with animals of far reaching significance which could not have been anticipated. Mr Fry accepted the point, which had also been made to him by the Medical and Agricultural Research Councils, and suggested that the relevant clause be amended "to satisfy that kind of objection".

Mr Fry's Bill also differs substantially from Lord Halsbury's over the granting of licences to experiment with animals. It recommends four different grades of licence covering all types of procedure. Grade 1 licences, explained Mr Fry, would be for the simplest procedures, such as giving injections. A Grade 2 licence would be the equivalent of the single licence now existing under the current legislation. It would allow surgical procedures under anaesthesia from which the animal is not allowed to recover. A Grade 3 licence would cover surgical operations where the animal is allowed to recover afterwards provided that it is suitably anaesthetised throughout the entire procedure. And a Grade 4 licence would be granted for "research in which pain is inevitable as part of the experiments". Mr Fry expects that this latter category will raise the most objections from the antivivisectionists.

The Bill had a successful second reading and now goes forward to the committee stage. However, Mr Timothy Raison, Minister of State, Home Office, reminded MPs that a European Convention on animal experiments was currently being drawn up and that it would be wise to wait for that before passing legislation. The government, he said, could "not regard the Bill as it stood as an acceptable way of dealing with issues of a fundamental natures concerned with animal experimentation". Nevertheless, it would not stifle the debate by opposing the Bill at this stage.

news in brief

Academics call for removal of Boston University President: Scientists and academics at MIT and other institutions in the Boston-Cambridge area have called for the removal of John Silber as President of Boston University. A petition circulated by Dr Salvatore Luria, Nobel laureate, and Professor Emeritus of biology at MIT, condemns Silber's administration of the university as "notorious in the academic community and the nation at large."

The current calls for censure, described by the petition as "the latest in a pattern of violations of civil liberties", have arisen from the threat by Silber to dismiss or suspend five tenured professors who had, at the beginning of September, expressed their support for striking clerical workers at Boston University. In order not to cross picket lines, the five gave their lectures in places other than the assigned class-rooms. This, said Silber, constituted a breach of contract.

The petition was launched on 5 November. Within ten days, Silber was saying that the five professors could avoid disciplinary action if they submitted a written apology. He denied that the university had ever "threatened" dismissal or suspension although these options were not, he said, "ruled out". Some milder form of sanction, such as reprimand or docking of pay was, however, possible.

USSR has no oil crisis: A new Swedish report, sharply disagreeing with current CIA estimates, claims that Soviet oil reserves are 100% larger than current Western estimates allow. The report, by Petro Studies, an independent Swedish oil research firm specialising in analysing Soviet oil and gas industries, contradicts recent conclusions made by other Western analysts. Using a systematic literature search of all Soviet information released over the past 20 years, the report says that the "large underestimation of the USSR reserves by Western analysts requires that the world's oil reserves must be revised upwards by an amount equalling the combined proved reserves of the US, Canada and Mexico." The report claims that the USSR has been the world's leading producer since 1974 exceeding the US by a factor of four and Saudi Arabia by 25% and that it will increase its oil exports to the West in order to earn hard currency. "There is no danger at all that the USSR will become a net importer of oil in the next ten years at least and it will not compete with other nations in the purchase of OPEC oil." *Soviet Proved Oil Reserves* 1946-1980. PetroStudies Co. Sjöblads väg 27, S-21370 Malmö, Sweden.

UK nuclear information restricted since Three Mile Island: An official internal memorandum advocating tight control over the amount of nuclear reactor information to be allowed to reach the public was circulated among high officials of the Central Electricity Generating Board last April shortly after the Three Mile Island accident. The memorandum, leaked to the *Guardian* on 19 November, was signed by Mr Roy Matthews, the CEGB's director of health and safety, and advocates a two step process for dealing with telephone calls from the "nuclear opposition". Step one is to refuse to provide the information and step two, in the event that the caller persists, is to request a written question which "then can be considered centrally and if it is agreed that answers should be given then we will have to insure that this is done on a consistent basis."

Windscale widow awarded £67,000: The widow of a former worker at British Nuclear Fuels Ltd's Widscale nuclear plant was awarded £67,000 in a Crown Court settlement last week. The case was brought by the General and Municipal Workers Union on behalf of Mrs Bridget McAreavey after her husband, Mr Malcolm Pattinson died of myeloid leukaemia at the age of 36. Pattinson worked as a process worker and general worker at Windscale from 1957 to 1970. He died on 28 May 1971. The case was the first in the UK in which a co mpany has admitted liability for radiation caused injury or death. (In a similar case in 1976 British Nuclear Fuels agreed to an out of court settlement of £22,500 to the widow of Jonathan Troughton and £8,000 to the widow of Harry King,both of whom died of leukaemia after working at Windscale.) An official BNFL statement said that the "settlement has been reached on the particular facts and issues in this case and should not be considered prejudicial for any future claim, pending claim, or past claim." David Gee, national health and safety officer for the GMWU was "relieved" at the action but was "not pleased" at the length of time it took to reach a decision. "These court room scenes are quite stressful and we have pressed BNFL for an automatic compensation scheme since the Troughton and King settlement in 1976. BNFL agreed to consider this but there has been no response so far. We have 30 workers at Windscale who have received maximum permissable lifetime doses and we need a protection of earnings scheme for them. Someone who is made redundant at 35-40 has a long way to go and their level of skilled wages must be protected."

ESA-NASA to launch Halley-Tempel 2 comet mission: The European and US space agencies, NASA and ESA, are seeking experimental proposals for a planned mission to two comets, Halley's and Tempel 2. The mission has been timed to take advantage of the once every 76 year appearance of Halley's comet during the winter of 1985-1986 and will last four years. NASA will be responsible for the launching and mission operations and ESA will be responsible for the Halley comet probe system.

US Army seeks new funding for nerve gas weapons: The US Army is again seeking funds for a facility to produce nerve gas weapons, halted since the early 1970s following widespread protest against the use of chemical weapons in Vietnam. Last year President Carter rejected a request from the Army to start construction of such a facility, which would produce so-called binary shells containing two separate nonlethal chemicals which combine to form a nerve gas after the shell has been fired. A report in the *New York Times* last week stated that the Army had received "tentative approval" for its request, which it has resubmitted for inclusion in the 1981 budget. However, the report also says that administration officials are split over whether the decision to proceed with the production of nerve gas weapons would alarm other member countries of the North Atlantic Treaty Organisation, where such weapons are most likely to be used in combat.

Although President Carter turned down the request last year, his budget proposal included funds to continue development work on the weapons.

Johns Hopkins gets space telescope institute: A group of US universities responsible for running a number of major US research facilities, has proposed that the Space Telescope Science Institute planned by NASA should be located at Johns Hopkins University in Baltimore, Maryland. The recommendation was made last week by a board of directors of the Association of Universities for Research in Astronomy (AURA) which is preparing to submit plans to NASA for an institute to direct space telescope research on the university's Homewood campus. The 2.5m diameter telescope is scheduled to be launched from the space shuttle in late 1983 and to operate for at least 20 years. AURA selected Johns Hopkins after examining offers to host the institute from seven separate universities.

Weiss appointed director of Institute of Cancer Research: Robin Weiss, aged 39, presently head of the Laboratory of Viral Oncology at the Imperial Cancer Research Fund, has been appointed Director of the Institute of Cancer Research in London. The ICR is a major European cancer research organisation with a staff of 450 and an annual budget of £5 million. Weiss' appointment is seen as a move by ICR to strengthen its basic research approach to cancer research.

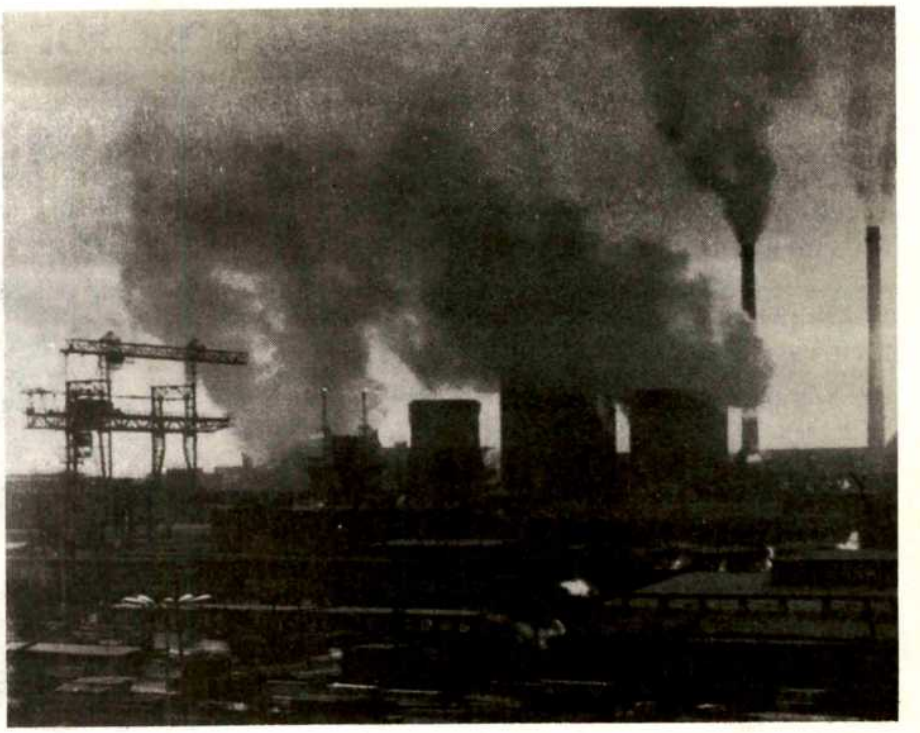
East Germany may debate pollution



LAST week, the Mecklenberg Synod of the Evangelical Lutheran Church issued a call for public discussion on the dangers of nuclear energy — the first time that the issue has been raised in the GDR. The church in East Germany is not often outspoken on matters outside its immediate concern, and the Mecklenberg proposal for talks between politicians, scientists and churchmen on the nuclear issue is unlikely to receive unqualified official approval.

Judging from the listed "priorities" for science and technology in the current five year plan, environmental issues are not a prime concern of the East German planners, except perhaps as regards water resources which are extremely scanty (2,100 m^3/year per head of the population, according to 1970 Comecon figures, as against the Soviet Union with 19,600 m^3/year, Bulgaria with 24,000 m^3/year, and Hungary (12,000 m^3/year per head).

Conservation, to the East German planners, seems primarily to mean energy saving — as exemplified in last week's address of State Secretary Ziergiebel to the "Urania" society for the dissemination of scientific knowledge. The future problems of the energy industry are enormous and are by no means easy to solve, he said. Energy saving, in the present world situation, is "a principle of socialist economic management", which, by the use of effective technologies, can effect, as in the case of the Leuna combine, "a million-fold saving".

The Magdeburg appeal, however, seems to reflect a wider concern with environmental issues among the East German public at large. The GDR is a notoriously difficult country in which to gauge public opinion — unauthorized communication of information to foreign journalists can merit a 12-year jail sentence. However, a recent "exchange of letters" in the prestigious philosophical journal *Sinn und Form* may well serve as a pointer.

'Walter Ubricht' chemical plant, Halle, East Germany: effluents as well as profits

In the first of the letters, Gunter Kunert, a well-known writer, addresses the editor on the dangers inherent in modern technology. He ironically dismisses the "class-standpoint" that science and technology in the hands of "progressive forces" never have the same negative consequences as occur under capitalism". To take but one example, in "industrialized agriculture", "we have a metaphorical tiger by the tail", yet, in spite of the risk of poisoning, "agriculture will get nowhere without insecticides and pesticides", and to abandon them would result in world famine. Quickly he runs through a "catalogue" of possible disasters more familiar to a western than East German readership: the possibility of climatic change through CO_2 buildup and the ensuing melting of the polar ice-caps, destruction of the ozone layer by aerosol propellants, the hazards of nuclear energy — in the GDR, he said, all these dangers inherent in the development of civilization are put out of mind. DDT is banned, but new substances, whose effects are only vaguely known, are spread on the fields. No one is concerned with long-term hazards, and people simply proceed on the principle that "the human race will survive — it always has so far!"

Kunert's letter is a moderate and reasoned appeal, not for the abandoning of technological advance, but simply to a greater awareness of long-term and cumulative effects. His stance on pesticides, for example, seems very similar to the attitude of Hungary's plant protection officers. To Wilhelm Girnus, Editor of *Sinn und Form*, however, Kunert's proposals seem tainted with western doomwatch. Girnus does not, of course, dismiss environmentalism altogether; in his reply, more than three times the length of the original letter, Girnus mentions, though with some doubt, work done on the smoke-pollution of pine-trees, and even waxes enthusiastic over the Soviet Union's integrated plans (which include conservation) for the region to be spanned by the new "Baikal-Amur-Mainline".

However, his major task is dialectic. From an argument which ranges from the content of socialism to the views of a "certain Herr Schicklgruber" on the vocabulary of "Jewish liberalism", the message emerges; a doomwatch mentality, always on the lookout for "black possibilities" can lead only to "manic sweeping judgements", helplessness, and moral paralysis. In the capitalist world, he says, "a kind of addiction to catastrophic experiences" is becoming rampant. While politely agreeing with Kunert that the "warnings of a serious scientist about the dangers of a new discovery must be taken seriously", in his capacity as editor of a leading philosophical journal, Girnus makes the official standpoint abundantly clear. If citizens of the GDR do want to discuss ecology, they must eschew the doomwatch edition.

A revival for Islam, a boost for science?

TODAY is the first of the fifteenth Islamic century: a century in which Islam again is becoming a potent force in world affairs. **Ziauddin Sardar,** *Nature* correspondent for the Muslim world, recently visited eight key states — Iran, Turkey, Syria, Saudi Arabia, Egypt, Pakistan, Malaysia, and Tunisia — to report on their varied attitudes to science and technology policy. He found an increasing interest in the concept of an 'Islamic Science', a socially concerned science set within the philosophy of Islam. In the first of a number of articles which will appear in *Nature* over the next few months, Sardar here reviews opinion on whether science and technology can be so 'Islamised'. Next week he will discuss thinking in Iran; after that, nuclear power in Turkey.

Oil pipelines in Saudi Arabia: Islam's new technology

THE global middle belt: from the shores of Senegal and Morocco to the Pacific Ocean and the islands of Indonesia, and north to south from the Mediterranean coast of Turkey to Somalia; almost one billion people, constituting one-third of humanity, and speaking over 50 languages; 46 sovereign states at various stages of development and with ethnic backgrounds as diverse as those of Arabs and Afghans, the Housa and the Pathans, the Chinese and the Malays, welded together in a bond that goes back fourteen hundred years to this very day; the bond of Islam; the Muslim world.

Only three decades ago, the Muslim community was a subject community. The fifties saw the independence of many Muslim states. However, they soon learned that political independence alone is not enough. To be free and yet to be dependent on the departing colonial powers for scientific expertise, technology transfer and foreign aid is not real freedom. The Muslim world is now beginning to take the view that the post-independence development strategies occidental-style have been in error. This awakening is based on a strong self-assertion of the Muslim world's Islamic identity and brotherhood, and is seen by many as a new revival of Islam.

The Muslim world is going through a deep, although turbulent, process of self-examination and self-renewal. Almost everything is placed under the microscope and investigated from the perspective and world-view of Islam. Both western consumer materialism and eastern (dialectic) materialism are dissected with fervour. Serious attempts are being made to seek and pursue Islamic alternatives.

How would this sense of revival affect science and science policy in the Muslim world?

There is little doubt that most Muslim countries with science policies are re-examining and re-evaluating those policies. Iran, for example, is taking a very deep look at its science. Syria is reorganising its science with concern for the culture and values of its society. Iraq and Algeria are going through a process of 'Arabisation'. Attempts are being made, largely due to the efforts of the Jeddah-based Organisation of Islamic Conference, to persuade Muslim countries without science policies to formulate down-to-earth policies based on their needs and requirements. An Islamic Foundation for Science, Technology and Development (IFSTD) has been set up by the Tenth Islamic Conference of Foreign Ministers, held in Fez, Morocco, in April 1979, to help and encourage the development of science in the Muslim world, draw programmes for co-operation and co-ordination of research activities amongst the Muslim countries, and help give a unified direction to science policies (see box).

The revival of Islam is also providing an impetus for science. Mohammed Ajaz al-Khattib of the University of Damascus thinks that this is a natural process. "The pursuit of science is an obligation for an Islamic society. If an Islamic society experiences an increase in the awareness of its Islamic identity, it will fulfil its obligation to pursue science with more vigour."

According to al-Khattib, for Muslim societies science is not a luxury, but a necessity. "Some 750 verses, almost one-eighth of the Qur'an, exhort the believers to study nature, reflect, make the best use of reason, and make scientific enterprise an integral part of the community life. In contrast, the legislative verses are only 250", he says.

Kalim Siddiqui, Director of the London-based Muslim Institute for Research and Planning, told *Nature*: "The new and invigorated civilization of Islam which is now re-emerging has a solid body of axioms that have stood the test of time without the help of 'reformation' or otherwise 'revised' or 'authorised' versions. The new civilization of Islam will be capable of boosting scientific activity and scientific knowledge to heights and achievements unknown to man before".

Zia Sardar is the author of 'The Future of Muslim Civilisation' published today by Croom Helm, price £10.95 (hardback) £4.95 (paper)

IN the history of Islam, science occupies a central position. Although known to the West largely for its historical influence on the development of European scientific thought, it also had a powerful effect on the development of Muslim civilization itself. Islamic science is considered to be one of the basic ingredients that provided the drive for the "Golden Age of Islam". So it is now being realised that science is even more essential for a Muslim civilization of the future. This realisation is obviously related to the sense of revival that is sweeping through the Muslim world. There are, however, two special factors that have helped to create this scientific consciousness.

The first was the publication of Seyyed Hossein Nasr's book, *Science and Civilization in Islam* (Harvard University Press, 1968). This was the first serious attempt to examine Islamic science *within* the context of the civilization of Islam. But more than that, because Dr Nasr, an Iranian scholar now in self-exile in London, commanded attention and respect in the West, he made it possible for many a Muslim scientist, with the usual developing country background and sense of inferiority, to speak about Islamic science without feeling ashamed. His second book on the subject, *Islamic Science: An Illustrated Study* (World of Islam Festival Trust, London, 1976), took the discussion to the popular and student level. It is responsible for generating much excitement and discussion on the campuses of the universities of Muslim countries.

The Islamic Solidarity Conference on Science and Technology, sponsored by the University of Riyadh and held at Riyadh's ultra-modern King Faisal Conference Hall in March 1976, was the second catalyst (see *Nature* **260**, 663; 1976). The conference spent a great deal of its time soul-searching and discussing "Islamic ways of doing science". At the conclusion of the conference it was declared that the future of the Muslim world is closely linked to the revival of Islamic science and the operationalisation of its concepts and principles.

That was in 1976. Since then much discussion has ensued on the nature of Islamic science. At the same time, there have been a number of attempts to 'breath the spirit of Islam in natural sciences' and to 'Islamise' the teaching of science. Notable amongst these are the innovations concerning the teaching of 'Islamic technical subjects' at King Abdul Aziz University, Jeddah; various attempts at "Arabisation of science" in Syria, Iraq and Algeria; and the entire reorganisation of education and the radical approach being planned and developed to the teaching of science in Iran.

Much of the discussion on Islamic science is woolly and confused. This is only natural. In its practical form Islamic science existed in a distant past and the Muslim civilization has been out of touch with science for over four centuries. During this period the Muslim civilization degenerated to reach its nadir, was consequently colonised, and has only recently reemerged to face what are probably the biggest fundamental material changes human life has ever experienced. Furthermore, there is an acute poverty of analytical and historical literature on the nature and style of Islamic science.

Four points of view

The discussions on Islamic science centre around two basic questions: what is Islamic science? And how does it differ from the practice of conventional science? Some Muslim scientists, however, are asking an even more fundamental question: Is there such a thing as Islamic science?

Four points of view can be distinguished on these questions. The first is what we may call the traditional (western science) ethos. The second and third viewpoints maintain that Islam has a great deal to say about science, but are divided on where exactly Islam enters the picture. The fourth argues that Islamic science is something quite different from science as it is practised today.

Ali El Hili, Dean of the Faculty of Mathematics, Physics and Natural Sciences, University of Tunis, presents the traditional view of science simply and forcefully: "there is only one science: it is universal, neutral and value-free. The study of nature is impersonal and free from human values. It *has* to be that way", he says. Discussions of Islamic science worry him. "We cannot compromise the basic rationality of science with our religious concerns". And he warns: "if we compromise the basic objectivity and neutrality of science with Islamic values and ethics we will destroy the very foundations of science".

Tevfik Karabag, Secretary-General of the Scientific and Technical Research Council of Turkey, agrees with Hili. "Science is universal", he argues, "but a value-judgement may be applied in giving emphasis and pursuing a particular area of science". Thus the Muslim countries may choose not to pursue research on fermentation due to restrictions on alcohol in Islam. However, the choice of undertaking or not undertaking a particular area of research is available only in applied fields. "Basic scientific research, in all areas, must be pursued for its own sake", says Karabag. If one were to talk about Islamic science in Turkey today, he says, one is likely to be ignored and isolated by one's colleagues and labelled a "fanatic".

There is no such danger in Egypt. Fahamy Ramadan, General Secretary of the Cairo-based National Research Centre, who spends most of his free time reading the Qur'an, declares unambigiously: "science has no home, no religion, no particular bias. Everyone contributes to it, irrespective of race, creed or culture". He

Ancient Islamic Science: an astrolabe

mourns the sorry state of science in the Muslim world and is convinced that "the road to the future of science in the Islamic world lies through Arabisation". "This is the link between our past and present", he says.

Fahamy argues that science and technology will not settle in "Muslim homelands" unless Arabic becomes, for the Muslim people, the language of science. "Only through Arabic can we encourage cultivation of sciences in the Arab and Islamic countries, encourage science to become a genuine component of Arab and Islamic thought, and assimilate the love of science in the mentality and minds of our citizens", Fahamy says.

Many Muslim scientists would agree whole-heartedly with him. Indeed, serious attempts are being made to Arabise science in Iraq and Syria. But there are a large number of Muslim scientists who argue that the issue of Islamic science is deeper than simply doing and teaching science in Arabic.

Secular or Islamic approach?

The second position on Islamic science is articulated by Affifin Suhaimi, Dean of the Faculty of Science and Environmental Studies, University of Agriculture, Selangor, Malaysia. "Science is neutral", he says, "but the attitude by which we approach science can be secular or Islamic". What is the Islamic approach to science? "We recognise the limitation of human reason and human mind; and we acknowledge that knowledge is the property of God", explains Suhaimi. "This knowledge is granted to us as a trust. We can use it for the benefit of society or we can put it to destructive use. Either way, we as scientists, are responsible before God for the use of that trust", he says.

Like Hili, Suhaimi too is concerned about the discussions on Islamic science. The argument that Islamic science is

something different from western science, complains Suhaimi, is sometimes used to block the transfer of scientific knowledge from the West to Muslim countries. "Science, in its pure, value-free form, we can take from all sources", he argues. "We should take from the West as much as we can". To support his argument he quotes a tradition of the Prophet Muhammad who is reported to have said that "knowledge is like the lost camel of a Muslim. Take hold of it whenever you come across it". "Our people forget", says Suhaimi, "that Islam is within us: we put the science to Islamic or un-Islamic use. Science is Islamised in the way we practise it and utilise it", he says.

Zafar L. Sawaf, Director of Centre for Industrial Research and Development, presents a similar argument. "Islam comes not with science, but after it", he says. "To what use do we put science in our societies? This is the Islamic question". Sawaf argues that science, in the Muslim world, has to be pursued for its own sake. "But we cannot allow certain results of science to destroy our values and culture and take our societies towards excessive materialism. We must exercise discretion in the use of scientific results and in pursuing research projects we must be aware of the effect our results could have on the moral fibre of our society", he says.

For Sawaf, the use to which science is put in society must be determined by Islam. "It is a question of preserving our values and culture. That science has led industrialised societies towards an ugly materialism and an excessive consumerism, we cannot deny. We cannot let that happen in Syria", Sawaf declares. "What we need is an Islamic approach to science."

Goal-oriented science

Values and preservation of culture also figure largely in the thinking of those who take the third stand on Islamic science. This group suggests that Islamic science is more a matter of philosophy than science but at the same time, it argues that both modern science and technology are distinctively occidental. Today, throughout the world all significant science is western both in style and method, whatever the pigmentation or creed of the scientist.

Ali Kattani, Professor of Electrical Engineering at the University of Petroleum and Minerals in Dahran, Saudi Arabia, makes the point: "Science is intricately linked with ideology in its emphasis, scale of priorities, control and the direction of research, to such an extent that scientists have now become ideologues. Their craft is not neutral, but promotes a certain pattern of growth and development and a certain ideology."

According to Kattani the Muslim scientists are only apprentices of the western scientific establishment. "Most of the research that is going on in the Muslim world is taking our societies away from Islam", he says. It has linked the Muslim scientists scientifically and emotionally with the western establishment. "So we are

Foundation for science, technology and development

AN important decision concerning science and technology in the Muslim world was taken by the Tenth Conference of Foreign Ministers of Islamic States meeting in Fez, Morocco, during 8-12 May. The decision related to the establishment of the Islamic Foundation for Science, Technology and Development (IFSTD), a supranational body that will promote, coordinate and, some hope, supervise science and technology activities throughout the Muslim world.

IFSTD had been on the agenda of the Foreign Ministers Conference for at least five years; the project was first proposed to the Fifth Islamic Foreign Ministers Conference, held at Kuala Lumpur in June 1974. Since then several studies on IFSTD have been prepared; and for the last three years a Group of Experts has been meeting to draw-up plans for launching the Foundation and finalise the $50 million first phase of its expansion.

The news of the establishment of the Foundation was greeted with considerable enthusiasm throughout the Muslim world. As Ariffin Suhami of the University of Agriculture, Seradang Selangar, Malaysia, says, "the Muslim scientists have been waiting for some considerable time for an international organisation which encourages R&D activities within an Islamic framework, and which would help solve some of the current problems of the Muslim world in particular and mankind in general. At last the Islamic Conference has responded to our needs". Many Muslim scientists see IFSTD as a key instrument in bringing the Muslim scientists together. Says Waqar Husaini of Department of Civil Engineering, King Abdul Aziz University of Jeddah: "to promote cooperation and coordination in science and technology within the Muslim world *is* to strengthen the bonds of Islamic solidarity".

The greatest hopes, however, are placed on the funding function of IFSTD. Ahmad Bourani, Director of Institute de Récherche Scientifique et Technique, Tunis, sums up the feeling of many Muslim scientists. "IFSTD can easily become another Muslim organisation with a rather large bureaucracy, unless it actively seeks viable projects that are dormant because of lack of funds. Tunisian examples would be research on arid zones, water economy and olive plants. We used to get some UNESCO backing. But it seems that they have lost interest in us. Let IFSTD pick up where UNESCO left us".

The Charter of IFSTD outlines its interest: geological surveys and resources maps, energy resources, petroleum, water resources and desalination, electronics, medical research, oceanography, space research, defence technology, ecology and food and agriculture. The accent is definitely on high technology; there is conspicuous absence of alternative technologies, though solar energy gets a passing mention. A vague reference to technology assessment is made when it is stated that the Foundation will "conduct studies on the impact of utilisation of science and technology in socio-economic plans on Islamic culture and heritage".

There are, however, a number of very original goals that IFSTD hopes to pursue, the realisation of which would make a considerable contribution to science development in the Muslim world. These include the development of "appropriate (Muslim) models of science policy" and assistance to Muslim countries to adopt them; preparation of "plans for the training of scientific manpower capable of disseminating Islamic scientific culture", and "establishment, where needed, of scientific and technological institutions in (Muslim) countries, particularly technical universities in Africa and South East Asia".

IFSTD will also study and make recommendations to Muslim countries for improving the status of scientists and technicians. In particular, special care will be given to Muslim scientists working in the West; IFSTD even proposes "to set up one or more Islamic universities for science and technology in the (developed) countries".

Science policy organisations of all Muslim countries will particularly attract IFSTD's attention. The foundation will urge them to operate within an "Islamic strategy", to promote science and technology at all levels of society, and give priority to "the creation of distinctive technologies indigenous to the Islamic world". Countries which do not have national organisations responsible for science policy and planning will be urged to establish such bodies which should be affiliated to the highest authority in the country. Where it is not possible to establish such bodies, IFSTD will undertake advisory role in science planning and policy making.

The Islamic Secretariat in Jeddah, which is also the headquarters of IFSTD, is now actively looking for a director — an "eminent scientist" — to lead it. □

0028-0836/79/470356-01$01.00

working for a society that is elsewhere, in the West. Most of our work ultimately benefits the developed countries", he argues. "Because we are working within a system of science whose emphasis and priorities reflect the aspirations of an alien culture, science in the Muslim world is either in a state of struggle or in a state of continous degeneration".

Islamic science, according to Kattani, is that science which reflects the needs and aspirations of Muslim people. "Western science places man at its centre, in the position of a demi-god. Islamic science emphasises the position of man in the universe: he can rise to the level of angels or sink to unimaginable depths, but he is responsible for all his actions, and the after-effects of his action, to a Supreme Authority. Scientific activity carried out under such a realisation is an entirely different proposition. The actual content of such a science may not be radically different. But the priorities and emphasis

Abdullah Naseef: science serves goals

will certainly be different. And so will the quality and quantity of the content of this science. And finally, the use to which this science will be put will also be different", he says.

The argument is further clarified by Raghib El Naggar, Professor of Geology also at the University of Petroleum and Minerals. "The belief in a Creator makes Muslim scientists more conscious of their activities. It places their reason and curiosity under the authority of a Supreme Power to whom they are responsible for all their actions". He quotes the verse of the Qur'an that says: "whosoever kills a human being for other than manslaughter or corruption on Earth, it shall as if he has killed all mankind; and whosoever saves the life of one, it shall be as if he has saved the life of all mankind". "We, therefore", says Naggar, "cannot let our scientific curiosity run blind for if our activities result in a single death, even indirectly, we will be accountable for it".

Thus, Naggar argues, science in Islam must be a goal-orientated activity. "Islamic science", he says, "cannot be isolated from wisdom. Neither can it be isolated from values". The integration of wisdom and values in Islamic science, according to Naggar, is in no way a restriction on thinking. Rather, "it gives one's thinking a direction". He rejects the notion of science for science's sake and considers the social function of science to be more important than science itself. "Our destiny as Muslims is determined not by science *per se* but by its social function", he says.

The fourth and the final stand on Islamic science also emphasises the social function of science but argues that Islamic science has its own, unique entity that differs considerably from science as it is practised and nourished today. Western science, it is argued, draws its inspiration from the Enlightenment and its assumption are those of the *Philosophes* and the rationalist world-view. Some of its underlying assumptions are those of medieval Christianity. As such, science, as we know it today, is a product of western civilization and an embodiment of its culture, ethos and values.

The proponents of Islamic science argue that Islamic science is based on entirely different assumptions about the relationship between man and man, man and nature, universe, time and space. Because the basic axioms of Islamic science are different from those of western science, and its method of knowing is also different, it is a science with its own identity and character.

Says Abdullah Naseef, Vice Rector of King Abdul Aziz University of Jeddah, "under Islam, science is subservient to the goals of society. The goals of an Islamic society are to increase brotherhood, reduce consumption and increase spiritual awareness. A science with these goals has to be different in nature and style from science as it is practised today. Furthermore, these goals cannot be pursued by any means. They can only be pursued by those means which are permitted by Islam. Aggressive rationalism, to give an example, is considered by Islam to be anti-human. So Islamic science does not accept the tyranny of one, supreme method. We emphasise methods in conformity with the nature of enquiry. Within these parameters, Islamic science has access to reason and experience, observation and experimentation, deduction and induction but always we turn to revelation as the supreme authority. Islamic science is the most exact of sciences without being fooled into believing that the method of experimental and theoretical sciences can lead to eternal truths."

In the post-revolution Iran, there are many scientists who hold this view. And one hears these arguments time after time. Mahdi Mumkin, Deputy Minister at the newly established Ministry of National Guidance in Iran and a theoretical architect of the Iranian revolution, holds very similar views but adds that Islamic science keeps the long-term future of society in perspective. "Muslim scientists do not seek short term expedient answers to socioety's needs. The long term view is an essential element of Islamic science. The pile-up of military weapons in the US and the Soviet Union, to give an example, is totally unrelated to any concept of a viable human future", he says. Mumkin makes an even bigger claim: "the axioms of Islamic science, its concepts of man, nature, environment, and the universe, do not permit Islamic science to become part of a system of violence — and violence is defined here in very broad terms — or of a system of power and control", says Mumkins.

Waqar Husaini of the Department of Civil Engineering, King Abdul Aziz University, Jeddah, suggests that this is because "Islamic science is

Affifin Suhaimi: objective and Islamic

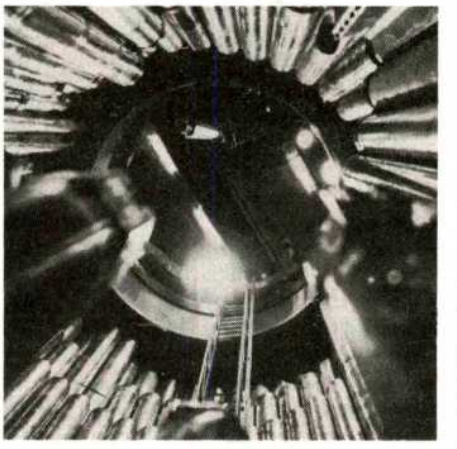
epistemologically and ontologically inseparable from the Islamic concept of God." He argues that under no circumstances can Islamic science pursue research "at the expense of socio-ethical indicators of spiritual development, sanctity of family life, exploitation of natural resources without due consideration or future generations, and weapons, such as nuclear, chemical and biological, which have no regard for humanity". According to Husaini, "Islamic science is a public interest science. It operates with in the parameters of the Islamic concept of *al-maslaha* (loosely translated as the "common good") and promotes, preserves and develops 'five universal principles' which constitute the common good, namely — the Islamic way of life, life itself, reason, posterity and property".

Clearly Islamic science has a strong input from the ethics and morality of Islam. It is equally clear that it is a fuzzy concept that needs a great deal of clarification. For it to become acceptable to a wide cross-section of Muslim scientists, as well as western scientists, Islamic science has to prove itself both theoretically and practically. Considering the vast array of issues, from food, water, housing, transportation, medicine to health that now confront the Muslim world, there is no shortage of problems to work on. It will be worthwhile to observe if Muslim scientists can show that Islamic science has its own unique nature and style; and live up to their declared ideals. □

correspondence

Fast reactors will be problematical and expensive

SIR,—I did not reply at once to Dr Smith's letter (23 August, p630) which criticises my article (26 July, p 270) on fast reactors as I was not sure quite how to reply. It now seems to me that the best way I can deal with the issues he has raised and his list of my supposed errors — elementary, outstanding and otherwise — is to quote other authors who have made similar points, with appropriate references so that any interested readers can check for themselves. So this letter is rather long but the issues are important in view of the continuing discussion in Britain on CFR 1.



I will start with my four "outstanding errors" in physics. One is the misprint on the Doppler effect. It is remarkable that Dr Smith felt it necessary to refer to this "error" as the full version[1] of the lecture I gave at a conference in London last year has been available to him at Risley since May. My July article was simply a shortened version of the lecture, but there was no misprint in the full version.

The second "outstanding error" is my statement that a thermal reactor has less than one critical mass. If Dr Smith does not accept me as an authority on this point, perhaps he will accept Hans Bethe (Director, Theoretical Physics Division, Manhattan Project, Los Alamos 1943-46; Professor of Theoretical Physics, Cornell University since 1937; Nobel Prize for Physics 1967). Bethe[2] states in his testimony in support of nuclear power to the State Legislature of California in 1975: "The most important difference between a fast and a slow neutron reactor is that a fast reactor contains more than one critical mass. (By contrast the material in a light water reactor can never form a critical mass because the concentration of the fissile isotope ^{235}U is very low.)" The point is, of course, that a thermal reactor goes critical only in the presence of a moderator whereas a critical mass of a substance is that mass (at normal density) which goes critical by itself.

The third "outstanding error" is that "thermal reactors are designed to be in their most reactive nuclear configuration". This is indeed a possible design requirement for a thermal reactor, although not for fast reactors, and is sensible design practice for commercial thermal reactors. Compare Fauske's lecture[3] at the International Conference on Containment of FBRs at San Francisco in 1977 where he said "Unlike LWRs LMFBRs can be very sensitive to dimensional changes or relocation of core materials since the intact LMFMR core is not in its most reactive configuration". Farmer's examples (12 April, page 593) are not really relevant — *overcooling* is not a hazard for electricity-generating PWRs although it may have caused incidents in small submarine reactors.

My fourth "outstanding error" is the re-criticality scenario leading to a core-disruptive accident. A more detailed account of such accidents is given in Wilson's article[4].

So much for the "outstanding errors". Dr Smith then claims that "these errors are important in that they convey the impression that fast reactors are difficult to control, unsafe and not well understood. On the contrary . . . Their safety has been the subject of intense study for very many years and is well understood." I agree that FBR safety has been studied intensely for many years; unfortunately, however, it will have to be studied intensely for many more. This is in fact the conventional view. At the 1976 meeting in Chicago on Fast Reactor Safety, spokesmen for the UK Nuclear Installations Inspectorate stated[5] "we have indicated the seriousness with which the NII views the possibility of whole-core accidents in a thermal reactor system . . . At the present time however we believe that there are doubts about the adequacy of fault lists, about some of the physical phenomena which might play a part in an accident sequence, about structural materials behaviour, and the performance of protective systems . . . A sound programme of theoretical analysis backed up by suitable model tests is a minimum requirement." My claim that proceeding with a large fast reactor such as CFR1 with a large positive sodium void coefficient will cause even more problems is also shared by others, even by strong proponents of fast reactors such as Professor Bethe[6]. He said at Chicago[7]: "In my opinion, reactor should if possible be so designed that there is no positive void coefficient."

Inside Dounreay's PFR

If we now turn to FBR economics, the argument hinges on two basic points[8]: the comparative capital costs of FBRs and other reactor systems, for example PWRs; and the future price of uranium. Keck[9] has demonstrated in the only case study[10] available that SNR-300 will have cost 5 times as much as an equivalent PWR when it is completed. Dr Smith's comments on SNR-300 are incorrect and the interested reader should consult Keck's massive thesis[10] where a blow-by-blow account is given of how the increased costs were incurred. It may well be that the factor 5 will not be appropriate for the cost of CFR1 compared with a PWR system. Dr Smith claims that an estimate of this factor would be 1.5±0.5. I would suggest that it would be wise for the government and electricity board concerned to double this estimate to 3±1 in line with the factor of 3 assumed[11] for the proposed Clinch River breeder reactor in the US. The economist Duncan Burn who has studied the British nuclear industry for many years[12] made essentially the same point at the London conference last year[13]: "I do not doubt that following on the long development of the FBR in the UK which has culminated so far in the PFR at Dounreay we can at great cost proceed to construct one or more large 1300 MW prototypes and make a plant which will work and be safe. But it would not necessarily satisfy the economists' criteria."

Dr Smith then claims that "there is little doubt that lower fuel cycle costs will more than compensate as uranium prices increase due to pressures in the next few decades on limited supplies of uranium ore". My colleagues at the Science Policy Research Unit here are engaged in an SRC sponsored study of fuel cycle costs. Their conclusions on the future price of uranium, in line with authoritative sources in the uranium industry, are that[14] "In the longer term reserve estimates are rising rapidly, demand growth is being cut back, higher grades of ore will come on stream in the 1980s and some cost-cutting technical improvements are likely. In the probable absence of an effective cartel, this will provide strong pressure towards a lowering in the long-term real price of uranium for the remainder of this century and possibly even longer."

Dr Smith ends his letter by regretting that my article "gave such an unbalanced view of fast reactor safety". I hope that your readers will prefer the opinion of a distinguished scientist in government service who wrote to me saying "what an excellent and very fair summary".

Yours faithfully,

NORMAN DOMBEY

Affecting the effect

SIR,—While affiantly reading page 618 in *Nature* of 25 October, I found it effascinating how an effroyable use of 'effect' effectively effeebled the meaning. Effacing the 'e' and affixing an 'a' had an efficacious effect on the affected sentence. The affeebled article's meaning now effulged.

Your affatuated reader,

T. W. COLE

Anomalous ionic conductors

from Robert W. Cahn

GOOD ionic conductors such as beta-alumina, zirconia and silver oxide are the object of research in a number of laboratories on account of their potential use in high-performance batteries such as the sodium/sulphur battery. These conductors are ionically bonded crystals in which one ionic species migrates readily under the influence of an electric field; there is no electronic conduction of the metallic type.

Two recent papers in the Chinese journal *Scientia Sinica* indicate that Chinese scientists are also actively investigating at least one ionically conducting species, though curiously their interest does not seem to focus on electrical behaviour. Yang Zhen, Niu Shiwen and Cheng Yufen at the Institute of Atomic Energy of the Academia Sinica (*Scientia Sinica,* **22** (9), 1000; 1979) have studied the anomalous enhancement of neutron diffraction intensities from α-$LiIO_3$ resulting from an applied non-alternating electric field. The $\alpha LiIO_3$ crystals (made at the Institute of Physics of the Academy) are hexagonal and the field was applied along the *c* axis. The integrated intensity of the (0002) diffraction peak, measured by neutron diffraction, is sharply enhanced by a field: the factor of enhancement can reach 6 times, and saturates at a few kV cm^{-1}. α-$LiIO_3$ is polar (non-centrosymmetric) and it is thus not unexpected that equal fields of opposite polarities have effects of different magnitude on the diffracted intensity.

The applied field enhances the width of the diffracted peak as well as its height. a.c. fields also have an effect though this drops as the frequency is raised and disappears above $\sim 10^3$ Hz. The effect is anisotropic and (100) and (010) reflections are not influenced by a field, whatever its direction. Curiously, X-ray diffraction is very little enhanced!

Systematic experiments were done on relaxation of the diffraction enhancement at various temperatures in the range 8 - 71 °C; relaxation of the whole integrated intensity and of the height of different parts of the diffraction peak were separately studied. A particularly intriguing series of experiments involved heating a crystal from ~100 K with a field switched on and monitoring the diffracted intensity continuously. The enhancement effect does not show up till the temperature passes 200 K, and above this same temperature an increasing ionic current flows through the crystal.

This paper is accompanied by a second, from the Academy's Institute of Physics (Gu Benyean, Xu Zhengyi, Zhao Shifu and Zhang Andong, *Scientia Sinica* **22** (9), 1010; 1079). Here a d.c. field applied to α-$LiIO_3$ crystals is found to enhance the diffraction of light. This fact had been previously reported, and the effect depends on field polarity, field strength and temperature in much the same way as does neutron diffraction. The present paper works out the mathematical implications of the hypothesis that the d.c. field drives mobile impurity ions along the *c* axis until they come to rest along a series of layer-like defects (stacking faults?) lying parallel to the six pyramidal planes of the form {101}. The hypothesis is confirmed both by comparing the anisotropic diffraction patterns recorded in the presence of a field with calculated patterns, and by micrographs of a slab cut in such an orientation as to show a single family of defects edge-on.

The defect-piling hypothesis can presumably explain the neutron diffraction anomaly, though it is not altogether clear why that effect is restricted to the (0002) reflections, in view of the fact that the defects are not perpendicular to the *c* axis.

The literature cited in both papers indicates that the two laboratories have been systematically studying α-$LiIO_3$, at least since 1972. The initial motive may have been, at least in part, interest in the applications of this crystal in non-linear optical devices (see for example Sailor *Phys. Stat. Sol.* (*a*) **4**, K173; 1971), but the near success in confirming the origin of the various anomalies deserves attention from the various groups elsewhere studying ionic conductors.

Several of these conductors in fact contain lithium, and intensive research on several such crystals has been done in recent years, especially by a team at the Max-Planck-Institut für Festkörperforschung in Stuttgart. Some species show uniaxial preferred ionic conductivity, like α-$LiIO_3$: thus ß-eucryptite, $LiAlSiO_4$, has a hexagonal quartz-like structure with lithium ions arranged in channels parallel to the *c* axis, and conductivity $\parallel c$ is about 10^3 times higher than $\perp c$ (v. Alpen, Schulz & Talat *Solid State Comm.* **23**, 911; 1977; *Electrochim. Acta* **22**, 805; 1977). It would be most interesting to test whether α-eucryptite responds anomalously to d.c. fields in a way similar to α-$LiIO_3$, another uniaxial conductor.

Another Li-bearing ionic conductor, Li_3N, which has a layer structure of Li_2N and pure Li layers, has been extensively grown and investigated in Stuttgart, and a detailed survey of its properties has been published (Rabenau *Festkörperprobleme* **18**, 77; 1978). X-ray structural studies of quite remarkable precision (Schulz & Schwarz *Acta Cryst.* **A34**, 999; 1978; Schulz & Thiemann *ibid,* in the press) have shown that at room temperature the Li_2N layers have about 1% of Li^+ vacancies whereas the interleaving pure Li^+ layers are fully occupied. At 400 °C, the vacancy concentration in the Li_2N layers goes up to 4%. On this basis, the considerably higher ionic conductivity in the plane of the layers compared with that at right angles can be interpreted. This crystal species, therefore, has two-dimensional rather than one-dimensional conductivity, and if Li_3N shows any behaviour akin to α-$LiIO_3$, it may well obey quite different crystallographic laws.

The Stuttgart experience suggests that the best way to understand anomalous behaviour in ionic conductors is to combine a number of quite distinct experimental techniques focused on the same crystal species, preferably including structural analysis at a very high level of accuracy. This seems also to be the strategy that the Chinese are following in their study of α-$LiIO_3$.

Yang's interesting experiments on frozen impurity migration at low temperatures put one in mind of the little-known technique called Ionic Thermo Currents (ITC). This method, formally

©1979 Macmillan Journals Ltd

analogous to thermoluminescence analysis, involves cooling an ionic crystal in a field, switching off the field and then reheating the crystal connected to an ultra-sensitive electrometer which detects the microcurrent resulting from the randomisation of the aligned vacancy-impurity electric dipoles (Bucci & Fieschi *Phys. Rev. Lett.* **12**, 16; 1964; Strutt, Weightman & Lilley *J. Phys. E. Sci. Instr.* **9**, 683; 1976). This technique could perhaps be applied with advantage to α-$LiIO_3$, to monitor the microcurrents resulting from the randomisation of segregated ionic impurities.

It would be fascinating to know why X-ray diffraction intensities from α-$LiIO_3$ are affected by electric fields so much less strongly than are neutron diffraction intensities. Perhaps the active impurities will need to be identified and their atomic scattering factors for X rays and neutrons identified, before sense can be made of this anomaly within an anomaly. □

Standards for microwave radiation

from R. P. Blackwell

THERE has been growing concern in recent years over the possible biological consequences of exposure to microwave and radio frequency radiation, partly stimulated by the thousand-fold difference between the maximum permissible exposure standards current in Western and Eastern Europe. The much stricter Eastern standards have raised questions of safety in the West, but a realistic appraisal of the basis for this difference is hard to achieve.

Microwaves and radio frequency radiation are absorbed to a greater or lesser extent by biological materials, the energy appearing as heat; the predominant mechanism being dipole relaxation of water molecules. The photon energies of this radiation lie in the range 10^{-3} to 10^{-7} eV; orders of magnitude below the activation energies of molecular interactions (Cleary, *Health Phys.* **25**, 387; 1973). The generally accepted view is that the biological changes which are observed, such as cataract formation in the eye, are a result of heat production, although the view that non-thermal effects are important at low levels of exposure is held by some, particularly in Eastern Europe.

The Western standard of 10 mW cm^{-2}, which is considered to be the maximum safe exposure, was derived from thermal considerations. Because the body effectively deals with the transport of quantities of heat greatly in excess of the basal metabolic rate of 1 W kg^{-1}, whole body exposure at a power density which results in the dissipation of about 1 W kg^{-1} of heat is considered to be safe. The Soviet exposure standard seems to be the result of a different philosophy; their industrial safety standards often represent an ideal rather than a practical limit. They assume that any detectable biological change constitutes a hazard and consequently their exposure standard of 10 μW cm^{-2} was reached by adding safety factors to a power density at which no change has been observed.

Many Soviet papers report biological effects at power densities which do not seem capable of producing any thermal change, and are therefore often ascribed to 'athermal' effects. An appraisal of much of this research is difficult. Many reports which are quoted in reviews are not available in translation; most of those which have been translated are difficult to follow. Of the reviews available, that by Baranski and Czerski (*Biological Effects of Microwaves*, Dowden, Hutchinson & Ross, 1973) is among the most recent and comprehensive. Many of the reports of experiments performed by Soviet workers have been criticised, particularly in terms of dosimetry and experimental detail. For example many of the apparent effects on the nervous system detected by electroencephalography (summarised by Baranski and Czerski) need careful interpretation. The presence of recording electrodes during irradiation and simultaneous recording makes it impossible to rule out artefacts due to thermal and electrical stimulation by the electrodes themselves.

A large proportion of reports from Eastern Europe concern behavioural, electrophysiological and strongly subjective changes of a generalised nature, which are notoriously difficult to quantify. Fatigue, memory loss and loss of concentration have been reported. Such reports include, for example, surveys of the health of people exposed to low levels of microwave radiation in the course of their work. The body of evidence produced in the West is not in accord with many of those findings.

A recent publication of the National Research Council of Canada (*The Biological Effects of Radiofrequency and Microwave Radiation*, Assenheim *et al.*, NRCC 16448; 1979) provides an objective, well referenced synthesis of the important topics in this field. What is particularly useful is the attention paid to explaining the relevant backgrounds in physics and biology, and the philosophy behind the setting of exposure standards. Research in this field is complicated by the experimental problems of exposure and dose measurement. The interaction of electromagnetic radiation and biological tissues depends on several variables, including the wavelength of the radiation and the size and electrical properties of the tissues. Diffraction and reflection may occur at tissue interfaces, which may lead to focusing and resonance, with the consequent uneven distribution of heat, and formation of 'hot spots'. Assenheim *et al.* provide a comprehensive survey of the important topics in this area, dealing with both the prediction of absorption patterns and the techniques for temperature measurement required.

There is now sufficient material available, for example the *R. F. Dosimetry Handbook* of Durney *et al.* (Report SAM-TR-78-22, USAF School of Aerospace Medicine, Texas), to enable reasonable estimates to be made of the power distribution in a given situation. Thus it is now possible to extrapolate experimental data on biological effects to man, and to predict with a reasonable degree of accuracy the pattern of power deposition in man in most exposure situations, and the resultant biological effects, if any. Such information is necessary for the design and implementation of realistic, practical safety standards.

Many questions remain unanswered Perhaps one of the most interesting is posed by the work of Bawin *et al.* (*Ann. N. Y. Acad. Sci.* **247**, 74; 1975). They report that changes in the calcium ion efflux of chick and cat brain tissue *in vitro* can be modified by exposure to amplitude modulated VHF fields of 1 mW cm^{-2}. Unmodulated fields do not produce an effect; however electrostatic fields alternating at the modulation frequency (between about 6 and 30 Hz) do. These exposure values are somewhat lower than might be expected. This could have implications for effects on the central nervous system, if a similar process occurs *in vivo*.

There remain many problems associated with experimental work, particularly in terms of physiological measurement in a microwave field. Such measurements rely on transducers which normally contain some metallic components, and these may distort the field and lead to unpredictable power deposition patterns. It is possible that some of the confusion over low level effects is a result of this. For example, a metal coaxial recording electrode, implanted in cat cortex, can cause a complete shift in the pattern of power absorption, and an increase of two orders of magnitude in power deposition near the electrode tip.

Although the controversy over thermal versus athermal effects has not been completely resolved, it has had the effect of stimulating a re-appraisal of exposure standards throughout the Western world. One major development which any revised standard must take into account is the resonance effects which occur in man in the low VHF region. It is likely that more attention will also be paid to considering the amount of power that temperature-sensitive organs, or those with a poor blood supply — for example the lens of the eye and the testis — can safely dissipate. □

Do nuclei have a neutron skin?

from John Edgington

EXACTLY 50 years ago the systematics of alpha-decay led Rutherford to the conclusion that the radius of the uranium nucleus must be less than 10 fm (10^{-14} m). An explanation for this incredibly small value, and an understanding of how and why it varied between nuclides, was a prime objective of the liquid-drop model. This viewed the nucleus as a close packed, incompressible array of neutrons and protons; the observed constancy of the binding energy per nucleon was seen as a consequence of the short range of the nuclear force and the resultant bonding between nearest neighbours only. The effect of this 'saturation' of bonds is that the nuclear radius increases as the cube root of the nucleon number, in agreement with earlier deductions from alpha-particle scattering. The more recent, and very extensive, measurements of electron scattering distributions have added flesh to this skeleton, and the distribution of electric charge within nuclei is now known quite accurately.

The distribution so revealed is remarkably model-independent. It is characterised by an almost constant central density, a rapid decline within one or two fm to a low value and an exponential decay thereafter. These features can be reproduced by any of a wide variety of shell models which, with their assumption of quasi-independent nucleon motion within some effective potential, have replaced the liquid drop model in structure calculations. The charge distributions themselves are thus too blunt instruments for the task of discriminating between the various models.

What then of the matter distribution, that is, the joint density of protons and neutrons? There is evidence, at least to first order in the electromagnetic corrections, that the strong forces between nucleons are charge independent, that is, indifferent to whether the particle is a proton or a neutron. One therefore expects protons and neutrons to have similar, if not identical, density distributions in nuclei. In terms of the single parameter which often summarises experimental results, their rms radii, $\langle r_p^2\rangle^{\frac{1}{2}}$ and $\langle r_n^2\rangle^{\frac{1}{2}}$ would be equal. Indeed, in a study of isobaric analogue states, Nolen and Schiffer showed 10 years ago that this equality holds quite well for a variety of medium to heavy nuclei (*A. Rev. Nuclear Sci.* **19**, 471; 1969).

Many subtle effects, however, conspire to produce this near-equality. For example, the destabilising effect of Coulomb repulsion causes all but a few light nuclei to contain fewer protons than neutrons; despite this, the excess neutrons do not contribute very much to the total strength of the pairwise n–n bonds. This follows from Pauli's exclusion principle which limits the interactions between identical particles. The total p–n bonding strength is not so limited. The presence of excess neutrons thus has little effect on the effective potential in which the neutrons move, although strengthening that experienced by the protons. Thus the protons are more tightly bound, and confined to a smaller radius. Conversely the Coulomb repulsion acting on the outer protons will tend to expel their wave functions and thus increase the protons' rms radius. The interplay of these competing effects, and others of lesser magnitude, is imperfectly understood, and in addition there is conflicting experimental evidence for a neutron-rich region, or 'skin', at large radii.

For example, isotope shifts in atomic spectra indicate only small differences, of varying sign, between the charge radii whereas similar shifts in the spectra of muonic atoms correspond to somewhat larger differences, the charge radius generally becoming greater as neutrons are added in heavier isotopes. The whole problem has been addressed afresh by the meson factories with their intense beams of muons and pions. For example, isotope shifts in pionic atoms have been measured at LAMPF, Los Alamos, and a sensitivity to radii changes of 0.02 fm is claimed. Unfortunately, in many of these experiments, the extraction of radii differences from the raw data is an opaque and model-dependent process, and theoretical uncertainties swamp the experimental ones.

A new method of measuring neutron radii has been reported from TRIUMF, Vancouver, which, it is claimed, is not only very sensitive to different values of $\langle r_n^2\rangle^{\frac{1}{2}}$ but is also virtually model-independent. In contrast to other radius determinations, this measures the neutron radius directly, not a difference between the charge and matter radii. R.R. Johnson *et al.* (*Phys. Rev. Lett.* **43**, 844; 1979) have scattered low energy π^- beams from pairs of isotopes, and measured the ratio of their differential cross sections. This ratio, it turns out, is sensitive to differences between the neutron radii of the two isotopes, almost regardless of what proton radius is assumed. The basic cause of this sensitivity is that the amplitude for π^-–n scattering is much larger than that for π^-–p at low energies, but the measurements at TRIUMF have, as a bonus, an additional enhancement arising as follows. The difference between π–n and π–p scattering arises from an interference between s and p-wave π–nucleon amplitudes, which has its maximum effect at extreme forward and backward scattering angles. Now in π-nucleus scattering a Coulomb-nuclear interference term is of course present, and Johnson *et al.* had already shown (*Phys. Lett.* **75B**, 560; 1978) that at very forward angles this interference is constructive for π^--scattering, but destructive for π^+. Thus any variations in neutron density distributions should show up with enhanced sensitivity in π^--scattering compared with π^+. Indeed a recent measurement of π^+–^{6,7}Li scattering at 50 MeV (*Phys. Rev.* **C18**, 2316; 1978) saw no such effects.

Johnson *et al.* scattered π^- beams of 30 and 50 MeV from ^{12,13}C and ^{16,18}O, and their results indicate that the heavier isotope has the greater neutron radius, by 0.04 fm and 0.21 fm in the two cases. Quoted errors of ±0.03 fm in each case include, for once, an estimate of the sensitivity to variations between the different models used in the calculations. The relatively small change between carbon isotopes is of particular interest.

Some other techniques for measuring neutron radii, such as studying the absorption of K^- mesons, find a gross neutron excess in the nuclear surface. In comparing the various methods one must bear in mind that the radial distances being sampled are very different; kaonic and antiprotonic atoms are probes of the farthest reaches of the nuclear surface, whereas the experiment of Johnson *et al.* is investigating the region of rapidly rising density close to the rms radius. It is to just this region that the various nuclear models principally address themselves, and this new evidence, the first measurement of $\langle r_n^2\rangle^{\frac{1}{2}}$ independently of $\langle r_p^2\rangle^{\frac{1}{2}}$, has an importance that is more than circumstantial. □

John Edgington is in the Department of Physics, Queen Mary College, London.

Next in succession

from Peter D. Moore

MUCH current research on the process of succession in forests concentrates on the probability of a given species being replaced by an alternative species within a number of generations. This can lead to the development of a model describing a replacement series (see for example, Horn in *Theoretical Ecology* (ed. R.M. May) 187 Blackwell, Oxford, 1976). Certain non-linearities are quite frequently encountered, such as the persistence of populations from early in the sequence as a result of regular destruction of the forest, either by natural or human agencies. There are occasions on record, however, where such persistence of what one would normally consider an early successional tree species, can occur even in the absence of regular forest disturbance. The tree may even form the dominant component of an

Peter D. Moore is a Senior Lecturer in the Department of Plant Sciences, King's College, London.

©1979 Macmillan Journals Ltd

apparently stable community.

Perhaps the most familiar example in Europe is the birch forest of the north-western extremities of the continent, and which is best developed in northern Norway and Finland. This forest (described floristically by Hamet-Ahti, (*Ann. Bot. Soc. Vanamo* **34** (4); 1963) is an open scrub of birch trees 2–12 m in height, with no other tree species present, except scattered pine (*Pinus sylvestris*) in the more southern regions. Taxonomically there is some degree of confusion since at least two subspecies of *Betula pubescens* (ssp. *pubescens* and ssp. *tortuosa, sensu Flora Europaea* (ed. T.G. Tutin *et al.*) Cambridge, 1974) are present, but these are trees which would be replaced by others at lower latitudes.

It is of interest to note that arctic and subarctic forests dominated by birch also occur in certain subalpine situations, for example in the Carpathians, and in parts of the Eurasian steppes, but that they tend to be mainly associated with oceanic areas, such as Kamchatka in Pacific north-east Asia. In north America, the birches are accompanied by coniferous trees (such as *Abies, Picea* and *Larix*) and form pure stands only under disturbed conditions. The birch forests of northern Fennoscandia, by contrast, seem to have been stable over a considerable period. Fossil pollen data from these areas show an invasion of pine into the region between 8000 and 6000 years ago (Birks & Saarnisto *Boreas* **4**, 77; 1975) but the pine pollen levels attained by 4000 years ago are no higher than those of the present day (Hicks *New Phytol.* **78**, 715; 1977; Prentice *Boreas* **7**, 131; 1977). It seems therefore that the northern birchwoods have not developed in response to any human disturbance. The same applies to the birch woods of the northern part of the Isle of Skye in Scotland (Vasari & Vasari *Acta — Bot. Fenn.* **80**, 1; 1968).

As noted by Walter (*Vegetation of the Earth*, Springer-Verlag, New York, 1973) the coniferous trees of lower latitudes may be held back by a failure in seed set or by desiccation as a consequence of frost and wind. Such species as *Pinus sylvestris* extend into the birch forest zone along the sheltered valleys. Regeneration of birch, which is a light-demanding tree, probably depends on the death of adults, thus maintaining an open, light canopy forest.

Birch forests of this kind are not found in the southern hemisphere, although deciduous *Nothofagus* species which form woods in southern Chile may be considered an ecological equivalent (Godley *Proc. R. Soc. Lond* **B152**, 457; 1960). Recently an analogous vegetation type has been described from the Galapagos by Hamman (*Bot. J. Linn. Soc.* **78**, 67; 1979). Here an endemic woody composite, *Scalesia pedunculata* dominates the humid forests of Santa Cruz Island. The growth and population dynamics of this species have been investigated by means of permanent quadrats established in 1970 and recorded on three occasions since then. By this means the survival and growth characteristics of individual trees have been measured.

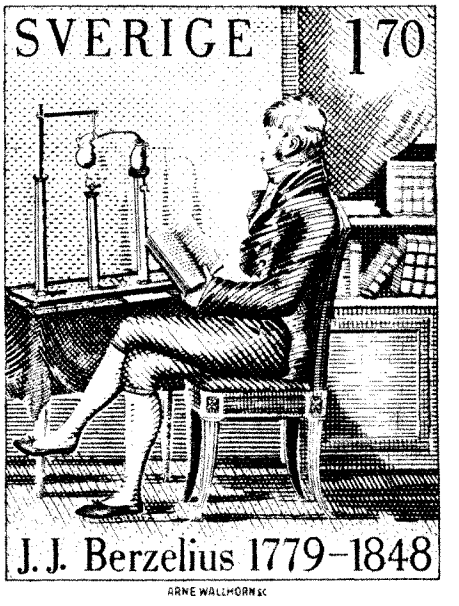
Mortality among *Scalesia* seedlings is high in the early years (only 40% survival after the first 2 years) and then decreases (2% survival after 7 years). Initial growth rates are very high, the trees reaching 7–8 m in 3–6 years. Height stabilises at about 10–12 m and girth increase becomes pronounced after about 5 years, coinciding with the onset of flowering. Few individuals survive beyond 10 years.

Many of these features such as short life span, rapid early height increase, and early flowering are characteristics normally associated with an early successional forest species. *Scalesia* persists and dominates the vegetation by means of a high seed production and a rapid population turnover. Although there is some disturbance of the forest by grazing animals, particularly giant tortoises, the *Scalesia* population does not seem to depend on this for survival. Vegetation zones on the Galapagos generally seem to be climatically determined (Hamman *Biotropica* **11**, 101; 1979) and the post-glacial climatic history of the Galapagos has been essentially stable as reflected by the vegetational history (Colinvaux & Schofield *J. Ecol.* **64**, 989; 1976). The *Scalesia* woodland should therefore be regarded as climax, in the sense that no further succession should be expected.

In both of the cases quoted, the Fennoscandian birchwoods and the Galapagos *Scalesia* forest, an over-riding biogeographical factor has restricted the invasion or success of those tree species which could be defined as late successional (or 'persistent multilayer' in the sense of Horn, *The Adaptive Geometry of Trees*, Princeton University Press; 1971). In the former case the restrictive factor is climate and in the latter it is geographical isolation. These simplified exceptions to the normal course of successional processes would repay more detailed investigation regarding regeneration and survivorship.

Inside the Earth

from David T. Rickard



JÖNS Jacob Berzelius was born 200 years ago in the village of Väversunda in Sweden, and was to become one of Sweden's greatest, but least appreciated, scientists. Linnaeus, who had died the year before, represented the culmination of descriptive science; Berzelius' birth ushered in the analytical age.

One of Berzelius' major scientific contributions was his chemical system of mineralogy. Previously, minerals had been classified on the basis of form and colour in the same way as Linnaeus had classified plants. Berzelius chemically analysed minerals and classified them according to their compositions.

This introduction of chemistry into geological science was remembered by the Swedish Royal Academy of Sciences in their choice of a theme for a Nobel Symposium to commemorate the Bicentenary of Berzelius' birth. The Academy invited twenty-five distinguished scientists to discuss the chemistry and geochemistry of solutions at high temperatures and pressures.*

This subject is very much in the spirit of Berzelius. It represents an area of endeavour which only the most careful theoretical and experimental chemistry can hope to penetrate. It also reflects the conditions under which most of our planet exists.

The zone on the Earth where temperatures around 25 °C and pressures of about 1 atmosphere, or bar, predominate is

represented by a thin surface sheath about 12 km thick. Because we happen to inhabit this sheath our knowledge of inorganic and physical chemistry under these conditions is relatively good. However, the remaining 6,371 km down to the centre of the Earth are characterised by considerably higher pressures and temperatures. The PT (pressure-temperature) conditions in the first 250 km are illustrated in Fig. 1. It is in this high PT zone that the bulk of the Earth's rocks and ores are formed and where the major material transfer processes occur.

In contrast to 25 °C and 1 bar, our knowledge of inorganic and physical chemistry in the rest of the PT spectrum is

*The 48th Nobel Symposium was held at Bofors, Karlskoga, Sweden on 17–21 September, 1979. The Symposium proceedings are expected to be published in 1980. The symposium was organised by David T. Rickard and F.E. Wickman of the Geological Institute, Stockholm.

extremely limited. The symposium was therefore not a summary of achievements in a well-established and well-researched field. Rather it was a delineation of our areas of ignorance and a discussion of various methods of tackling the problems.

Take the best known fluid, water, as an example. S.D. Hamann (CSIRO, Melbourne) noted that our present knowledge of the PVT (pressure-volume-temperature) behaviour of water is known quite accurately up to 100 °C and 1 kbar, less accurately to 1,000 °C and 10 kbar, and progressively more uncertainly above these limits. The highest temperature reached by conventional techniques is 1,200 °C (at 4 kbar) and the highest pressure is 34 kbar (at 175 °C). Shock-wave PVT data, which are less reliable, have been obtained up to 400 kbar and 3,100 °C but are very uncertain above 30 kbar. The actual nature of water under these extended conditions is not well known. E.U. Franck (Karlsruhe University) suggested that treating it as $H_3O.OH$ was a good approximation; that is, as hydronium hydroxide, very similar to fused sodium hydroxide.

The data are even more limited for systems which contain other components in addition to water. The best-known system, H_2O-NaCl, has only been extended this year to 400 °C, 4 kbar and 25 weight percent salt. The few other systems that have been studied are known over a much more limited range of conditions.

Apart from the mechanical problem of confining solutions at high pressures and temperatures within a limited space, the solutions of interest are often highly corrosive. H.L. Barnes (Pennsylvania State University) pointed out that a major problem concerning geochemical experimentation was the relatively long reaction times often needed to reach equilibrium. Materials have to withstand temperatures of several hundred degrees and pressures in the kilobar range for up to one month. It is not without reason that these experimental systems are called bombs.

Materials in themselves are not the only problems facing the experimentalists at high temperatures and pressures. Experimental apparatus must be constructed so that measurements can actually be made. That is, it is not only necessary to confine the reactants but also to have access to them. Particular interest was engendered by spectroscopic methods of measurements of the chemical properties of solutions up to 5 kbar and 500 °C by M. Buback (Karlsruhe University). These techniques involve constructing a bomb with a window of a transparent, chemically resistant material, such as sapphire. Spectra of the reactant solution may be examined. Infrared adsorption spectra are commonly observed, but Buback also described the advantages and potential of laser Raman spectroscopy for these types of systems.

David T. Rickard is at the Geological Institute, Stockholm University.

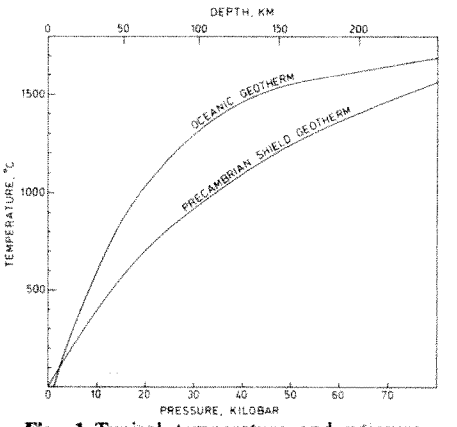


Fig. 1 Typical temperature and pressure variations with depth (geotherms) in the Earth for an oceanic and ancient Precambrian situation (from Wickman & Rickard, Chemistry and geochemistry of solutions at high temperature and pressure: an introduction to the symposium).

Even if experiments could be performed simply and quickly, the variety of solution compositions occurring in nature is so great that centuries of labour would be required to complete the work. Furthermore, it is not, at least at present, possible to examine experimentally the chemical properties of many systems under the extreme conditions that occur in the Earth. It is obvious that a major goal of high PT research is the construction of reliable methods for the theoretical prediction of the chemistry of solutions under extended conditions.

H.C. Helgeson and K.S. Pitzer, both from the University of California, Berkeley, presented alternative approaches to this problem. Helgeson discussed the 'ion association' approach, which provides specifically for ions combining together as a function of pressure and temperature. He argued that we know that solutions at high temperatures and low pressures contain a large proportion of combined or associated ions and that therefore the ion association model is more realistic.

The 'virial coefficient' approach used by Pitzer treats the solutions as though they contained only separate ions, and divergences from this ideal behaviour are accounted for in the coefficients of a single equation. Pitzer argued that the concentration of associated ions is not always unambiguously determinable and that there is essentially a continuous distribution of populations of ions at varying distances from one another.

However, these different approaches should not be regarded as competitive, but rather as complementary. For example, H. Eugster (Johns Hopkins University) showed, in a contribution to the discussion of Pitzer's paper, that use of the virial coefficient approach had solved for the first time a long-standing problem in physical chemistry — the theoretical prediction of salt precipitation during the evaporation of seawater. No other approach had resolved this problem which has been known since van't Hoff's work at the beginning of this century. In comparison, application of the ion association model has already given much information about the nature of geological processes under extreme physical conditions — information which is not available experimentally at present nor is likely to be for some time to come.

The application of theoretical and experimental high PT solution chemistry to geological and technological problems was a recurrent theme of the symposium. On the geological side delegates discussed the formation of igneous rocks, the origin of ore deposits and the response of rocks to solutions at high temperatures and pressures. Geothermal energy was a topic of some considerable interest and various aspects were reviewed from source to power station chemistry. T. Seward (DSIR, Petone, New Zealand) combined several themes in his poignant tale of drilling for hot water and finding a source that deposited gold in large quantities. His chemical studies were able to show how the gold was transported in these hot solutions, combined with sulphur-containing ions.

One of the prime purposes of the 48th Nobel Symposium was to initiate a dialogue between chemists and geologists working in the same field, often unaware of each other's contributions. In this the meeting succeeded and several firm suggestions were made for future cooperation and for future meetings on this theme. Berzelius would have been happy! □

Erratum

In the article 'Dissecting the red cell membrane skeleton' (*News and Views* **281**, 426; 1979) the sentence beginning on page 427, third column, four lines from the bottom, should read ". . This suggests that the lower *molecular weight forms are degradation* products of the parent band 2.1 molecule." On page 429, first column, the two lines following line 13 were inadvertently omitted. The complete sentence should read "This is probably the end of the molecule where actin and band 4.1 bind since interactions between acting and crude spectrin preparations are phosphorylation *sensitive (Pinder et al. Nature 270, 752; 1977). Unfortunately, so far at least, it has not been possible to recapture the phosphorylation* dependence in more purified systems (Brenner & Korn *op. cit.;* Cohen & Branton *op. cit.*). On page 429, line 9 of the second column is incorrect: the complete sentence should read "This implies that spectrin has evolutionarily critical functions and, since its only known functions relate to the *membrane skeleton, that the skeleton is an* evolutionarily critical structure".

Interferons and cellular regulation

from Mike Clemens

INTERFERON is best-known for its antiviral activity, but the principal message of a recent meeting on 'The Regulatory Effects of Interferon'* was that the multiplicity of other biological effects attributed to it are holding up now that pure interferons from several sources are available and have been tested.

Interferon of very high specific biological activity has been prepared after induction of its synthesis in either human fibroblasts (J. Heine & A. Billiau, University of Leuven; E. Knight, E.I. du Pont de Nemours & Co.) human lymphoblastoid cells (K. Zoon, National Institutes of Health, Bethesda or mouse Ehrlich ascites tumour cells (P. Lengyel, Yale University). Convincing evidence for homogeneity of the purified material was provided by amino acid sequencing studies conducted by M.W. Hunkapiller (California Institute of Technology). He described several technical improvements which have allowed identification of the first 20 N-terminal amino acids from less than 1 μg of interferons from each of the above sources. Interestingly, the human lymphoblastoid and fibroblast interferons show no sequence homology in this region (at either the protein or possible DNA codon level), whereas one species of mouse interferon does have some sequence similarities with human fibroblast interferon. Evidence was presented by D.C. Burke (University of Warwick) for the presence of the gene for human fibroblast interferon on the short arm of chromosome 9, rather than on chromosome 5 as has been previously suggested. As yet, however, no information is available concerning the structure of the interferon gene and reports on progress towards the possible cloning of the gene were conspicuous by their absence.

A great deal of information was presented on the effects of the various interferons on a wide range of cell types. More knowledge has been accumulated about type II or 'immune' interferon, produced principally by T lymphocytes in response to mitogenic or antigenic stimulation. Both S. Baron (University of Texas, Galveston) and E. Falcoff (Institut Curie, Paris) reported that it is antigenically distinct from virus-induced (type I) interferons. Many of its biological effects, including the induction of new enzyme activities in mouse L cells, are similar to those of type I interferon, but its ability to inhibit the growth of tumour cells is relatively higher.

The inhibitory effects of interferon on cell multiplication are also of particular interest. A.A. Creasey (Stanford University) suggested that, in some human melanoma cell lines, interferon may prevent a metabolic event required for commitment to a new round of DNA synthesis. The nature of this event and the mechanism by which it is modulated by interferon remain unknown. However, the series of 2′5′-linked adenylate oligonucleotides, synthesised by an interferon-induced enzyme in several cell types, has been implicated in this regulatory system. Inhibition of thymidine incorporation into DNA by the 2′5′ oligo(A) series was reported in L cells (A.G. Hovanessian, Institut Pasteur, Paris), concanavalin A -stimulated lymphocytes (A. Kimchi, Weizmann Institute, Israel) and human lymphoblastoid cells (I.M. Kerr, National Institute for Medical Research). Whether these effects are consequences of an earlier inhibition of protein synthesis remains unclear. Techniques for *in vitro* screening of the responsiveness of human ovarian carcinoma cells from patients for possible growth inhibitory effects of interferon were described by L.B. Epstein (University of California, San Francisco).

It is now clear that the interferons also have a wide range of effects on cells of the immune system. Those effects which may be particularly important for the anti-tumour actions of interferons include activation of natural killer cells (B.R. Bloom, Albert Einstein College, New York; G. Trinchieri, Wistar Institute, Philadelphia; R.B. Herberman, National Institutes of Health) and macrophages (S.I. Hamburg, New York University; M.A. Chirigos, National Cancer Institute). Tumour cells stimulate normal lymphocytes to synthesise interferon *in vitro*, and this has obvious implications for the control of tumour growth in the intact animal. A comforting conclusion which can be drawn from much of this recent work is that the various biological effects of earlier crude interferon preparations can also be elicited using the material purified to homogeneity (J. De Maeyer-Guignard, Institut Curie, Orsay; S. Pestka, Roche Institute, Nutley). Interferon has thus acquired a respectability which should stimulate further detailed molecular and cell biological analysis of its modes of action.

The recognition that interferon has a wide spectrum of hormone-like actions has also led to the realisation that it may exert harmful effects under certain circumstances. These may include some of the symptoms associated with certain autoimmune diseases, since a high proportion of patients with systemic lupus erythematosus or rheumatoid arthritis have elevated serum interferon levels (J.J. Hooks, National Institutes of Health). I. Gresser (IRSC, Villejuif) described the deleterious consequences of giving large amounts of interferon to new-born mice and summarised his view of these effects: "Interferon is a good thing. Too much of a good thing is sometimes a bad thing".

There have also been significant developments in understanding the anti-viral effects of interferon. There is now a considerable amount of information on the involvement of 2′5′ oligo(A) in the regulation of protein synthesis in interferon-treated cells. The interferon-induced enzyme responsible for synthesis of this series of oligonucleotides in the presence of double-stranded RNA (dsRNA) has been purified to homogeneity in the laboratory of P. Lengyel (Yale University). This group has also extensively purified both the endonuclease which is activated by 2′5′ oligo(A) and the protein kinase involved in inhibition of polypeptide chain initiation after interferon treatment. B.R.G. Williams and I.M. Kerr (National Institute for Medical Research, London) presented evidence that intact interferon-treated, EMC virus-infected cells synthesise 2′5′ oligo(A) and that the oligonucleotide will prevent virus replication when added to permeabilised infected cells. Thus the model which implicated 2′5′ oligo(A) in the antiviral actions of interferon, which was originally derived from studies with cell-free systems, has been confirmed in these whole cell experiments. L.A. Ball (University of Wisconsin), who has also extensively purified 2′5′ oligo(A) synthetase from interferon-treated chick cells, showed that the enzyme elongates the oligonucleotides in the 2′5′ direction non-processively, and will also add AMP residues to other small molecules such as NAD and ADP-ribose. C. Baglioni (SUNY, Albany, New York) described the structural requirements for dsRNA for activation of both the 2′5′ oligo(A) synthetase and the protein kinase. A minimum of 60 base-pairs of dsRNA is necessary and mismatching of bases lowers the efficiency of activation. It is not yet clear whether 2′5′ oligo(A) can inhibit viral protein synthesis selectively *in vivo*, for example by being synthesised and acting only in the vicinity of dsRNA-containing viral replication complexes, as suggested by Baglioni. In the case of Mengo virus-infected L cells host cell protein synthesis is also shut off, but later recovers in the interferon-treated cells (R. Falcoff, Institut Curie, Paris), perhaps because the 2′5′ oligo(A) is subsequently degraded by a cellular enzyme.

A more subtle way in which interferon inhibits the replication of tumour viruses was described by both P.M. Pitha (Johns Hopkins University, Baltimore) and R.M. Friedman (National Institutes of Health). Several steps in the maturation of these viruses are impaired in interferon-treated

*Held by the New York Academy of Sciences on 23-26 October.

cells and the particles which are released show reduced infectivity. The latter phenomenon may be due to defective glycosylation of a virion protein. Interestingly, Friedman also reported that vesicular stomatitis virus produced by interferon-treated L cells is non-infectious, is deficient in G (glycoprotein) and M (matrix) protein content and appears abnormal in the electron microscope. □

Multiplying growth factors

from Denis Monard

MORE knowledge about the events regulating the initiation of DNA synthesis will certainly shed more light on the phenomena regulating the differentiation of animal cells which remains one of the main challenges of modern biology. Such basic knowledge should also contribute to understanding better how and why a tumour cell differs from a normal cell.

Opening a recent discussion* on this topic R.W. Holley (Salk Institute, San Diego) re-emphasised that all growth is regulated by a multiplicity of complex extra and intracellular events. The discovery of proteins which can trigger cell growth, such as migration factor, epidermal growth factor (EGF), fibroblast growth factor (FGF) and platelet growth factor has revealed that extracellular macromolecules have an important role as regulators of the cell cycle, and the number of such factors known is steadily increasing.

Platelets have provided several new growth factors. The stimulation of cell growth by three polypeptides released by platelets has been reported (D. Paul, Temple University, Philadelphia). All three polypeptides cross-react immunologically and chromatograph under the same conditions in heparin Sepharose. They differ, however, in their molecular weight. One of them, a basic protein, is displaced by β-thyroglobulin or EGF. But, in contrast to growth stimulation by EGF, its biological activity is impaired by heparin. Another growth factor has been obtained from platelet extracts (W.J. Pledger, University of North Carolina, Chapel Hill) but analogies with the other growth factors released by platelets are premature.

Virus-transformed BHK fibroblasts also produce and release two proteins which stimulate the migration and DNA synthesis of normal fibroblasts (P. Leuthard, Friedrich Miescher-Institut, Basel).

A cell line with an especially large number of EGF receptors has been used to purify a sarcoma growth factor (SGF). After being fixed with formalin, these cells still bind the growth factor released by cells transformed by mouse sarcoma virus. The growth promoting activity was then eluted from the fixed monolayer by a *p*H change. A homogeneous preparation of SGF, biochemically and immunologically distinct from EGF, could be obtained after only two elution cycles. Interestingly, SGF and EGF differ in their biological activity. In contrast to EGF, SGF stimulates the normal fibroblasts to assume a 'transformed' morphology and to form colonies in semi-solid medium, a characteristic attributed only to tumour cells (G.J. Todaro, NIH, Bethesda). This elegant modification of affinity chromatography with fixed cells should certainly allow the discovery of other proteins able to trigger the initiation of DNA synthesis.

It is possible at this stage to distinguish two classes of cell growth promoting proteins, that is, those released by normal cells which could be considered as the normal growth regulators and those released by tumour cells or by virus-transformed cells. More detailed biochemical and immunological analyses are now required to bring some order into the classification of such macromolecular growth factors.

In addition, greater knowledge of their mode of action would allow a better classification. However, the following facts reported at this round table discussion illustrate the complexity of such studies.

For example, growth-stimulating molecules such as prostaglandin $F_{2\alpha}$ and FGF can act synergistically in 3T3 cells (V. Richmond, Friedrich Miescher-Institute, Basel).

Cells also release high and low molecular weight factors which stop the cell cycle and, therefore might be able to antagonise or alter the biological effects of the growth factors. For example, a macromolecule has been isolated which reportedly arrests cells in G_1, an effect also produced by ACTH, thyrotropin or interferon (Holley).

Culture conditions also indirectly influence the sensitivity of cells to growth factors. For example, the number of receptors for EGF drops with increasing cell density and the binding kinetics are also affected (Holley). Moreover, viral transformation of cells can lead to a loss of EGF receptors (Todaro). It is also important to remember that cell growth regulation *in vitro* can be influenced by physical parameters which are not exactly similar to those predominant *in vivo*. For instance, the type of collagen used to coat Petri dishes can modify cell sensitivity to EGF and cell survival (W.R. Kidwell, NIH, Bethesda).

However, the macromolecular factors are apparently not solely responsible for the regulation of the initiation of DNA synthesis. Low molecular weight substances such as the classical hormones and nutrients (prostaglandin $F_{2\alpha}$, glucose, inorganic salts and so on) are also able to potentiate the effects of macromolecules or to elicit growth alone (Richmond; Holley). The field is now entering a phase in which one might consider as a working hypothesis, the existence of metabolic steps which are simultaneously triggered by all these different substances to initiate cell division. Nevertheless, it remains possible that the regulation of cell growth is due to a delicate balance between many chains of events which are not all metabolically linked. □

Denis Monard is at the Friedrich Miescher-Institut in Basel.

Tokamaks still to the fore

from R.J. Bickerton

AT the 9th European Physical Society Conference on Controlled Fusion and Plasma Physics* the tokamak continued to hold the centre of the stage. Tokamaks are toroidal discharges maintained to a satisfactory level of stability by the superposition of relatively strong toroidal fields. The system has many advantages — not least the simplicity and ease with which hot, well-confined plasmas can be obtained. It has however two serious disadvantages. Powerful additional heating is needed to get high temperatures and the ratio of plasma pressure to magnetic field pressure is usually very low. The heating requirement has been met in the past with outstanding success by injecting powerful beams of fast (~40 keV) neutral atoms. Record ion temperatures of the order 6 keV were achieved in this way last year with more than 2 MW of injected beam into the Princeton tokamak PLT. But the longer term prospects for this technique are dim because for reactor scale plasmas higher energy beams are needed, making it technically difficult, expensive and inefficient. Thus great attention was given at the meeting to the new results on radio-frequency heating. In one set of experiments a few hundred kilowatts of power at the frequency of ion cyclotron resonance were injected into the tokamaks TFR (Paris) and PLT. In both cases the ion temperature was increased by several hundred electron volts with an efficiency comparable to that of low energy neutral injection. In this frequency range (20-60 MHz) there is no technical problem in generating the power; the main difficulty is in coupling the power to the plasma. Heating of tokamak plasmas at other plasma resonance frequencies was also reported, the most notable being the use of

*Held in Oxford on 17-21 September, 1979.

©1979 Macmillan Journals Ltd

100-200 kW of power at the first harmonic of the electron cyclotron resonance (~85 GHz) to raise the electron temperature in the Soviet tokamak T-10. In this frequency range the generation of high powers is the major difficulty; coupling to the plasma is through relatively simple wave-guide launchers. A general feeling at Oxford was that plasma heating in tokamaks by the injection of electromagnetic waves is at last becoming competitive with neutral injection. With the rich possibilities arising from a variety of frequencies it is hoped that an efficient method can eventually be found to deposit megawatts of power into the plasma core.

A second potential disadvantage of the tokamak arises from the same strong toroidal field that gives it its stability and general robustness. The ratio of plasma pressure to magnetic field pressure (β) tends to be very low, typically less than 1%. To be near economic a reactor needs β averaged over the volume ($\bar{\beta}$) to be in excess of 5%. New results included β values of the order 2-3%, seen in the ISXB (Oak Ridge), T-11 (Moscow) and TOSCA (Culham) devices. These values are obtained in circular cross-section devices and there are theoretical grounds for hoping that the higher values needed will be obtainable in non-circular cross-section systems such as JET. It should be emphasised that all three of these high $\bar{\beta}$ experiments are in effect limited by the available input power. Thus we only know that the values of $\bar{\beta}$ at which instability leads to a decrease in confinement are greater than those seen so far. Apart from these advances in tokamak heating and $\bar{\beta}$ there were many other results reported — notably the operation of the large Soviet tokamak T-10 at low values of q(~1.6) without a decrease in the confinement properties.

First results were reported from the new ETA-BETA II reversed field pinch experiment at Padua. This is approximately a one-third scale version of ZETA with some additional control of the toroidal magnetic field. To the surprise of some, the main features of the so-called quiescent period in ZETA have now been reproduced in this smaller device. Fluctuations in dI/dt are markedly reduced following field reversal and the electron temperature rises during quiescence from ~40 eV to ~100 eV. It will now be possible to study this quiescence phase in detail with modern diagnostics and hence to assess the potential of the reversed field system.

Research on the mirror system of magnetic confinement is now concentrated on two versions. The first is one in which the initial field of the mirror is reversed by plasma currents to give a final configuration which is similar to a compact tokamak without toroidal field and which has closed field lines and is therefore not a mirror at all. This is being studied at the Lawrence Livermore Laboratory and so far all attempts to achieve field reversal by pumping up the plasma pressure have marginally failed. New experiments are planned in which a low temperature plasma with field reversal is first created by a plasma gun and then heated by intense neutral beams. The second version is the so-called tandem mirror in which a long straight solenoid has intensely heated minimum |B| mirrors at each end. This line is also being studied at Livermore as well as in Japan and Novosibirsk. The aim of the tandem mirror is to create an electrostatic potential at the ends of the solenoid in such a way as to confine the ions. A major difficulty with all these open-ended systems is the heat conduction along the field lines by the highly mobile electrons. First results from the Livermore tandem mirror TMX were presented at Oxford. These show encouraging evidence of electrostatic plugging and of effective electron heat confinement. Thus the electron temperature in an end mirror is ~160 eV while in the solenoid the ion temperature is low (<100 eV), the density ~10^{13} cm^{-3} and the end loss small.

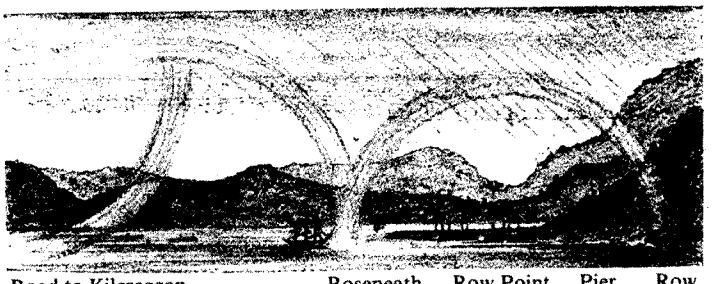
In the field of inertial confinement attention is now focused on ablative compression of complex pellets using as driver systems either lasers, electron, light ion or heavy ion beams. In the USA 10 kJ, 20 TW lasers at 1 and 10 μm wavelengths are now operating at Livermore and Los Alamos respectively. With the big Livermore laser (SHIVA) the D-T fuel has been compressed to ~160 times liquid density. These ablatively compressed cores are relatively cold and the next step will be to increase the implosion velocities through the use of higher power lasers on to larger targets. An interesting technique reported at the meeting was the use of radiochemical methods to deduce the density of the compressing shell. Transmutations are produced by the neutrons from the core and the subsequent radioactive decay is measured.

The choice of the best system is still open with lasers clearly ahead for research purposes but with embarrassingly low efficiencies for an ultimate reactor. All the particle drivers are more efficient but there are greater difficulties in transporting and focusing them to a target. If the energy gain from a single implosion can be made large enough then the efficiency of a CO_2 laser (1-5%) may be tolerable. Such high gains (~100) are theoretically possible from complex targets, but there is then the problem of making them cheaply.

For the first time in this series of conferences there was a report on the fusion programme in the People's Republic of China. Many were surprised by the size, breadth and sophistication of this work which includes mirror machines, laser compression and several tokamaks. The programme is gathering momentum after the setbacks of the Cultural Revolution. The presentation at Oxford was limited to a catalogue of devices but we can expect a serious contribution to fusion physics from China in the near future. □

R.J. Bickerton works on the Joint European Torus project at Culham, Abingdon, UK.

Erratum



During printing a line was inadvertently ommitted from the article 'Road to unification' (*News & Views* **282**, 131; 1979). The first sentence in column 3, page 132 should read "Experimentally, weak neutral currents were discovered *at CERN in 1973*[19] *and parity-violation in neutral currents of precisely the right size was discovered* in the remarkable experiment[20] at SLAC last year." Our apologies to CERN.

100 years ago

A curious rainbow

I send you a rough sketch of a curious rainbow group seen in Gareloch about 8.25 a.m. on October 20. I would have written sooner but I delayed till I had obtained sketches from several different sources. I only saw the junction of the two bows at C, that being the only part of Row Bay visible from my standpoint, but several observers saw the whole group as I have drawn it. The sea was quite glassy, so that the inverted rainbow A must have been formed by the sun's rays reflected from the water. The wind was just beginning to rise and some scudding showers were passing up from the Firth of Clyde from the south-west, but the bay was quite calm.

Road to Kilcreggan. A Roseneath. B Row Point. C Pier. D Row.

The bow D was perfectly full and bright, while B died away at its highest point. I can only imagine that B was formed by light reflected by some bright cloud, but I did not observe any bright enough. The view is nearly north-west.

Brownian motions of flexible polymer chains

P. G. de Gennes
Collège de France, 75231 Paris Cedex 05, France

The dynamics of flexible chains in solutions and in melts has recently been investigated using photon beat methods, inelastic scattering of neutrons, and also the stimulated Rayleigh effect. Relatively simple scaling laws have emerged, but some features of entangled systems remain unexplained.

THE stochastic motions of flexible polymer chains in a liquid phase are very complex. They fall into two classes: first, local motions, involving conformational changes inside a small number of adjacent monomers; second, large scale motions, where the whole polymer chain deforms and drifts in the neighbouring solvent.

The frequencies involved are in the range 10^{10} cycles for local motions, and 1–10^5 cycles for large scale motions. Here only the latter will be considered. These relatively slow modes have mostly been studied through mechanical experiments[1,2]. A very small concentration of flexible polymer is sufficient to increase significantly the static viscosity of a solvent; if we repeat this measurement at higher frequencies (using acoustic shear waves) we find an elastic component to the response with the chain behaving like an elastic spring. The frequency dependence of the response indicates a certain relaxation time of the chains. A similar time can be measured using certain mechano–optic and dielectric effects[3].

The 'photon beat' method has allowed the study of large scale motions. Here a very monochromatic laser beam (of frequency ω_0) is scattered inelastically from the polymer coils and the outgoing beam (frequency $\omega_0+\omega$) is probed at a well defined angle θ (or scattering wave vector $q=4\pi \sin\theta/\lambda$). The useful range of $\omega/2\pi$ is 1–10^6. The new feature of this method is the choice of a wave vector q. Qualitatively we may say that this method probes local fluctuations in the polymer concentration at spatial scales of order q^{-1} (ranging from 1,000 Å to a few microns).

Experiments using the weakly inelastic scattering of neutrons[4,5] have also become feasible; they give similar information, but for higher frequencies: from 10^{11} s^{-1} with 'back scattering spectrometers' down to 2×10^8 s^{-1} with the most recent 'spin echo' method. The range of q vectors available with neutrons is also different: for most experiments q^{-1} is between 10 and 100 Å. From these optical and neutron data, a physical picture has emerged for the stochastic motions of polymer chains, which is summarised below.

Dynamics of a single chain in solution

When considered at small magnification (low q) a polymer coil behaves likes a point-like brownian particle, with a certain diffusion coefficient D: this is conveniently measured by photon-beat experiments. For flexible coils in good solvents, D is found to be a decreasing function of the molecular weight M, and is often well described[6] by a relationship of the form $D\sim M^{-x}$ where x is of the order of 0.55. This does not agree with the classical theory for D (due to Kirkwood[7]) which predicts a Stokes–Einstein form:

$$D=\frac{kT}{6\pi\eta_0 R} \tag{1}$$

where T is the temperature, η_0 is the solvent viscosity, and R an effective radius of the coil. In a good solvent we would expect R to be controlled by excluded volume effects (giving a swollen coil): this gives $R\sim M^{3/5}$. The discrepancy in the exponent is beyond experimental errors, and remained a mystery for a long time until an attractive explanation was proposed by des Cloiseaux and Weill[8]. They note that in most of the usual solvents, which are not 'very good' the pair correlation function $g(r)$ between monomers of the chain, is of the ideal chain form $[g(r)\sim 1/r]$ for short distances $r<r_c$, while $g(r)$ decreases more rapidly at larger r: $g(r)\sim \text{const}\, r^{-4/3}$ $(R\gg r\gg r_c)$. This 4/3 law is the classic result due to Edwards[9], and reflects excluded volume effects typical of good solvents. The length r_c has been displayed in certain neutron diffraction experiments[10,11], and may be of the order of 20–100 Å (depending on the solvent quality). The main observation is that all static determinations of the coil radius are derived from an average of r_{ij}^2 between two arbitrary monomers

$$R_{\text{stat}}^2\sim \int r^2\, g(r)\, \mathrm{d}\mathbf{r} \Big/ \int g(r)\, \mathrm{d}\mathbf{r} \tag{2a}$$

while the dynamic properties are dominated by backflow properties[7]: the motion of monomer (i) induces a flow field near monomer (j) proportional to $1/r_{ij}$. This means that

$$\frac{1}{R_{\text{dyn}}}\sim \int \frac{1}{r}\, g(r)\, \mathrm{d}\mathbf{r} \Big/ \int g(r)\, \mathrm{d}\mathbf{r} \tag{2b}$$

The static average, equation (2a), is dominated by the contributions at large r, for which the excluded volume law behaves well. But the dynamic average, equation (2b), is more sensitive to the short range portion of $g(r)$, and for chains of not too large M, this makes R_{dyn} closer to the ideal chain value ($\sim M^{1/2}$). (Ultimately, at very high M, when $R\gg r_c$ the two values converge $R_{\text{dyn}}\sim R_{\text{stat}}\sim M^{3/5}$.) Future experiments using solvents of variable quality (variable r_c) should test the des Cloiseaux–Weill explanation in detail.

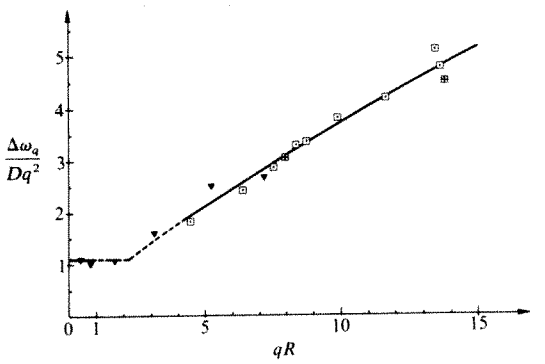

Fig. 1 Characteristic frequency $\Delta\omega_q$ for fluctuations of wavelength $2\pi/q$ in dilute polystyrene solutions. A scaling law is constructed by plotting $\Delta\omega_q/Dq^2$ versus qR where R is the coil radius and D the diffusion coefficient. Note that the points measured for two molecular weights (∇, $M = 8\times10^6$; $\square$, $M = 24\times10^6$) fall on one curve (after ref. 12).

The motions of the chain can be described in terms of an overall diffusion only when the probing length (q^{-1}) is much larger than the coil size R. The opposite limit has been studied[12] in very large polystyrene coils (with M values up to 2×10^7). The resulting plots of inelastic linewidth $\Delta\omega_q$ versus q (Fig. 1) can be summarised in the form:

$$\Delta\omega_q = Dq^2 f(qR) \tag{3}$$

where f is a dimensionless function. The long wavelength limit ($qR < 1$) is the diffusion law $\Delta\omega_q = Dq^2$ and imposes $f(0) = 1$. At the other end ($qR \gg 1$) we expect $\Delta\omega_q$ to become a characteristic frequency for a chain portion of spatial extension q, and to be independent of the overall chain size R. Because $D \sim 1/R$ from equation (1) then $f(x)$ must be linear in x for $x \gg 1$, giving:

$$\Delta\omega_q = \text{const}\,\frac{kTq^3}{\eta_0} \qquad (qR \gg 1) \tag{4}$$

This scaling law is followed relatively well by the data (although in practice the comparison is complicated by the des Cloiseaux–Weill correction). Theoretically, equation (4) was originally derived using a special model[13] for ideal chains, but it has a more general range of validity. Note the analogy between equation (4) and the rotational relaxation rate for a sphere of radius $q^{-1}[1/\tau_q = (kT/8\pi\eta_0)\,q^3]$.

Some measurements of $\Delta\omega_q$ have also been obtained from inelastic scattering of neutrons. As already mentioned, the results are limited to rather large $\Delta\omega_q$ values, and this imposes relatively high q: the data always fall in the domain $qR \gg 1$. Early work[14,15] was mainly concerned with melts and concentrated solutions, for which the situation is complex. Recent studies, using the 'spin echo' frequency analyser, have been performed on solutions of polydimethyl siloxane and polymethyl methacrylate, in benzene[16]. They give $\Delta\omega_q \sim q^z$ with z close to 3—in reasonable agreement with equation (4). Typical values of q are of the order of 0.1 Å^{-1}, hopefully small enough to warrant the continuum description (Fig. 2).

The above discussion on $\Delta\omega_q$ has been restricted to good solvents, where the chains were strongly swollen. In early theoretical discussions[2] the emphasis was more on the so-called 'Θ solvents' where the steric repulsions between monomers are exactly compensated by Van der Waals interactions: this led to simple random flight statistics for the coils ($R \sim M^{1/2}$) and eliminated the complications of excluded volume effects. However, another difficulty appears (at least for very long chains) in Θ conditions: as each coil is less swollen, it has a strong tendency to become knotted on itself. These knots could complicate the dynamics, the coil behaving as a whole like a small rubber ball[17]. Present experiments, however, have not shown any clear-cut effect of knots in Θ solvents, and this point remains unclear.

Diffusion in semi-dilute solutions

Let us now consider many coils in a good solvent, with a concentration c (g cm^{-3}) such that different coils overlap very strongly. The internal concentration of a single coil is of the order of $c^* = MR^{-3} \sim M^{-4/5}$ and the present regime corresponds to $c \gg c^*$. For large M values c^* is very small, and, the condition $c \gg c^*$ is achieved for a broad range of 'semi-dilute' solutions.

In these solutions, we can define two distinct diffusion processes: (1) 'cooperative diffusion' (D_{coop}) is associated with long wavelength fluctuations of the polymer concentration, and can be probed by photon beat experiments[12]. For instance, with polystyrene, in relatively good solvents, one finds a value of D_{coop} which is independent of molecular weight and increases with concentration: $D_{coop} \sim c^m$ with $m \sim 0.67$.

These are natural features: all the chains drift simultaneously, and behave as an elastic 'sponge' moving in a viscous medium. The size of the holes in the sponge (called the correlation length ξ (ref. 18) depends on c but not on M: both the elastic restoring forces and the friction forces involve only ξ and are independent of M in the semi-dilute regime: the same holds for D_{coop}. Furthermore, when c increases, the elastic rigidity of the 'sponge' increases very fast, and this explains the increase in D_{coop}.

It is easy to construct scaling laws for ξ and for D_{coop} (ref. 19). For the correlation length:

$$\xi = R\left(\frac{c^*}{c}\right)^n \qquad (c \gg c^*) \tag{5}$$

noting that for $c = c^*$ (close packed system of non-overlapping coils) the size of the interstices is comparable to the single coil radius R. Furthermore, we want ξ to be independent of M. Since $R \sim M^{3/5}$ and $c \sim M^{-4/5}$ this means that $n = 3/4$, a value confirmed by neutron diffraction data[18]. Similarly for the cooperative diffusion coefficient we can write:

$$D_{coop} = \frac{T}{6\pi\eta_0 R}\left(\frac{c}{c^*}\right)^{3/4} = \frac{T}{6\pi\eta_0\xi} \tag{6}$$

Equation (6) ensures that, for $c \sim c^*$, D_{coop} returns to the single coil value of equation (1) and the exponent is such that D_{coop} is independent of M. The remaining discrepancy between the theoretical exponent (3/4) and the experimental value for polystyrene ($m = 0.67$) is probably another effect of the des Cloiseaux–Weill correction.

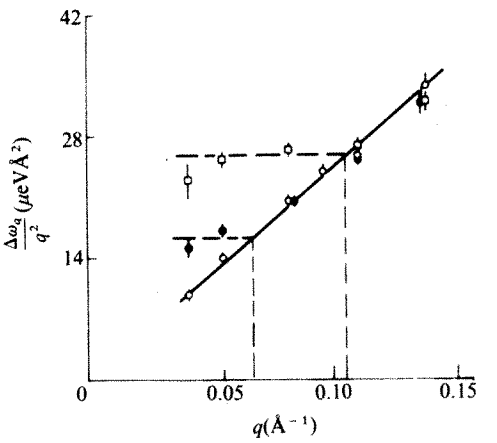

Fig. 2 Plot of $\Delta\omega_q/q^2$ versus q for three solutions of polydimethyl siloxane in benzene ○, PDMS/B 0.05 g; ●, PDMS/B 0.15 g; □, PDMS/B 0.3 g (after ref. 16). Note the difference in q values with Fig. 1: neutrons probe higher qs. The relevant curve of the present discussion corresponds to the most dilute solution (○). At higher concentrations and low q values ($q\xi < 1$) a more complicated regime appears.

The friction factor between the 'sponge' and the solvent can also be measured directly by sedimentation studies; data on polymer solutions have been collected for a long time[20] but it is only recently that a systematic study in semi-dilute solutions of low c has been carried out[21]. The sedimentation coefficient of polystyrene in good solvents is found to decrease like $c^{-0.59}$ while scaling would predict $c^{-0.5}$.

(2) 'Individual diffusion' (D^*) is associated with the brownian motion of one labelled chain immersed in a solution of chemically identical (but unlabelled) other chains. The diffusion coefficient D^* is rather small and very different from D_{coop}: it is a decreasing function of concentration and also of molecular weight. D^* is controlled by certain wiggling motions of the probing chain among the other chains, all being strongly entangled; therefore a theoretical study of D^* is difficult. I suggested previously[22] a simpler physical situation, where a single mobile chain moves in a fixed network of other chains: this has been called reptation. For the reptation model, D^* is proportional to M^{-2}. Various realisations of the model have been achieved[23]. However, the simplest idea was realised only recently: it replaces the network by a solution of 'ambient' chains, chemically identical to the probing chain, but longer: then the motions of the ambient chains are so slow that effectively they behave like a fixed network.

Two main experimental approaches have been used to study the very slow diffusion described by D^*. In the Klein experiments[23] the labelled chains were deuterated, and their concentration was measured by IR spectroscopy. The diffusion times involved were measured in months, and the diffusion lengths were ~ 2 mm. In recent experiments by Hervet, Léger and Rondelez[24], a photochrome was attached to the probing chain, and the diffusion was monitored through the stimulated Rayleigh effect.

The principle is as follows: at time 0, with a strong laser pulse, we create an interference fringe pattern (of wavelength $2\pi/q$) in the solution. The photochrome molecules are chemically modified in the bright regions, and this creates a periodic modulation of the refractive index; a phase grating is constructed in the fluid. We then cut out the power laser; the amplitude of the refractive index modulation Δn at a later time t decreases like $\exp(-D^*q^2t)$ where D^* is the diffusion coefficient. We monitor this amplitude with a probing (weak) laser, measuring the intensity of a Bragg reflection on the grating. This method detects diffusion over very small lengths ($2\pi/q \sim 1$ μm) and thus allows measurements of very small diffusion coefficients D^* (down to 10^{-9} cm^2 s^{-1} at present). The main difficulty in this programme is chemical: the attachment of a photochrome at the end of a polystyrene chain, prepared by anionic polymerisation is a delicate operation (performed under direction of P. Rempp). The labelled chains and the ambient chains were both polystyrenes of the same length. (This is not the ideal reptation situation, where the ambient chains would be longer than the probe. However, it has been argued that the difference is not essential[25,26].) It was found that $D \sim c^{-\alpha}$ where $\alpha = 1.7 \pm 0.1$.

It is possible to predict an exponent of this magnitude by combining the rules of reptation ($D^* \sim M^{-2}$) with a scaling ansatz:

$$D^* = \frac{T}{6\pi\eta_0 R}\left(\frac{c}{c^*}\right)^{7/4} \tag{7}$$

The form of equation (7) ensures that D^* crosses over correctly to the single coil D at $c = c^*$. The exponent 7/4 is then chosen to make $D^* \sim M^{-2}$.

In spite of its apparent success, equation (7) must still be considered with some suspicion: (1) the self diffusion D^* is associated with a natural relaxation time τ_r proportional to $R^2(c)/D^*$ (where $R(c)$ is the size of the chain at concentration c). Using known scaling laws for $(R(c)$ (ref. 2) this leads to $\tau_r \sim M^3$ (a typical reptation result[27,28]) (Fig. 3). However, most mechanical data on τ_r (ref. 1) suggest a higher exponent $\tau_r \sim M^{3.3}$. The discrepancy remains completely unexplained at present. (2) Similar scaling arguments could be applied to the viscosity η of the entangled solution: making η equal to the solvent viscosity η_0 when $c \lesssim c^*$, and demanding that η be simply proportional to τ_r (to M^3) in melts. One would then reach

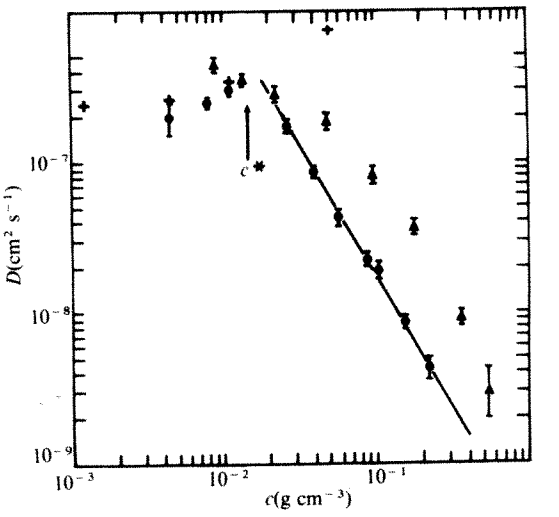

Fig. 3 Self diffusion coefficient D^* versus concentration in polystyrene–benzene solutions for two molecular weights (after ref. 24). ▲, $M = 123{,}000$; ●, $M = 245{,}000$; +, calculated from ref. 7; slope $\alpha = -1.75$.

$$\eta \cong \eta_0\left(\frac{c}{c^*}\right)^{15/4} \tag{8}$$

The actual exponent of $\eta(c)$ has not been measured in many clear-cut cases with low c^* values; but recent data (M. Adam and M. Delsanti, personal communication) suggest a higher exponent (~ 4.5). Thus either the scaling ansatz, equation (8), is wrong, or some minor complications occur: one of them may be due to a competition between monomer–solvent friction (described by η_0) and monomer–monomer friction: in equation (8) we might have to make the replacement

$$\eta_0 \rightarrow \eta_0 + \eta_1 c + \ldots \tag{9}$$

where η_1 describes monomer–monomer friction (and is independent of M); if the term $\eta_1 c$ dominates on η_0, even at relatively low c, the apparent exponent in equation (8) may be modified. However, if we accept this idea, we probably need a similar renormalisation of η_0 in equation (7) which might upset the agreement with the experiment.

Conclusion

The combination of the classical (mechanical) data on polymer dynamics, and other information (optics, neutrons) produces a reasonably consistent description of the long range, low frequency motions of polymer coils. However, (1) certain features, like the des Cloiseaux–Weill correction, or the viscosity renormalisation of equation (9), complicate the situation; (2) there remain some mysteries such as the possible role of knots in Θ conditions, or the exponent for the relaxation time $\tau_r(M)$ in entangled systems. The problem raised by $\tau_r(M)$ is central: as mentioned earlier, the experimental relaxation times are longer than expected. Polymers of high molecular weight may never be absolutely linear, but rather show some branching. Branched species cannot reptate freely, and are expected to have exponentially long relaxation times. One long branch is enough to achieve this; and a single branch point should be invisible by all traditional methods of detection (UV, IR spectroscopy, and so on).

Thus mechanical data on long, entangled chains may be dominated by a small number of uncontrolled branch points. However, this explanation is difficult to reconcile with the

apparent universality of the result: $\tau_r(M)$ is proportional to $M^{3.3}$ or $M^{3.4}$ for a wide variety of chemical structures.

Apart from branching effects, polydispersity may also be important: if the sample has a distribution of molecular weights M, the mechanical data in the entangled state are extremely sensitive to the high M tail of the distribution. We hope to see this point clarified by systematic studies on blends with a small fraction of very long chains in a matrix of smaller chains[26].

This review is largely based on a workshop on polymer dynamics held in Les Houches 1979 under the direction of J. P. Cohen Addad, and I thank the participants for many stimulating discussions.

Thermal minima along the axis of the Mid-Atlantic Ridge

J-G. Schilling & H. Sigurdsson

Graduate School of Oceanography, University of Rhode Island, Kingston, Rhode Island 02881

Mid-Atlantic Ridge basalts erupted near fracture zones seem to have lower quenching temperatures than along unfractured ridge segments probably because of enhanced cooling by exposing magmas to colder fault planes and more intense seawater circulation. The cooling effect is most pronounced along segments over hotspots with close ridge displacement fabric and recurrent rift jumping, probably reflecting additional complications, including subaxial magma flow about 'plumes', or the presence of an unusually large magma chamber on the Azores Platform and the southern part of the Iceland Plateau.

LARGE-SCALE heterogeneities in the abundance of heat-producing elements in the mantle should generate varying heat production rates. Given sufficient time after such heterogeneities have been produced, unusual melting conditions or convective flow patterns may develop in regions of the mantle richer in U, Th and K. Surface reflection of such unusual mantle activity may be the locus of the so-called 'hotspots' such as Iceland, the Azores and Galapagos regions which are characterised by more vigorous volcanic activity than adjacent mid-ocean ridges. The progressive increase in the content of K, U, Th of basalts collected along the Reykjanes Ridge and Iceland may reflect such mantle heterogeneity[1,2]. On average, Iceland basalts are enriched in K, U and Th by factors of 3.8, 6 and 9.6, respectively, compared with Mid-Atlantic Ridge basalts located south of 61° N. A significantly higher heat production rate is thus expected beneath Iceland relative to the Mid-Atlantic Ridge further south. However, it is uncertain whether such a higher heat production rate would manifest itself in generating higher heat flow, greater extent of melting, higher magma temperatures, unusual mantle convective flow, or a combination of these phenomena. It is also not known when these mantle heterogeneities were produced. High heat flow has been measured over Iceland[3] and steeper geothermal gradients have been inferred for Iceland compared with the Mid-Atlantic Ridge[4–6], but no direct heat flow measurements are yet available on the Mid-Atlantic Ridge crest. Lava production rates over Iceland are two to four times higher than on the Mid-Atlantic Ridge judging from crustal thickness and the Iceland topographic bulge[3,7–9]. This would indicate higher convective heat transport beneath Iceland than along the Mid-Atlantic Ridge. However, it is uncertain whether the higher basalt production rate on Iceland represents a higher degree of melting (melt–solid mass ratio) or segregation of interstitial melts from a larger volume of mantle rock beneath Iceland.

Lava temperatures are another useful way of investigating thermal phenomena, although also limited. Lava temperatures, whether directly measured or calculated from petrological data, only reflect temperatures of the magma at the time of eruption. The temperature of primary magma generated in the mantle is affected by cooling, partial crystallisation and possibly volatile loss as the magma ascends. The extent of polybaric fractional crystallisation of primary melts during ascent is a source of debate. While some workers maintain that all basalts have suffered extensive fractionation[10] others consider that some basalt compositions reflect relatively primary liquid[11]. Despite these limitations the determination of liquidus temperatures of basalts erupted along the Mid-Atlantic Ridge encompassing hotspots or fracture zones can be useful[12,13]. An estimation of the variation of temperature of magmas along the ridge may not only provide clues on thermal conditions in the underlying mantle, but also clarify the relative ascent rate and cooling

0028-0836/79/470370-06$01.00

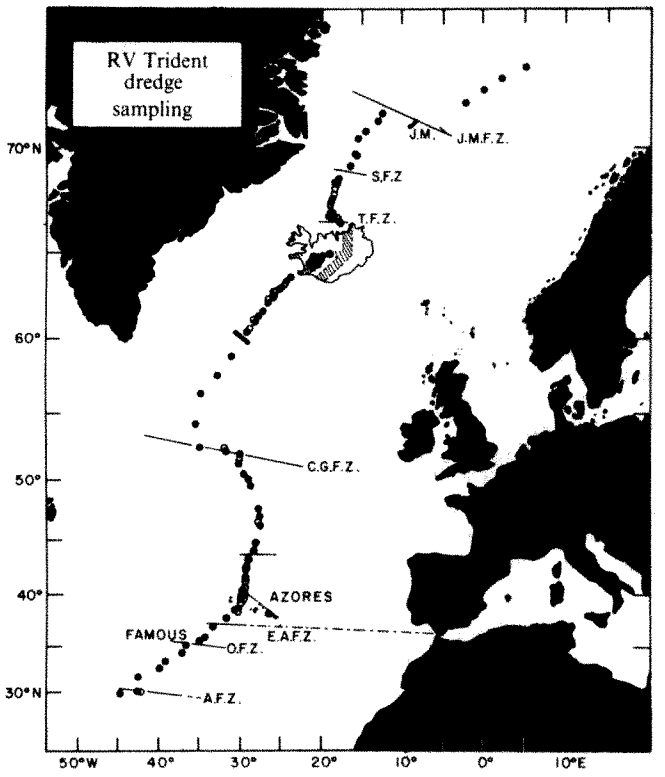

Fig. 1 Location of the Mid-Atlantic Ridge dredge stations used for the study (●). Not all locations contained glasses.

history of magmas in relation to tectonics. Further comparison of liquidus temperature variations along the ridge with other petrological and geochemical data, including heat producing elements U, Th and K, should also help to develop more realistic models for magma emplacement, ridge evolution and formation of unusual oceanic plateaus such as the Azores, Iceland and Jan Mayen. The first use of such an approach was made by Hermes and Schilling[12] along the Reykjanex Ridge and Iceland.

Here we examine the variation in calculated olivine crystallisation temperatures of 100 young Mid-Atlantic Ridge basalt glasses along the axis of the ridge from 29° N to 73° N, including traverses over Iceland (13 sub-glacial pillow lava localities from the western volcanic zone) and the Azores Plateau (Fig. 1). The submarine glassy rocks were dredged by RV Trident from 66 stations located either within the rift of the Mid-Atlantic Ridge or on the axis of the elevated crest of the Reykjanes and the Kolbeinsey Ridges. The stations are spaced at an average interval of 55 ± 63 km (1σ) and provide a reasonably representative sampling of recent magmatic activity on a 4,900-km long segment of the mid-ocean ridge system. Whenever possible, several samples were studied per station[14]. Liquidus temperatures were computed on the basis of the temperature-dependence of the equilibrium partitioning of Mg between olivine and co-existing glass[15–18]. The olivine crystallisation temperatures reported here are all based on the rim composition of olivine 'microphenocrysts' and surrounding glass in quenched pillow lava rinds and are considered to be realistic approximation of temperatures of Mid-Atlantic Ridge basalts at or close to the time of extrusion. Detailed discussion of this electron microprobe study, including the methods and the validity of the calculated temperatures of olivine crystallisation, are reported elsewhere[14].

Petrology

Phenocrysts are present in the majority of the glassy basalts studied. Modal analyses show that total phenocrysts are generally < 10 vol.% in the variolitic zone of the pillows, with maximum phenocryst content up to 23% near Iceland, the Azores Plateau and the Gibbs Fracture Zone (Fig. 3). Plagioclase phenocrysts are generally more abundant than olivine, and clinopyroxene is uncommon except over and near the Azores, Iceland and Jan Mayen plateaus. The composition of the olivine microphenocrysts studied ranges from 71.8 to 88 mol% fosterite, with a mode at 85 mol% Fo. A good linear relationship exists between the Fe/Mg content of these olivines and that of the glass. The corresponding K_D equal to 0.27 ± 0.01, 1σ suggests that equilibrium conditions prevailed[14]. (The Fe^{2+}/Fe^{3+} values of the glasses were estimated on the basis of an oxygen fugacity equivalent to that of the quartz + magnetite–fayalite exchange reaction at the liquidus temperature calculated from the Mg partitioning, using Waff and Weill's empirical relationship (unpublished data). The Fe^{2+}/Fe^{3+} obtained this way compared well with those actually measured on whole rock by a wet chemical method (Schilling *et al.* unpublished).

Within the normative classification scheme of Yoder and Tilley[19] the bulk compositions of the basalts studied correspond to either quartz–hypersthene or olivine–hypersthene normative basalts, and only two Ne-normative lavas were observed near 33–35° N. Stations TR119-8D recovered basalts which are just nepheline normative, and the glassy rims of picritic basalts at station TR123-4D are also just nepheline normative whereas the whole-rock is not. As expected, glass compositions are slightly more evolved than bulk rocks. Silica content of glasses ranges from 47.4 to 53.1% (mean 50.9 ± 1.0, 1σ) and in bulk rock analyses from 46.9 to 52.0% (mean 49.9 ± 1.0, 1σ). The chemistry of these pillow lavas, as well as of the glasses, reveals two major compositional groups which may be related to distinct petrological provinces (Fig. 2). One group forms a narrow iron enrichment trend with little change in alkali content for the region of the Mid-Atlantic north of the Gibbs Fracture Zone up to 70° N including Iceland (group *A*); the other group shows a notable enrichment and significant scatter in soda and comparatively more limited Fe enrichment and comprises basalts from the segments of the Mid-Atlantic Ridge between 53° N to 28° N including the Gibbs Fracture Zone and the Azores Plateau, as well as from 70° N to at least 73° N, which includes the Jan Mayen region and the Mohns Ridge (group *B*). Group *B* basalts can further be subdivided into ridge segments with distinct content of soda at equivalent Mg-value. The difference between the two groups is amplified in the more evolved magmas. The forsterite content of olivine from group *A* varies from 87 to 72 mol% Fo, and from 88 to 74 mol% Fo for group *B*. At equivalent olivine compositions, the Mg and Fe content of group

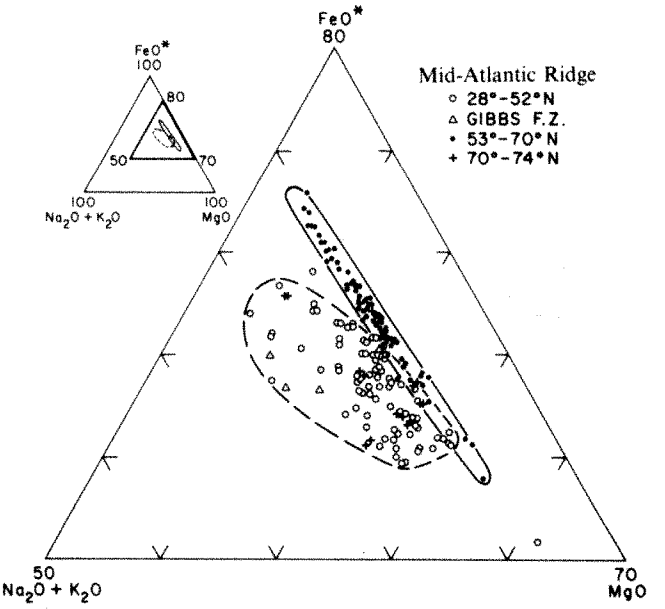

Fig. 2 Relative Mg, Fe, alkali content variation of the Mid-Atlantic Ridge basalt studies based on whole-rock analyses. Not all basalts are glassy.

A glasses is consistently higher than in glasses of group B, over the entire compositional range. Consequently, the olivine/glass partition coefficients for both Fe and Mg are higher in group A than in group B, but the corresponding K_D values for the two groups are indistinguishable within the error quoted earlier. The differences in olivine/glass partitioning of Fe and Mg between groups A and B can be attributed to melts composition, particularly differences in SiO_2 (or Si/O ratio) which is generally higher in group A basalts at equivalent indices of fractionation[14]. These observations also suggest that the Fe and Mg partition coefficients are affected to a similar extent by composition, since K_D is the ratio of these two partition coefficients.

Temperature variations along the Mid-Atlantic Ridge

We have calculated the crystallisation temperatures of olivine microphenocrysts in Mid-Atlantic Ridge basalt glasses by using the temperature-dependency of the olivine/melt (glass) partition coefficient (D) for Mg defined as D_{Mg} = weight fraction of Mg in olivine/weight fraction Mg in liquid. The temperature dependency of the Mg partition coefficient has been experimentally determined at one atmosphere under controlled fugacity of oxygen for a wide range of basaltic compositions[15–18]. The relationship is of the form: $\log D = A/T\ (K) + B$. These studies have also shown that the compositional dependancy of D_{Mg} is small. The pressure dependancy remains poorly studied. We have calculated the temperature of crystallisation of the olivine '*microphenocrysts*' using the one-atmosphere D_{Mg} calibration of Fisk *et al.*[18]. This calibration was obtained on the Reykjanes Ridge basalts, which should further minimise possible compositional dependency of D_{Mg} in the case of the Reykjanes Ridge glasses and other glasses from group A. There are several uncertainties in the calculated temperatures of olivine crystallisation: (1) uncertainties in parameters A and B for the linear regression correlation between D_{Mg} and temperature can be as large as 30 °C between various calibrations[15–18]; (2) uncertainties due to analytical precision for MgO may translate into ± 5 °C error on the calculated temperatures; (3) uncertainties due to the compositional variation of individual olivine microphenocrysts has been examined by compilation of average core and rim compositions for 144 Mid-Atlantic Ridge basalts as well as intensity line scans for Fe and MgKα across selected microphenocrysts. The number of olivine analyses per sample ranged from a minimum of 6 to >20. Zoning was taken to be significant when the difference in core and rim composition exceeded the precision of the microprobe analysis method (± 0.25 mol% Fo). On this basis 40% of the samples have olivine microphenocrysts showing significant zoning. Of these, 49 samples exhibit normal zoning (decreasing forsterite content from core to rim) amounting to average of 1.4 mol% Fo, which corresponds to an ± 5 °C error on the calculated temperature. Reverse zoning was detected in 10 basalts, with average range of 0.75 mol % Fo. Maximum normal zoning observed was 2.82 mol% Fo (or an absolute uncertainty of 10 °C on calculated temperature), and maximum reverse zoning of 1.50% (a 6 °C absolute uncertainty). The composition of the glasses was determined by a minimum of three probe analyses of the glass, well away from crystal phases. Only average compositions of olivine 'microphenocryst rims' were used to calculate the Mg partition coefficients.

Variations in temperature of crystallisation of olivine along the ridge using this method are shown in Fig. 3. Based on our analysis of errors and uncertainties and systematic analytical procedure, we estimate that individual temperatures shown in Fig. 3 should not deviate by more than ± 8 °C on a relative basis. The temperatures range from a maximum of 1,225 °C in an Icelandic picritic glass (IC-117) to a minimum of 1,067 °C in quartz-normative tholeiite glasses on the southern margin of the Azores Plateau at 38 °N (TR154-10D). These values are within the range of liquidus temperatures of basic igneous rocks determined in the laboratory[20]. Temperature variations on a single site were evaluated from data on glasses taken in 15 dredges from which two or three samples were selected for study. The temperature difference among several glasses from a single dredge varies from zero to 33 °C and two groups of sites can be recognised. Five of the dredge stations contain heterogeneous samples, with dissimilar glass compositions, petrography and crystallisation temperatures; with temperature differences between samples of 11–33 °C. These dredges have clearly sampled several unrelated volcanic units. Ten dredges, for which multiple temperature data are available, contain samples with temperature differences in the range 0–6 °C. Other criteria, such as glass chemistry and petrography, indicate that these dredge stations contain several samples of the same volcanic unit.

Basalts with highest olivine crystallisation temperatures at each site have been joined by a line to yield a temperature profile of the ridge (Fig. 3). Also shown in Fig. 3 are: a bathymetric profile of the ridge based on water-depths at the dredge stations; the Mg-value of the basalts; the volume % of phenocrysts based on modal analyses (Schilling *et al.* in preparation), and the La/Sm variation as an index of mantle source heterogeneity[1,21].

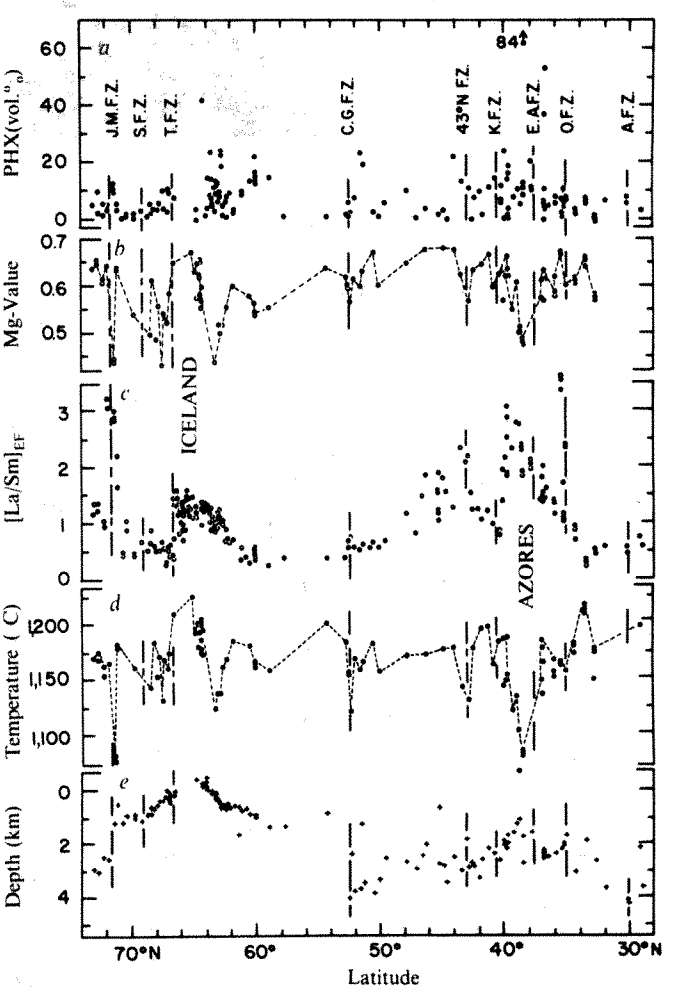

Fig. 3 Variation along the Mid-Atlantic Ridge, from top to bottom of: (*a*), total phenocryst volume per cent based on point counting modal analyses (Schilling *et al.* in preparation); *b*, $Mg/Mg+Fe^{2+}$ of glasses (atomic and using the method described in the text for estimating the Fe^{2+}/Fe^{3+} ratio)[14]; *c*, (La/Sm) enrichment factor relative to chondrites (refs 1 and 21 and Schilling *et al.* in preparation); *d*, calculated temperature of olivine and glass[14], using the calibration of Fisk *et al.*[18]; and *e*, water depth at the dredge stations. Note low temperatures at fracture zones, and the two well defined minima south of the Azores and Iceland plateau. Abbreviation for fracture zones (FZ) are: JM, Jan Mayen; S, Spar; T, Tjornes; CG, Charlie-Gibbs; K, Kurchatov; EA, East Azores; O, Oceanographer; and A, Atlantis.

The most notable feature of the temperature profile along the Mid-Atlantic Ridge is the tendancy of significantly lower temperatures at or near fracture zones. However, three possible minima are suggested by single dredges only; the Jan Mayen Fracture Zone (1,078 °C), the Gibbs Fracture Zone (1,122 °C), and possibly the 43° N fracture zone (1,131 °C). Although the existing sampling density along the ridge prevents us demonstrating statistically that lavas erupted at or near fracture zones are systematically lower, this trend is sufficient to warrant further discussion and testing. Furthermore, the lower olivine crystallisation temperatures observed for fracture zone basalts are in keeping with the occurrence of more evolved basalts in other Mid-Atlantic Ridge transform fault zones, most probably as a result of fractional crystallisation[22]. Some variation in the extent of partial melting along the ridge is also likely. Shallow depth fractional crystallisation may affect significantly the Mg value of magmas but has only a minor effect on the La/Sm ratio[21,23,25] (Fig. 3). On the other hand La/Sm is more and the Mg value less susceptible to variation in extent of partial melting[24,25]. Some local correlation may exist between La/Sm and the Mg value or the temperature of olivine crystallisation as a result of the combination of these two processes. However, the large amplitude and wavelength variations in La/Sm shown in Fig. 3 are primarily reflections of mantle source heterogeneities in this ratio beneath the ridge and clearly do not parallel the Mg value[21,25].

Two pronounced and statistically better defined thermal minima are also observed on the extension of the Reykjanes Ridge over the southern edge of the Iceland Plateau (~63°10′N) and the ridge transect over the southern part of the Azores Platform (~38°30′N) (Fig. 3). The temperature minimum south-west of Iceland first observed by Hermes and Schilling[12] was attributed to shallow-level fractional crystallisation. The presence of another well-defined minimum over the southern part of the Azores Plateau[13], again another hotspot, suggests the possibility of a common cause for such phenomena. Both minima share the following characteristics: (1) they occur on or over the flank of two major volcanic plateaus or topographic bulges; (2) they are probably underlain by a thicker crust than normally present along ridge segments further remote from the Azores or Iceland[3,5,26]; (3) the axis of these two ridge segments is displaced in en-echelon fashion by a series of small fracture zones[5,21]; (4) magnetic anomaly lineaments typifying ridge axes have lost coherency along these two ridge transects[5,27]; (5) complex recurrent rift jumping has also been suspected in these two regions[28]; (6) both ridge segments are geochemical transition zones characterised by large-scale radiogenic isotope and La/Sm gradients (Fig. 3) which have been interpreted as reflecting preferential flow and mixing beneath the ridge axis of mantle-plume derived with LILE-derived material[1,21]; (7) basalts erupted in these two regions are more evolved, have lower Mg values and contain larger proportions of phenocrysts than other MAR basalts, including particularly clinopyroxenes (Fig. 3; and Schilling *et al.* in preparation); and (8) basaltic glasses defining these two temperature minima also contain two populations of olivine and plagioclase phenocrysts. Macrophenocrysts have common resorption features suggestive of magma mixing[14], whereas late generation microphenocrysts do not.

Origin of thermal minima near the Azores and Iceland hotspots

Models describing the cooling of the crust–lithosphere along normal ridge segments, where volcanism occurs passively in response to plate divergence, have been treated primarily as a two-dimensional thermal problem in a plane perpendicular to a semi-infinite ridge axis[29–32]. We suggest that on or near 'hotspots' where subaxial and additional tectonic complication seem to occur[1,8,21], and across fracture zones, lithospheric cooling must be treated as a three-dimensional thermal problem. More efficient cooling in ridge segments cross cut by fracture zones is to be expected as the active ridge segment abuts against colder lithosphere across the transform fault. More extensive fracturing should also enhance circulation of seawater and heat exchange with magma chambers beneath such regions[33]. It has been suggested that the flux of 'mantle plume' material located beneath a ridge is largely independent of spreading rate of the plates above[34]. As a result, when the flux of mantle plume material per unit ridge length exceeds the rate of plate divergence by seafloor spreading above the plume, the excess material derived from the plume is accommodated in several possible ways: (1) by formation of an elevated ridge axis (rather than a rift valley) along the ridge branching from the plume; (2) stagnation and cooling of magma in unusually large magma chambers at the base of the crust; (3) development of a thicker crust above and about the plume[1,21]; and (4) lateral flow of magma derived from the plume, subaxial to the ridge, which mixes with complementary melts derived from the LILE-depleted asthenosphere[1,8,21,35,36]. Modelling and sorting of these different effects are difficult with our present knowledge. An attempt to evaluate the thermal effect of magma flowing and mixing beneath the ridge axis about these two hotspots is made in the following section.

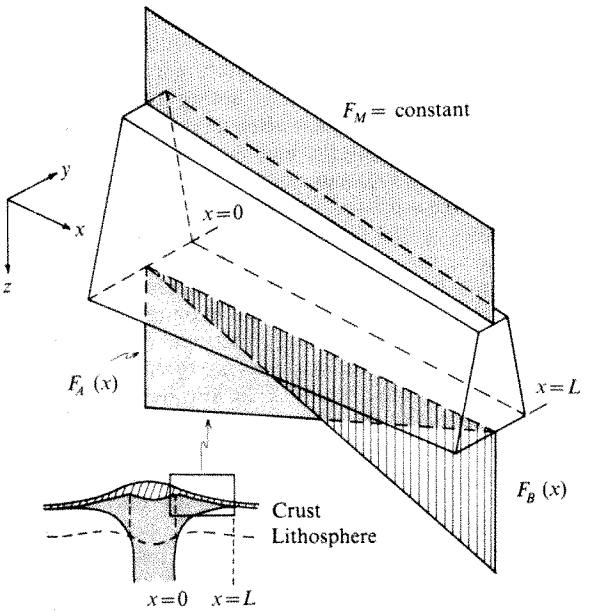

Fig. 4 Model for flow and mixing of magma in subaxial magma chamber. Flux variations with x of the two magma types entering the magmas chamber are shown as shaded areas: Grey shading indicates plume-derived magma type A; vertical strips indicate magma type B derived from the LILE-depleted asthenosphere; and dotted area show flux variation with x of mix-magma type M leaving the magma chamber and solidifying as new oceanic crust. Magma flow directions are not shown. Magma type A may enter partly from below or from the end face at $x = 0$ and flow along x. Magma type B probably enters mostly from below; whereas mix-magma M partly leaves the magma chamber from its top during dyke injection, or solidifies along both sides due to lateral crustal spreading in the y direction.

Several mechanisms have been suggested for flow of magma along rifted crustal zones. Vogt[35] has modelled sub-crustal and axial pipe-like flow down-slope about hotspot bulges on the basis of gravity and topographic gradients. Fiske and Jackson[37], Schilling[1] and Sleep and Rosendahl[38] have considered dyke propagation due to non-isostatically compensated topography which causes horizontal deviatoric tension. Direct evidence for intra-crustal flow of magma over 70–100 km distance within Iceland has been provided by Sigurdsson and Sparks[39]. Whatever the exact cause and nature of the transport mechanism, progressive cooling and crystallisation of the magma is to be expected during flow along the rifted zone. En echelon ridge axis displacements or recurrent rift jumping near hotspots will further complicate the nature of magma plumbing and enhance

cooling as discussed earlier. The subaxial transport process is also likely to be sporadic[8,40]. The material flowing may be entirely liquid or composed of a mixture of melt and solids (xenocrysts and/or phenocrysts). Cooling and partial crystallisation in the magma chamber, after mixing of the two magma types derived from the plume and the LILE-derived asthenosphere, is also likely to occur and obscure simple geochemical tests for the magma mixing model proposed. Clearly an exact solution of this complex thermal problem is not possible at present. Instead, we consider an empirical working model to account for the two thermal minima, which takes into consideration the preferential subaxial flow of plume-derived magma (or slush), its progressive cooling, fractional crystallisation and mixing with LILE-depleted magmas along the flow path.

Let the cartesian coordinate x be the horizontal direction along the ridge axis, z the depth and y the horizontal direction perpendicular to the ridge axis. Visualise an elongated magma chamber near the base of the crust beneath the ridge axis (Fig. 4). The magma chamber is fed in part by sub-horizontal flow of plume-derived magma A, whose flux F_A per unit length x decreases in intensity along the axis x, and in part fed from below by magma B from the LILE-depleted source, with a flux per unit length F_B increasing in intensity along the axis x. Mixing of the two types of magmas occurs within the magma chamber. The mixing proportions along x can be expressed in terms of the function

$$S(x) = F_A(x)/F_A(x) + F_B(x) \quad (1)$$

We set $x = 0$ at the periphery of the plume (chosen arbitrarily) and $x = L$ where the negative La/Sm and $^{206}Pb/^{204}Pb$ gradients[2] end some 400 km south-west of Iceland[1,2], or 1,000 km south-west of the Azores[21] (Figs 3 and 5). To satisfy the La/Sm and isotopic gradients along x, the function S must decrease from $S = 1$ at $x = 0$ to $S = 0$ at $x = L$. This presupposes that magma chambers over the plume are composed of melts derived entirely from the plume, whereas at $x > L$ magma is derived entirely from the LILE-depleted asthenosphere source[1,21]. The form of the function $S(x)$ between these two limits can be estimated by comparing the predicted La/Sm (or $^{206}Pb/^{204}Pb$) curve based on the binary mixing model, with the actual gradient observed using different empirical forms of $S(x)$ (Fig. 5). A linear function of the form

$$S = 1 - x/L \quad (2)$$

seems reasonable as a first order approximation. Finally we assume that the mixture of mass M per unit time and axial ridge length x (F_M) leaves the top of the magma chamber to generate new sea floor at constant rate along x. The system is assumed to be at a quasi-steady state, therefore

$$F_M = F_A(x) + F_B(x) \quad (3)$$

is constant and independent of x.

We assume that the net thermal result of the subaxial flow of plume-derived magma in the x–z plane is a decrease of the temperature $T_A(x)$ of this material from $T_{A,0}$ at $x = 0$ to $T_{A,L}$ at $x = L$. There are two reasons for making this assumption: First, the temperature of the country rock about a plume is likely to decrease outward[41]; second, the longer the path of travel of magma A outwards from the hotspot, the cooler it is likely to become. The temperature of LILE-depleted magma (T_B) is assumed to be constant along x, judging from the smaller range of liquidus temperature variations along normal ridge segments characterised by basalts with low La/Sm ratios (Fig. 3).

We further assume that: the two masses of magma type A and B have the same heat capacity (the heat capacity dependence on temperature is also ignored); and that the heat dissipated from the mixing of the two magma types is negligible. The net temperature of the magma mixture $T_M(x)$ after mixing of masses A and B is:

$$T_M(x) - S(x)T_A(x) + [1 - S(x)]T_B \quad (4)$$

The exact form of T_A with x is, of course, unknown. We can, however, set a minimum temperature $T_{A,L}$ of magma A at $x = L$ equal to 1,000 °C, so that the subaxial flow of magma can occur before complete solidification, whereas $T_{A,0}$ is taken as the olivine crystallisation temperature observed over Iceland and the Azores (Figs 3 and 5*b*). As a first approximation, we assume that T_A also varies linearly with x, that is,

$$T_A = T_{A,0} + bx \quad (5)$$

where the slope $b = T_{A,0} - T_{A,L}/L$. Combining equations (2), (4) and (5), we then obtain:

$$T_M = T_{A,0} + \left(\frac{T_B - T_{A,0}}{L} - b\right)x + \frac{bx^2}{L} \quad (6)$$

A broad minimum for T_M is predicted at $x = bL - T_B + T_{A,0}/2b$. The minimum occurs at $L/2$, if $T_B = T_{A,0}$ (Fig. 5). Higher order forms for $T_A(x)$ shown in Fig. 5 can displace the minimum to $x < L/2$, but do not really change the broad form of the minimum between $0 \leq x \leq L$ (Fig. 5). It seems, therefore, that the predictive curves based on such a mixing model cannot readily account for the rapid rise observed in T_M with x past the minimum (Fig. 5). The observed minimum south of Iceland and the Azores is narrower and more localised than the broad minimum predicted by a mixing model constructed on the basis of the boundary conditions imposed by the isotopic and La/Sm gradients.

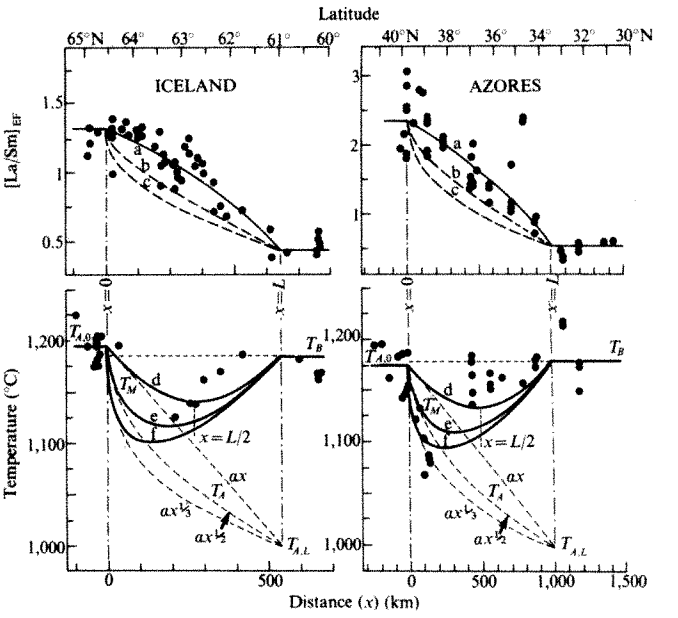

Fig. 5 Top, comparison of actual La/Sm variations with theoretical curve based on a binary magma mixing model assuming: curve a: $S = 1 - x/L$; curve b: $S = 1 - (x/L)^{1/2}$; curve c: $1 - (x/L)^{1/3}$. Average La and Sm content of end member melts are in p.p.m.: Iceland—$La_A = 6.9$; $La_B = 1.44$, $Sm_A = 3.7$; $Sm_B = 2.3$. Azores—$La_A = 15.0$, $La_B = 2.3$, $Sm_A = 4.5$, $Sm_B = 3.1$. Bottom, comparison of: predicted temperature of mix-magma M, based on the binary magma mixing model (lines), with calculated temperature based on Mg partitioning between olivine and glass (●). The following $T_A(x)$ functions (light dashed lines) were used to calculate curves T_M (heavy lines) for models d, e and f, respectively: Model d: $T_A = T_{A,0} + bx$ with $b = (1{,}000 - T_{A,0})/L$; Model e: $T_A = T_{A,0} + bx^{1/2}$ with $b = (1{,}000 - T_{A,0})/L^{1/2}$; Model f: $T_A = T_{A,0} + bx^{1/3}$ with $b = (1{,}000 - T_{A,0})/L^{1/3}$ All T_M models (d, e and f) were computed assuming $S = 1 - (x/L)$ correspond with solid line a on top diagram; and $T_{A,L} = 1{,}000$° C. Values for other parameters are: $L = 540$ km, $T_{A,0} = 1{,}195$ °C and $T_B = 1{,}184$ °C in the case of Iceland, and $L = 1{,}000$ km, $T_{A,0} = 1{,}175$ °C and $T_B = 1{,}178$ °C in the case of the Azores.

Conclusions

We conclude that subaxial flow of plume-derived magma and its progressive mixing with LILE-derived materials is apparently an oversimplification and cannot by itself account for the observed width of these two temperature minima. Additional tectonic

controls need to be invoked to explain the shape of these two minima. These include: (1) close-spaced fracture zone fabric near hotspots exposing magma to colder fault planes and further enhancing circulation of seawater within the crust and thus the efficiency of heat loss from the subaxial magma chamber, or (2) lack of a steady-state regime in the subaxial magma chamber beneath these two ridge segments, perhaps signalling recent rift jumping, or tectonic readjustment; or perhaps a simpler explanation (3) the two large temperature minima may reflect the temperature and composition of melts within two large subaxial magma chambers associated with the Iceland and Azores Plateaus.

We consider the cooling effects caused by close-spaced fracture zone fabric or the presence of a large magma chamber as the most probably dominant factors in producing the observed temperature minima south of Iceland and the Azores, as our empirical model alone, involving cooling by subaxial flow and mixing, provides too broad a minimum. However, this does not mean that subaxial flow and mixing does not occur, as it is also suggested by previous petrographic and geochemical evidence. We also suggest that the lower quenching temperatures of mid-ocean ridge basalts erupted near major fracture zones as compared with magma erupted along unfractured ridge segments may be caused by exposing magma chamber to colder fault planes due to seafloor spreading and by enhancing seawater circulation. The study of basalts collected at close intervals near other fracture zones and hotspots coupled with detailed state-of-the-art geophysical surveys should help in testing our inferences further.

Mesozoic ophiolite and blue amphibole on Timor and the dispersal of eastern Gondwanaland

Michael M. Earle
Department of Geology, Chelsea College, London, UK

A dismembered metamorphosed ophiolite on Timor is connected with Jurassic rifting of Australia's northwestern margin. The rift developed into an ocean basin which carried a microcontinental block northwards. During the middle to late Cretaceous the block accreted to South-east Asia and experienced a low grade metamorphism which generated crossitic amphibole.

IT is generally accepted that Timor is located in a collision zone between South-east Asia and the Australian continent, which separated from Gondwanaland during the Mesozoic. However, the place of origin of the different formations and tectonic units of Timor has been widely debated. Three principal models have been proposed that account for the tectonic development of Timor in radically different ways. Hence, its structure is regarded either as an imbricate subduction mélange of Australian components (the imbricate model)[1], a series of block-faulted Australian formations with surficial gravity slides (the autochthon model)[2], or as a number of overthrusted South-east Asian units on para-autochthonous Australian rocks (the overthrust model)[3].

These interpretations have not given adequate consideration to the importance of radiolarian cherts, a suite of metamorphosed igneous rocks, and reports of blue amphibole on Timor: these key elements can unravel the tectonic history of the island. A reappraisal of such data is used here to develop a new model.

Stratigraphic units and their relationships

The Lolotoi Unit is one of the main structural components of Timor. It comprises a diverse assemblage of ?Precambrian to Miocene age rocks[3]. The unit includes the Palelo Group and the Lolotoi Complex. The latter replaces and combines two lithostratigraphic groups—the crystalline schists and ophiolite–spilite complex (Fig. 1). These informal terms are used here.

The crystalline schists are divisible into a low grade younger component and a higher grade older component[4–6]. The older element is polymetamorphic and dominated by primary amphibolite facies assemblages. Semi-pelitic gneisses can contain a kyanite–staurolite–garnet paragenesis[7], typical of intermediate pressure and temperature conditions of regional metamorphism. The monometamorphic younger component is characterised by greenschist facies and lower grade mineral assemblages. Relict clastic and igneous minerals and textures are frequently preserved in the least altered rocks[4]. Typical lithologies include Mn-rich metachert, greenstone (such as spilite) and sericitic phyllite. The older component shows abundant evidence of widespread greenschist facies retrogression[8], possibly associated with the metamorphism which affected the

© 1979 Macmillan Journals Ltd

low grade rocks[6]. In several areas of Western Timor the crystalline schists are overlain unconformably by the Palelo Group (Fig. 1). This comprises a lower series which contains radiolarian cherts and altered basaltic rocks, and an upper part (the Haulasi Formation) dominated by flysch-type deposits.

There is sufficient field and petrographic evidence to demonstrate that the low grade crystalline schists of the Miomaffo district of Western Timor[4] are closely related to the lower Palelo, and that the ophiolite–spilite complex is broadly coeval with both. Spilite and keratophyre occur in the lower Palelo and low grade component of the Lolotoi Complex. Volcanic breccias near the base of the lower Palelo contain clasts of metamorphosed and strongly deformed basalts, presumably eroded from the low grade rocks, together with less-deformed and metamorphosed basalt clasts derived from interlayered flows. The lower Palelo itself is weakly metamorphosed and often strongly deformed[4]. Igneous activity and deposition were evidently broadly contemporaneous with, but outlasted by, metamorphism and deformation.

Cherts of the lower Palelo contain radiolaria of late Jurassic to early Cretaceous type, while limestones near the top of the sequence contain foraminifera of Aptian to Turonian age[9]. The occurrence of apparently related igneous rocks within the lower Palelo, ophiolite–spilite complex and low grade crystalline schists implies a Jurassic to Cretaceous age for the entire section.

The ophiolite–spilite complex includes gabbroic rocks and extensive masses of ultramafics, which show varying degrees of deformation and metamorphism. Published evidence suggests that serpentinite underlies the crystalline schists in the Mutis[7,10] and Miomaffo[4] districts. In other areas, however, serpentinite is intercalated with, or rests on top of, the schists[8,11]. All cases lack a high temperature thermal aureole and the ultramafics are generally strongly deformed. The ophiolite–spilite complex is older than the unmetamorphosed Haulasi Formation, in which clasts of the complex are found[7]. The tectono-metamorphic episode which affected the complex and the lower Palelo is thus bracketed between the Upper Jurassic and Upper Cretaceous.

The Boi Massif of Western Timor is composed of biotite–garnet–gneiss, serpentinite, metagabbro and amphibolite gneiss[11]. Homogeneous metagabbro is transitional between an interlayered sequence of amphibolite and metagabbro. This unit contains concordant intercalations of high-grade metasedimentary gneiss. Thin sections of the gneiss show sillimanite pseudomorphing biotite, and polygonal aggregates of cordierite and hercynite replacing biotite, garnet and sillimanite. The mineral assemblages record a temperature increase to around 700 °C and a pressure decrease equivalent to an uplift of over 7 km (ref. 11). I consider that intrusion of a gabbroic mass caused a thermal overprint during uplift of the lower continental crust. The pelitic gneiss was already regionally metamorphosed, but emplacement of the gabbro preceeded further metamorphism and deformation. If the gabbro is related to the ophiolite–spilite complex, this provides additional evidence for Jurassic–Cretaceous 'orogenic' events within the Lolotoi Unit.

The Haulasi Formation is a late Cretaceous to Palaeocene flysch sequence which contains clasts derived from the lower Palelo, crystalline schists and ophiolite–spilite complex[4,7]. There are also fragments of vesicular basalt which resemble alkaline lavas in the Permian Maubisse Formation of Timor.

The Lolotoi Complex and Palelo Group are intimately related. If they formed part of the northwestern margin of Gondwanaland, it should be possible to correlate their development with the geology of subsurface rocks to the south of Timor, and with Australian shelf and rise deposits which outcrop on the island. Recent marine and on-land investigations have shown that Australian continental crust underlies the Timor Sea[12] and most, if not all, of Timor[13]. Published accounts[14–16] of the Bonaparte Gulf and Wharton basins (Fig. 2) are used as a basis for the following discussion.

Pre-middle Jurassic correlation

It is generally agreed that the northwestern Australian shelf became fragmented by rifting and major uplift in the late Carboniferous. This exposed Precambrian rocks, on which were deposited late Carboniferous to late Permian sediments. This sequence has been considered as a lateral equivalent of the 'Permian' Aileu and Permian Maubisse formations of Timor[17]. The latter contains rift-type alkaline basalts[18] which are similar to those in the Australian facies Cribas Formation of Timor[17]. It has been suggested that reefal carbonates of the Maubisse Formation might have developed on a basement high near the northern margin of Australia, this basement being represented by the Lolotoi Complex[17] (probably the older component of the crystalline schists).

In the Bonaparte Gulf Basin, late Carboniferous to early Triassic sedimentation is characterised by a series of marine transgressions and regressions. On Timor, the reported interlayering of the Maubisse Formation with Australian continental

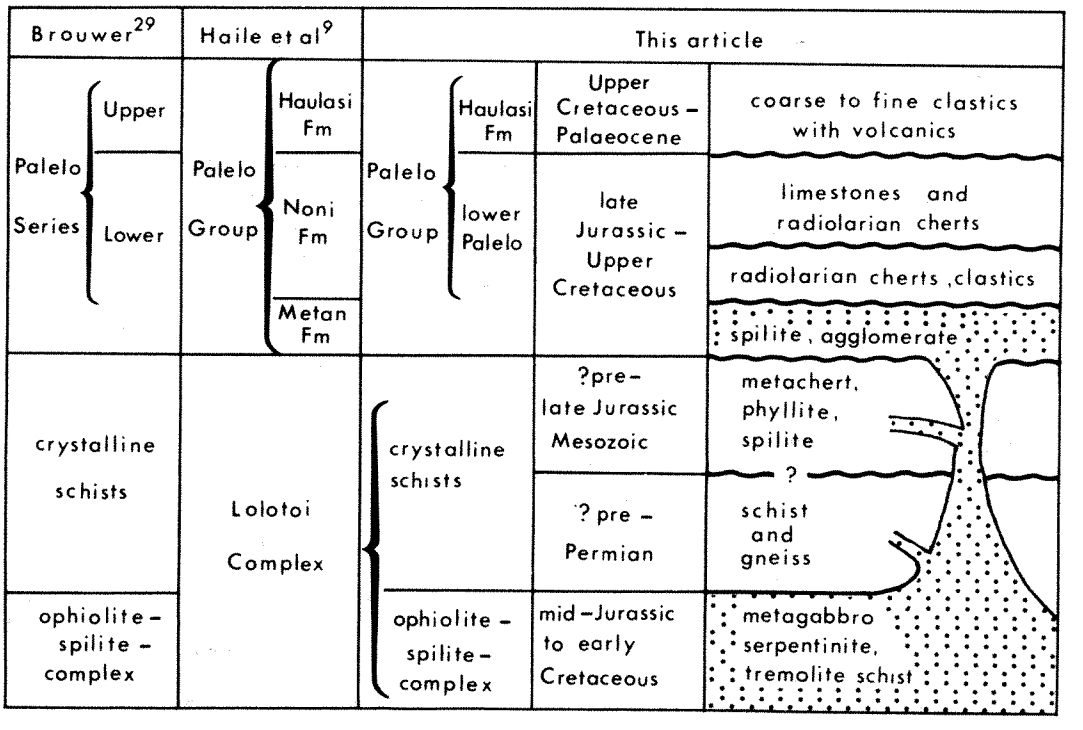

Fig. 1 Nomenclature and stratigraphy of pre-Eocene formations in the Lolotoi Unit.

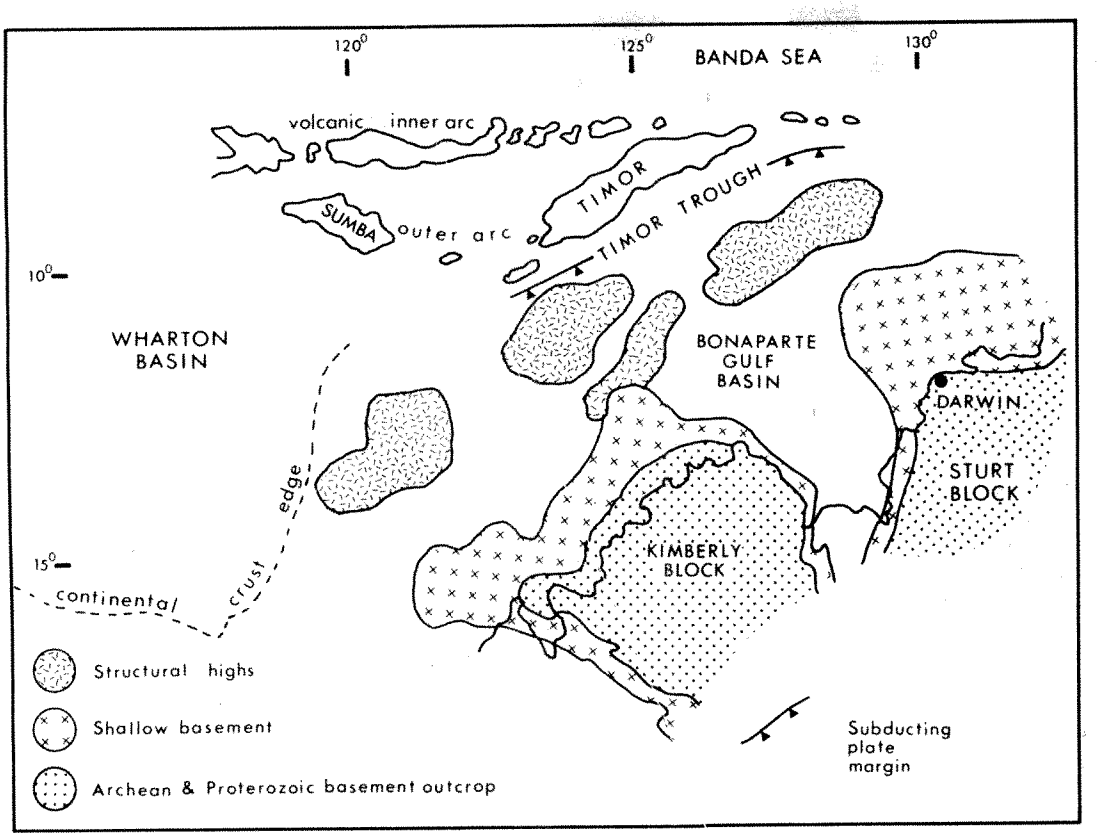

Fig. 2 Location map. Pre-Permian basement ornamented. Modified after Kaman-Kayes and Meyerhoff[19].

rise deposits (Cribas Formation)[17] is explicable in terms of these relative changes in sea level, which must have caused lateral facies changes. If these units intertwine it would prove that the Maubisse Formation was deposited on the northern margin of eastern Gondwanaland, and is not an allochthonous unit derived from South-east Asia as claimed by supporters of the overthrust model[3].

Middle Jurassic to middle Cretaceous correlation

In the Bonaparte Gulf Basin middle Jurassic sedimentation was interrupted by a major regional epeirogeny. Precambrian basement became exposed in highs of the horst and graben structures which developed before recommencement of deposition in the Upper Jurassic. Extensive areas of basaltic rocks on the north-west shelf[19] might be related to the formation of new ocean crust (the Indian Ocean)[15] and to uprisen mantle identified under the Bonaparte Gulf Basin[20]. It can be argued that part of the ophiolite–spilite complex represents middle to late Jurassic igneous activity associated with rifting of the Australian continental margin. Gabbroic magma invaded continental basement which was being uplifted and eroded as part of the rifting process.

In the Bonaparte Gulf Basin, Precambrian blocks supplied detritus until the Neocomian, when all traces of a northerly and northwesterly sediment source were eliminated, presumably by seafloor spreading[15,16]. The landmass which supplied the sediment has been identified as the submarine ridge which underlies Sumba and the islands towards Timor[20] (Fig. 2). Therefore, the rift possibly extended as far as Timor, and perhaps beyond. Rapid subsidence and a marine transgression in the Aptian allowed deposition of bathyal radiolaria- and glauconite-rich sediments in the Timor Sea region[15]. They rest uncomfortably on Upper Jurassic to Precambrian rocks, just as bathyal radiolarian cherts of the lower Palelo rest uncomforbably on the Lolotoi complex.

Thus far, the autochthon model[2,17] correlates well with the stratigraphic and structural development of Australia's north-western margin, but during the Cretaceous the two begin to diverge[21].

Middle Cretaceous to Palaeocene developments

Oceanic crust (the Indian Ocean) formed as a result of rifting which affected the continental crust right down the western side of Australia[22]. A separate plate, the Wharton Basin (Fig. 2), closed eastwards to a pole of rotation north of Timor[14]. This developing ocean basin must have transported rifted continental crust (the Western Landmass) northwards towards South-east Asia. It is inferred that this landmass included the Lolotoi Complex, and perhaps the Aileu and Maubisse formations. Using different criteria Barber[21] and Johnston[23] have proposed that a microcontinental block separated from Australia in the region of Timor, and accreted to South-east Asia during the Cretaceous.

The Haulasi Formation does not contain clasts derived from the Australian shelf and rise deposits of Timor[4,5]. This implies that throughout the Upper Cretaceous and Palaeocene the Lolotoi Unit was nowhere near the northern margin of Australia. A significant proportion of the fragments in the Haulasi Formation was derived from andesitic volcanics, and there are interlayered tuffs[4]. The minerals are often unaltered, in contrast with volcanic, schist and chert fragments eroded from the lower Palelo and Lolotoi Complex. The andesitic volcanics might therefore be products of middle to late Cretaceous subduction on the southern margin of South-east Asia.

Blue amphibole has been reported from Timor[4,5,7,18] and neighbouring Leti[24]. Petrographic descriptions of basaltic rocks from the Permian Maubisse Formation[18] and the ophiolite–spilite complex[7] show unequivocally the presence of crossite in these rocks. Crossite occurs as rims around, or as parallel intergrowths with, secondary green amphibole and primary pyroxene and brown amphibole. A crossite-bearing greenschist was found as a clast in the Haulasi Formation of the Miomaffo region[4]. If the amphibole has been identified correctly it implies that crossite grew before deposition of the Upper Cretaceous deposits, and after the formation of the ophiolite–spilite complex, which also contains crossite. This metamorphism possibly represents relatively high pressure–intermediate temperature conditions which could have been realised during accretion of the rifted crustal block against the leading margin of

South-east Asia. Subduction might have been short-lived so that isothermal surfaces were not sufficiently depressed to generate typical blueschist facies conditions. The postulated metamorphic episode is broadly contemporaneous with a major orogenic phase which produced greenschists on many other islands of the Outer Banda Arc[25]. The 'subducted' block was subjected to uplift and erosion, supplying detritus for the Haulasi Formation. This probably formed a prograding wedge of flysch deposited in the arc–trench gap[21].

Palaeocene to Recent developments

In several massifs of Western Timor, Eocene strata rest unconformably on the Palelo Group and/or the Lolotoi Complex[4,5,8,26,27]. The unconformable relationships are possibly connected with isostatic adjustments which probably attended cessation of seafloor spreading in the Wharton Basin (about 55 Myr ago[14]), and tectonic activity associated with back-arc rifting which generated the Banda Sea[28]. These events roughly coincide with the final separation of Australia from Antarctica during the Eocene, and with the culmination of a late Mesozoic to early Tertiary orogenic phase identified in the Outer Banda Arc and Eastern Sulawesi[25]. Presumably subduction must have occurred south of the microcontinent to explain the presence of andesitic volcanics in the Eocene formations[4,21]. Andesitic volcanics of Eocene age are also found on Sumba, which probably formed part of the same arc.

The Miocene to Recent history of Timor is well documented, but is open to radically different interpretations[1–3]. The ideas presented here include elements from each of the three main models. Sometime after the Oligocene, Australian continental crust reached the subduction zone. The outcrop trace of the plate boundary is currently located in the axis of the Timor Trough[1] (Fig.2). The Australian shelf and rise deposits which outcrop on Timor have thus been transferred to the overriding plate. Near the south coast of Western Timor, some of these deposits (the Kolbano Unit) are imbricated[3,10]. They form part of an imbricate wedge behind the trench axis, in accordance with the imbricate model[1]. Emplacement of overthrust units[3] from the north of this zone was caused by underthrusting of the advancing margin of Australia. They include units derived from the postulated microcontinent, as well as an olistostrome. Some of these formations originated from Gondwanaland, but the post-lower to middle Cretaceous sediments and volcanics were deposited on the southern margin of South-east Asia and in the ocean basin to the south.

Conclusions

The Lolotoi Unit contains a dismembered metamorphosed ophiolite which formed during the breakup of Australia's northwest shelf during the Jurassic.

A rifted block of continental crust drifted northwards from Australia, and accreted to South-east Asia during the Cretaceous.

Crossitic amphibole grew during low grade metamorphism within the block.

Subduction south of the block generated andesitic volcanics during the late Mesozoic and early Tertiary.

The block rifted from mainland South-east Asia and met with the northwards drifting Australian continent during the Neogene.

Australian deposits were transferred to the overriding plate and some became imbricated, whereas formations closer to the inner arc were emplaced southwards as overthrust units.

This work forms part of my PhD for which an NERC Studentship is acknowledged. I thank Drs A. Barber and A. Grady for stimulating discussions, and Professors D. Blundell and M. Audley-Charles for reviewing an earlier draft of the manuscript.

The transforming gene of Moloney murine sarcoma virus

Eli Canaani, Keith C. Robbins & Stuart A. Aaronson

Laboratory of Cellular and Molecular Biology, National Cancer Institute, Bethesda, Maryland 20014

A cleavage map of the Moloney murine sarcoma viral DNA was constructed and compared with that of a spontaneously occurring deletion mutant. By restriction enzyme analysis, it was shown that a region encompassing over 40% of the viral information was not essential for transformation or rescue of the deletion mutant. The transforming region was further localised by analysis of the transforming activity in tissue culture of isolated restriction fragments of linear double-stranded sarcoma viral DNA. In each case, DNA fragments that retained transforming activity preserved the cell-derived insertion sequences of the viral genome. Moreover, such transformants invariably expressed RNA specific to this region. By these two approaches, it was possible to demonstrate that the transforming region of the viral genome begins very near or within the cell-derived insertion sequences. Thus, the transforming gene of this mammalian sarcoma virus originates from within the mouse cell genome.

0028-0836/79/470378-04$01.00

RNA-CONTAINING sarcoma viruses that transform fibroblasts in tissue culture and induce solid tumours *in vivo* have been isolated from several mammalian species. These replication-defective viruses possess some genetic information of the type-C helper leukaemia virus isolated in association with them[1-3]. In addition, they contain non-helper viral sequences that are genetically related to cellular DNA of the species from which the sarcoma virus was derived[3-5]. By heteroduplex and oligonucleotide mapping, as well as by hybridisation techniques, non-helper viral sequences have been localised to a specific region of the sarcoma viral genome[6-8]. Thus, accumulating evidence suggests that mammalian sarcoma viruses may have arisen by recombination of a type-C helper virus with some cellular genetic information.

The replication-defective nature of mammalian sarcoma viruses has made genetic analysis of these viruses very difficult. Thus, it has not been possible to identify the region of the viral genome necessary for malignant transformation. Recently, the application of restriction endonuclease technology has led to generation of a physical map of the Moloney strain of murine sarcoma virus (MSV)[9]. In the present report, we have taken advantage of this biochemical approach to identify portions of the viral genome which can be deleted either in a naturally occurring mutant or in a restriction enzyme cleavage product, without affecting the transforming ability of the genome. By this strategy, it has been possible to identify and map directly the transformation-inducing information of MSV. The present findings have implications concerning the origin of transforming genes of mammalian sarcoma viruses.

Comparison of the physical map of a transforming deletion mutant with parental MSV-124 DNA

The major species of viral DNA in NIH/3T3 cells newly infected with the 124 strain[10] of MSV is a linear double-stranded molecule, postulated to be a complete transcript of MSV RNA[9]. Several restriction endonucleases cut this DNA, and a preliminary physical map of the MSV genome has been constructed[9]. Using the superior Southern technique of direct transfer of DNA fragments from agarose gels to nitrocellulose sheets[11], we refined and extended this map. Linear MSV-124 DNA was purified from infected cells and digested with several restriction endonucleases. The resulting fragments were fractionated on agarose gels, blotted onto nitrocellulose sheets, hybridised to ^{32}P-labelled viral complementary DNA (cDNA) and autoradiographed.

Linear MSV-124 DNA, with a molecular weight (MW) of $3.65 \pm 0.1 \times 10^6$, was cleaved by *Xho*I enzyme (Fig. 1*a*) into two fragments of MWs 2.4×10^6 and 1.25×10^6. Digestion with *Sal*I endonuclease (Fig. 1*b*) generated fragments of MWs 1.85×10^6 and 1.75×10^6. Digestion with *Bgl*II enzyme (Fig. 1*c*) produced two fragments of MWs 2.25×10^6 and 1.35×10^6. *Bgl*I (Fig. 1*d*) cut the DNA into fragments of MWs 2.35×10^6, 1.05×10^6 and 0.25×10^6. *Xba*I digestion (Fig. 1*e*) yielded fragments of MWs 2.4×10^6 and 1.25×10^6. The cleavage products of MSV DNA digested with *Hin*cII, *Hae*II and *Hin*dIII enzymes have been reported elsewhere[9]. More accurate determination of the size of the different fragments by the blotting method showed that *Hin*cII endonuclease cleaved the DNA into fragments of MWs 1.7×10^6, 1.05×10^6 and 0.85×10^6; *Hae*II enzyme cut MSV DNA into three fragments of MWs 2.4×10^6, 0.95×10^6 and 0.3×10^6; finally, *Hin*dIII enzyme cleaved the DNA into fragments of MWs 3.1×10^6 and 0.55×10^6.

The cleavage sites of *Hin*dIII and *Hin*cII enzymes on MSV-124 DNA were orientated with respect to the 3′ and 5′ ends of the viral RNA[9]. By a series of double digestions (not shown), it was possible to order the different cleavage sites of the enzymes above into a precise and detailed physical map of MSV DNA (Fig. 2).

We have recently isolated a series of transforming deletion mutants of MSV-124 following serial passage of the parental virus in mouse cells (E.C., K.C.R. and S.A.A., in preparation). Among the mutants analysed, MSV-124 clone 14 was found to have the smallest genome, composed of approximately 3,600 nucleotides. This viral genome was rescued from nonproductively transformed NRK cells by superinfection with a heterologous helper virus, woolly monkey type-C virus. The rescued virus was then used to infect NRK cells so as to obtain unintegrated viral DNA. The linear form of MSV-124 clone 14 viral DNA (Fig. 1*f*), which has a MW of 2.25×10^6, was analysed for its susceptibility to those restriction enzymes used for mapping the parental viral genome.

*Xho*I, *Sal*I and *Bgl*II enzymes (Fig. 1*g*, *h*, *i* respectively) did not cleave MSV-124 clone 14 DNA, indicating the lack of cleavage sites for these enzymes in the mutant viral DNA. The *Hae*II enzyme (Fig. 1*l*) produced fragments of MWs 1.30×10^6 and 0.95×10^6, whereas *Bgl*I digestion (Fig. 1*j*) generated two

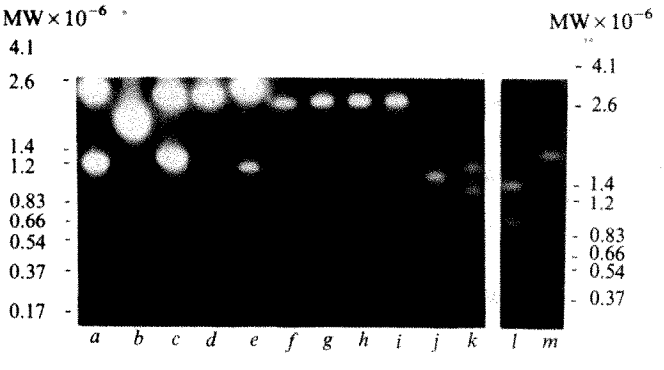

Fig. 1 Analysis of intact and endonuclease-digested MSV-124 and MSV-124 clone 14 DNAs. Linear MSV DNA was obtained from NIH/3T3 cells infected with the 124 strain of MSV or from NRK cells infected with MSV-124 clone 14. About 14 h after infection Hirt supernatant DNA was prepared by a modification of the Hirt procedure[28], and linear MSV DNA was further purified by sucrose gradient centrifugation[9]. Aliquots (2-μg) of MSV-124 DNA corresponding to the amount extracted from 5×10^6 cells, were incubated with endonucleases *Xho*I, *Sal*I, *Bgl*II, *Bgl*I and *Xba*I (lanes *a–e*, respectively). Similarly, 10-μg aliquots of MSV-124 clone 14 DNA corresponding to the amount extracted from 20×10^6 cells were sham treated (*f*) or incubated with enzymes *Xho*I, *Sal*I, *Bgl*II, *Bgl*I, *Xba*I, *Hae*II and *Hin*dIII (lanes *g–m*, respectively). Digestion buffers for *Hin*dIII and *Hae*II enzymes have been reported elsewhere[9]. *Bgl*I and *Bgl*II reaction mixtures contained 6 mM NaCl, 8 mM MgAc, 10 mM Tris-HCl, *p*H 7.5, 6 mM KCl (60 mM KCl for *Bgl*I), 2 mM dithiothreitol and 100 μg ml^{-1} bovine serum albumin (BSA). Reaction mixtures for *Sal*I, *Xho*I and *Xba*I digestions included 140 mM NaCl, 10 mM Tris-HCl, *p*H 7.9, 10 mM MgAc, 2 mM dithiothreitol and 100 μg ml^{-1} BSA. Digestions were carried out in 0.1 ml with the appropriate amounts of each enzyme (New England Biolabs). Following incubation for 2 h at 37 °C, DNAs were extracted with phenol, concentrated by alcohol precipitation, redissolved in 0.05 ml of 10 mM Tris-HCl, *p*H 7.5, and 1 mM EDTA and loaded on a horizontal slab gel of 1.4% agarose. Reference DNA markers of *Hin*dIII-digested λ phage DNA[29] and *Hae*III-digested ΦX174 phage DNA[30] were electrophoresed in parallel. The reference DNA markers at the left side apply to lanes *a–k*; those at the right side apply to lanes *l*, *m*. Electrophoresis was for 15 h at 30 V and 25 mA in a buffer containing 40 mM Tris-HCl, *p*H 7.7, 5 mM NaAc and 1 mM EDTA. The DNA was blotted from the gel and fixed onto nitrocellulose filters as described elsewhere[31]. The filters were incubated at 65 °C for 2 h with a solution of 3 × SSC, 0.02% BSA, 0.02% Ficoll and 0.02% polyvinylpyrrolidone, and further incubated at 65 °C for 2 h with the same solution supplemented with sheared native and denatured calf thymus DNA (50 μg ml^{-1} each), 0.1% SDS and 1 mM EDTA. The nitrocellulose sheet was then transferred to a hybridisation buffer containing 10^6 c.p.m. ml^{-1} of ^{32}P-labelled MSV(MuLV) cDNA. (This viral probe was prepared by reverse transcription of 30S MSV(MuLV)-124 RNA, primed with calf thymus DNA oligonucleotides. The reaction mixture included 20 mM Tris-HCl, *p*H 7.5, 20 mM KCl, 6 mM MgAc, 1 mM dithiothreitol, 18 μg ml^{-1} actinomycin D, 1 mM each of dATP, dGTP and dTTP, 0.5 mM ^{32}P-labelled dCTP at a specific activity of 2–3,000 Ci mmol^{-1} (Amersham/Searle), 10 μg ml^{-1} viral RNA, 1 mg ml^{-1} calf thymus DNA oligonucleotides[32] and purified avian myoblastosis viral reverse transcriptase. Following incubation for 3 h at 37 °C, the cDNA was deproteinised and treated with alkaline to remove viral RNA.) Following hybridisation at 65 °C for 40 h, the strips were washed for 1 h at 65 °C with five changes of hybridisation buffer without cDNA and then washed for 30 min at 65 °C with a solution of 0.1 SSC, 0.1% SDS. The filters were then dipped in 3 mM Tris at *p*H 9.3 at 4 °C and finally rinsed in 1 M NH_4Ac and dried. Strips were mounted on Whatman paper and subjected to autoradiography (Kodak X-Omat R film) for 24 h at room temperature. The small fragments of MN 0.25×10^6 and 0.55×10^6 in lanes *d* and *m* are difficult to visualise in this figure.

fragments of MW 1.1×10^6, which were indistinguishable in their electrophoretic mobility. These results indicated that the DNA of the deletion mutant retained only one of the two cleavage sites for both *Hae*II and *Bgl*I. Finally, the DNA was cleaved by *Xba*I (Fig. 1*k*) to fragments of MWs 1.25×10^6 and 1.0×10^6, and by *Hin*dIII (Fig. 1*m*) to yield fragments of MWs 1.7×10^6 and 0.55×10^6. Therefore, *Xba*I and *Hin*dIII sites were retained in MSV-124 clone 14 DNA. These series of digestions enabled us to construct the physical map of the deletion mutant and to define precisely the portion of MSV-124 DNA deleted during generation of the mutant (Fig. 2). This segment of 2,200 nucleotides resided between, but did not include, the *Xba*I and the 5′-terminal *Hae*II sites of MSV-124 DNA. The deletion mutant was efficiently rescued and possessed transforming activity of high titre, indicating that the deleted segment of the MSV-124 genome is not required for virus replication or cell transformation.

Identification of infectious MSV DNA

An independent approach for defining the region of the viral genome required for cell transformation involved the use of intact and fragmented viral DNA in transfection assays. First, we investigated whether *in vivo* synthesised MSV-124 DNA possessed biological activity. Low molecular weight DNA extracted from cells infected 14 h earlier with MSV(MuLV) was fractionated by agarose gel electrophoresis. The DNA was eluted from the gel slices and tested for focus-inducing activity by a modification of the Graham and von der Eb transfection method[12]. The transforming activity migrated as a single peak with a mobility slightly greater than that of a 4.1×10^6-MW linear marker DNA (Fig. 3). Thus, the focus-inducing activity in the Hirt supernatant consisted primarily of unintegrated viral DNA in the form of a linear double-stranded molecule of MW $3.7\pm0.2\times10^6$. We also analysed the Hirt supernatant DNA, fractionated by agarose gel electrophoresis, for the presence of infectious MuLV DNA. A single peak of reverse transcriptase-inducing activity was detected in the gel at a position of linear double-stranded DNA of MW $5.9\pm0.2\times10^6$ (Fig. 3), corresponding to the known MW of MuLV DNA[13,14].

Transformation by MSV-124 DNA restriction fragments

To establish the infectivity of DNA fragments and, thus, to localise further the region of the MSV genome responsible for transformation, MSV DNA was digested with *Xho*I, *Bgl*II, *Hpa*I or *Hin*dIII enzymes, and fractionated by agarose gel electrophoresis. DNA fragments were then extracted from the gel, and tested by transfection for transforming activity. The fragments were also subjected to agarose gel electrophoresis and blotting analysis to determine their purity. As shown in Table 1, much of the transforming activity of intact linear MSV-124 was retained after digestion with either *Xho*I or *Bgl*II enzymes. The focus-inducing ability was associated with the *Xho*IA and *Bgl*IIB DNA fragments, respectively (Table 1). Digestion of MSV-124 DNA with two enzymes, *Hpa*I and *Hin*dIII, which cut within the cellular insertion of MSV-124, abolished the transforming activity. As shown in Table 1, no focus-inducing ability was retained by either *Hin*dIIIA or *Hin*dIIIB fragments. Similarly, neither *Hpa*IA nor *Hpa*IB fragments retained biological activity.

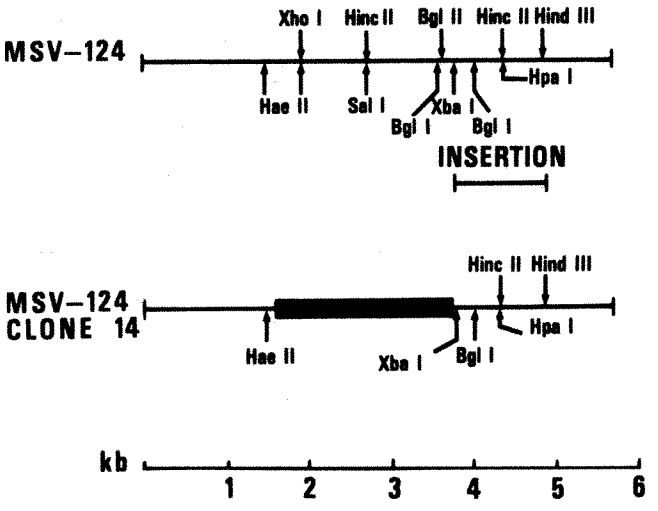

Fig. 2 Physical map of MSV-124 and MSV-124 clone 14 linear DNAs. The right-hand side represents the DNA region corresponding to the 3′ terminus of MSV RNA. The position of *Hpa*I cleavage site has been reported elsewhere[22]. The initial study on the topography of the cellular insertion in the MSV genome was made by Hu *et al.*[6]. The location and size of the insertion as shown here are based on more accurate recent data of G. Vande Woude and colleagues (personal communication) as well as our own results (Tronick *et al.*, in preparation).

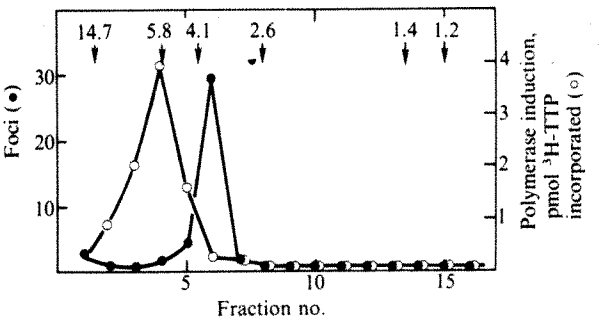

Fig. 3 Agarose gel electrophoresis of infectious MSV and MuLV DNA. Hirt supernatant DNA was prepared from cells infected with MSV-124 as described in Fig. 1. A 35-μg DNA aliquot, corresponding to that extracted from 3×10^7 infected cells, was fractionated by agarose gel electrophoresis as described in Fig. 1. DNA markers of *Hin*dIII-digested λ phage DNA were electrophoresed in parallel and are represented as MW$\times10^{-6}$. The DNA was extracted as described elsewhere[25] from 3-mm gel segments and used to transfect NIH/3T3 cells by modification of the Graham and van der Eb method[12]. Following sterilisation with alcohol, the DNA was redissolved in 0.05 ml of 0.1×SSC and 0.4 ml HEPES buffer, mixed with 25 μg of sheared calf thymus DNA and precipitated by addition of 2 M $CaCl_2$ to a final concentration of 125 mM. After 30 min, the precipitate (0.5 ml) was added to 100-mm Petri dish cultures of NIH/3T3 cells, seeded the previous day with 1×10^6 cells. After 20 min, 10 ml of growth medium were added and the cultures were incubated for an additional 3 h. Dishes were then rinsed twice with growth medium and exposed for 4 min to 5 ml of 15% glycerol in HEPES buffer (N. G. Copeland and G. M. Cooper, personal communication). Finally, the cultures were washed with growth medium and incubated for 10 d, at which time they were scored for focus formation and for release of virion-associated reverse transcriptase activity[33].

Expression of sarcoma viral information in cells transformed by MSV DNA fragments

Transformed foci induced by *Xho*IA or *Bgl*IIB MSV DNA fragments were isolated by the cloning cylinder technique, and several such focus-derived lines were grown to mass culture for further analysis. None of several individual transformants induced by each of the fragments released detectable levels of reverse transcriptase. These findings were not unexpected in view of the fact that these restriction enzymes inactivated the infectivity of helper viral DNA. By morphological criteria, cells transformed by either viral DNA fragment were indistinguishable from transformants induced by intact virus or linear viral DNA. The transformants consisted of round or spindle-shaped, highly refractile cells that grew to saturation densities ranging from 3 to 6×10^5 cells cm^{-2}, compared with 6×10^4 cells cm^{-2} for uninfected NIH/3T3 cells. Moreover, they formed colonies at high efficiency when suspended in soft agar and were tumorigenic in NIH/Swiss mice.

We next investigated cells transformed by individual MSV DNA fragments for expression of sarcoma viral RNA. *Xho*IA and *Bgl*IIB DNA fragments shared a segment of the viral genome, which included the region of MSV RNA previously shown to be MSV specific, that is, not shared with MuLV RNA[6].

Table 1 Transformation of NIH/3T3 cells by MSV DNA restriction fragments

MSV DNA	DNA extending (kilobase pairs)	DNA added (μg per plate)	Foci per plate Expt 1	Expt 2	Expt 3
Intact linear form	0–5.7	30	55	45	65
		15	34	ND	ND
Restriction fragment*					
*Xho*IA	1.9 –5.7	40	ND	25	38
B	0 –1.9	40	ND	0	0
*Bgl*IIA	0 –3.6	40	0	0	0
B	3.6 –5.7	40	11	32	43
*Hpa*IA	0 –4.3	40	ND	0	0
B	4.3 –5.7	40	ND	0	0
*Hin*dIIIA	0 –4.85	40	ND	0	0
B	4.85–5.7	40	ND	0	0

Transfections were carried out in 100-mm Petri dishes and focus formation assayed as described in Fig. 3 legend. ND, Not determined.

* 40 μg of linear viral DNA was digested with restriction endonucleases, deproteinised, precipitated with alcohol and fractionated by agarose gel electrophoresis. Extraction from gel segments was as previously reported[25]. The recovery of the different DNA fragments from the gel was comparable as determined by blotting analysis.

Thus, we reasoned that an MSV-specific cDNA probe could be used to detect transcription of *Xho*IA and *Bgl*IIB DNA. Such a probe was prepared from a DNA transcript of MSV(MuLV) RNA by a series of preparative hybridisations. This involved selection for MSV sequences by hybridisation with MSV(FeLV) RNA followed by selection against sequences annealing to MuLV RNA[15].

To characterise the MSV-specific probe, we determined its ability to anneal to MSV and MuLV sequences, respectively. As shown in Fig. 4*a*, RNA of NIH/3T3 or NRK cells nonproductively transformed by MSV-124 hybridised the entire MSV-specific cDNA, whereas RNA of NIH/3T3 or NRK cells infected with MuLV annealed no more than 6% of the same probe. Further, by analysis of hybridisation of the probe to different MSV DNA fragments (not shown), it was possible to conclude that the MSV-specific cDNA was composed predominantly of sequences included in the region of the genome containing non-helper viral sequences[6]. Finally, the cellular origin of the sequences in the MSV specific cDNA[3,15] was shown by the ability of normal NIH/Swiss embryo cellular DNA to anneal the probe to a large extent with kinetics reflecting single copy representation (Fig. 4*b*).

Cellular RNAs of transformants induced by MSV DNA fragments were next tested for their ability to anneal the MSV-specific cDNA probe. As shown in Fig. 5, RNAs of representative *Xho*IA and *Bgl*IIB transformants hybridised more than 40% and 60% of the probe, respectively, at C_rt values above 7×10^3. Similar results were obtained with each of several individual transformants induced by these two DNA fragments. In contrast, RNA of neither NIH/3T3 cells nor NIH/3T3 cells transformed by another murine sarcoma virus, Kirsten MSV, contained detectable amounts of RNA complementary to the MSV-specific cDNA (Fig. 5). These results establish that cells scored as transformed following transfection with MSV DNA fragments expressed MSV-specific RNA.

Comparison of transformants induced by MSV DNA fragments and intact viral DNA

It is well established that replication-defective mammalian sarcoma viruses can be rescued from nonproductively transformed cells by a type-C helper virus[16–18]. It was of interest to determine whether focus-forming activity could be rescued from cells transformed by MSV DNA restriction fragments. Following MuLV superinfection, none of several individual transformants induced by *Xho*IA or *Bgl*IIB fragments released detectable focus-forming virus (Table 2). In the same conditions, high-titre MSV was released by cells transformed by intact MSV-124 or MSV-124 clone 14 virus, or by linear MSV-124 DNA. The amounts of helper virus produced were comparable for all cell lines tested. These results established that only those transformants induced by the MSV DNA fragments lacked rescuable focus-forming activity.

Some MSV strains code for helper virus *gag* gene products[1,19,20]. By analogy with the avian type-C viral genome[21] the *gag* gene of the mammalian type-C virus is presumed to be localised to the 5′ region of the viral genome. By heteroduplex mapping, MSV has been shown to contain a long region of helper viral sequence homology beginning at the 5′ end and extending approximately 2.25 kilobases[6]. Thus, it is likely that this region contains the helper viral sequences coding for *gag* gene proteins.

To determine whether *gag* gene expression might serve as a useful marker of the intact MSV 124 genome, we analysed several MSV 124 and MSV-124 clone 14 nonproducer transformants for expression of the N-terminal *gag* gene protein, p15 (ref. 19). As shown in Table 2, p 15 was detected at levels of 30–500 ng per mg cellular protein in each virus nonproducer transformant analysed. Similarly, nonproducer transformants induced by linear MSV DNA expressed p15. As the *Bgl*IIB DNA and *Xho*IA fragments originate about 3.6 and 1.9 kilobase pairs from the 5′ terminus of the MSV genome, respectively, it was considered unlikely that transformants induced by these fragments would possess the coding capacity for MuLV p15. As shown in Table 2, none of the transformants induced by *Bgl*IIB or *Xho*IA DNA expressed detectable levels of this virus-coded protein. These findings are consistent with the assignment of transforming activity to *Xho*I and to *Bgl*II DNA fragments other than those encompassing the 5′ terminus of the transforming virus genome.

The transforming gene of mouse sarcoma virus

In the present studies, two independent approaches have been used to localise the region of the Moloney MSV genome

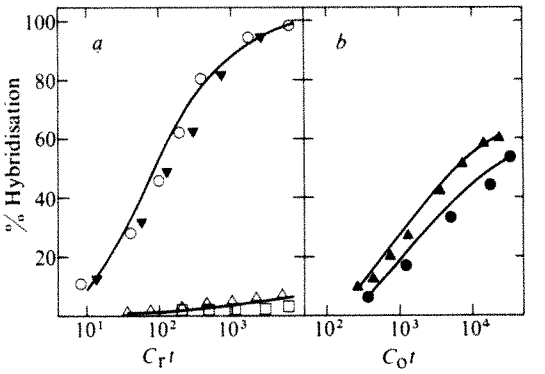

Fig. 4 Characterisation of MSV specific cDNA probe. MSV (MuLV) cDNA was prepared as described in Fig. 1 legend. MSV-specific cDNA was obtained from it by a series of preparative hybridisations in which cDNA sequences unique to MSV were selected by hybridisation with MSV(FeLV) RNA, followed by hydroxyapatite chromatography. Sequences in the cDNA shared with MuLV were removed by two cycles of hydroxyapatite after annealing with MuLV RNA[15]. Cellular RNA was purified by the method of Scherrer[34]. Cellular DNA was prepared as described elsewhere[35], and sheared to a mean size of 6–8S. Unique sequence cellular DNA was similarly prepared and highly reiterated sequences annealing at a C_0t of 50 mol $s\,l^{-1}$ were removed by fractionation on hydroxyapatite. For cDNA–RNA hybridisation, varying amounts of RNA were annealed to 500 c.p.m. of ^{32}P-labelled MSV-specific cDNA in 0.05 ml hybridisation mixtures containing 10 mM Tris-HCl, *p*H 7.5, 1 mM EDTA and 0.6 M NaCl. After incubation for 18–48 h at 68 °C, hybrid formation was determined with S_1 nuclease. cDNA–DNA annealing and hybrid detection were carried out in similar conditions except that the RNA was substituted with cellular DNA at 4 mg ml^{-1}, and the hybridisation was carried out for varying times at 62 °C. *a*, Hybridisation of MSV-specific cDNA by cellular RNAs of MSV-124 transformed nonproducer NIH/3T3 (○); MSV-124-transformed nonproducer NRK (▼); Moloney MuLV-infected NIH/3T3 (△); Moloney MuLV-infected NRK (□). *b*, Hybridisation of MSV-specific cDNA by NIH Swiss mouse embryo DNA (●). The rate of this reaction was compared with the rate of hybridisation of tracer amounts of mouse unique sequence cell ^{3}H-DNA by its homologous unlabelled cell DNA (▲).

involved in transformation. By comparison of the restriction endonuclease map of the viral genome with that of a deletion mutant isolated from the Moloney MSV stock following several cycles of virus passage, a large region encompassing almost 40% of the viral information was shown to be nonessential for transformation or virus replication. The dispensable sequences extend 1.5–3.7 kilobase pairs on MSV-124 DNA. Analysis of the transforming activity of subgenomic DNA fragments isolated following restriction endonuclease cleavage of linear viral DNA revealed that the *Xho*IA and the *Bgl*IIB DNA fragments were highly active. The *Bgl*IIB fragment, which is the smaller of the two, extends 3.6–5.7 kilobase pairs and therefore lacks not only the 5′ terminus, but also about two-thirds of the viral genome. Thus, the evidence obtained by these two approaches fixes the 5′ extent of the maximum information necessary for transformation at or near the *Xba*I site, about 3.7 kilobase pairs from the 5′ terminus.

In contrast to our findings that most of the transforming activity of the viral DNA was preserved after cleavage with *Xho*I or *Bgl*II enzymes, transforming activity was abolished after digestion with *Hpa*I or *Hin*dIII enzymes. As the first enzyme cleaves in the middle and the latter cuts near the 3′ terminus of the cellular insertion sequences, these findings suggest that the information within a large portion of the cellular insertion are essential for transformation.

Andersson *et al.*[22] have recently shown that subgenomic fragments of *in vitro* synthesised MSV DNA retain transforming activity. Their smallest transforming fragment spanned a region of 2.1 kilobase pairs encompassed by the *Sal*I and *Hin*dIII restriction sites. This fragment contains 0.9 kilobase pairs of additional genetic information at the 5′ end compared with the DNA segment shown here to be required for cell transformation. The preservation of transforming activity following *Hin*dIII digestion of the viral genome as reported by Andersson *et al.*[22] is in contrast to our results. The reasons for this discrepancy are unclear. We have also encountered at low frequency transformants induced by MSV DNA fragments generated by digestion with an enzyme, *Hin*cII, which cuts the viral genome within the insertion sequences. However, when these transformants were analysed, they were found to express viral RNA complementary to portions of the viral genome in addition to the *Hin*cIIB transforming fragment (spanning 2.7–4.4 kilobase pairs). We were thus unable to conclude that these transformants were induced by the *Hin*cIIB fragment alone.

Table 2 Properties of NIH/3T3 cells transformed by MSV DNA restriction fragment

NIH/3T3 cell line	Sarcoma virus rescue* No. positive/ No. tested	Sarcoma virus rescue* Range (FFU ml^{-1})	M-MuLV p15 expression† No. positive/ No. tested	M-MuLV p15 expression† Range (ng per mg cell protein)
Transformed by MSV-124 virus	4/4	$10^{5.4}$–$10^{5.8}$	4/4	30–500
MSV-124 clone 14 virus	9/9	$10^{5.4}$–$10^{5.9}$	3/3	30–200
Linear DNA MSV-124	5/5	$10^{5.6}$–$10^{5.9}$	2/2	50–100
*Bgl*IIB DNA MSV-124	0/5	$<10^{0}$	0/5	<5
*Xho*IA DNA	0/2	$<10^{0}$	0/2	<5
Uninfected	—	$<10^{0}$	—	<5

* Around 10 days after infection of each cell line with 10^5 XC plaque-forming units (PFU) of MuLV, 0.5 ml of tissue culture fluids were assayed for focus-forming units (FFU)[1] and XC PFU[26] on NIH/3T3 cells as previously described.

† Cultures were sonicated for 1 min in the presence of 10 mM Tris-HCl, *p*H 7.8, containing 200 mM NaCl, 0.05 mM EDTA, and 1% (v/v) Triton X-100. The soluble protein fraction, obtained from the supernatant of a 150,000*g* centrifugation, was tested at twofold serial dilution in an homologous Moloney-MuLV p15 radioimmunoassay as previously described[19]. Levels of viral protein expression were calculated on the basis of (1) the amount of cellular protein, determined according to Lowry *et al.*[27], and (2) the sensitivity of the p15 immunoassay.

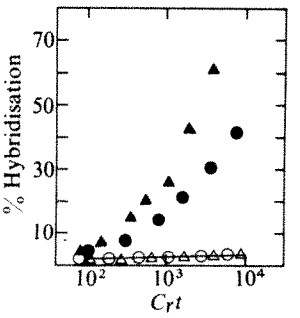

Fig. 5 Expression of MSV-specific RNA in cells transformed by MSV DNA fragments. Hybridisation was carried out as described in Fig. 4 legend. MSV-specific cDNA was hybridised to cellular RNA from uninfected NIH/3T3 cells (△), NIH/3T3 cells transformed by the *Bgl*IIB MSV DNA fragment (▲), NIH/3T3 cells transformed by the *Xho*IA MSV DNA fragment (●), and NIH/3T3 cells transformed by Kirsten MSV (○).

Transformants induced by *Xho*IA and *Bgl*IIB fragments were shown to express RNA specific to the region of the MSV genome from which the fragments were derived. Moreover, the transformants tested lacked the ability of the parental sarcoma virus to express translational products of the 5′ region of the viral genome. The lack of recovery of focus-forming activity from transformants induced by DNA restriction fragments provided even more striking evidence of the phenotypic differences between these cells and transformants induced by virus or intact linear viral DNA. The lack of rescuability of focus-forming activity from transformants caused by MSV DNA fragments remains to be resolved, but may reflect a requirement for preservation of termini of the viral genome for efficient virus rescue and for biological activity of the viral RNA. This possibility is favoured by our findings that the deletion mutant, which lacked a large portion of viral information but preserved both termini, was efficiently rescued and demonstrated transforming activity of high titre.

It has been shown that the genomes of replication-competent type-C viruses of both avian and mammalian origin possess leader sequences originating at their 5′ terminus. These leader sequences become associated with messenger RNAs originating from distal portions of the viral genome[23,24]. Neither of the *Bgl*IIB or *Xho*IA MSV DNA fragments with transforming activity contained 5′-terminal sequences of the parental viral genome. It can be argued that MuLV DNA present in the MSV DNA preparations may have acted to complement transformation by MSV DNA. However, we consider this highly unlikely as MuLV DNA represented only a small fraction (5%) of the viral DNA. Moreover, such MuLV DNA would have to co-migrage with each of the different-sized MSV-transforming DNA fragments used for transfection. Presumably, therefore, viral RNAs transcribed from the transforming MSV DNA fragments of *Bgl*II or *Xho*IA either do not contain leader sequences or derive such a sequence from cellular DNA.

The present studies demonstrate that the helper viral sequences extending from the 5′ end of the cellular insert to the 5′ end of the MSV genome were not essential for transformation. In contrast, cleavage within the cellular insertion inactivated transforming activity. These findings establish that viral information required for transformation by this mammalian sarcoma virus originates from within the cellular genome. By recombinant DNA techniques, it should be possible to obtain a homogeneous population of MSV DNA molecules for further analysis of these sequences. Such techniques should also allow the isolation, amplification and sequencing of the cellular gene homologous to the transforming region of MSV. These studies may make it possible to determine whether the MSV-transforming gene originates from an altered cellular gene or from one that is normally only expressed before the development of the fully differentiated state.

We thank Marcia Bolton and Claire Dunn for assistance, Dr Mariano Barbacid for helpful discussion, and Dr George Vande Woude for communicating results before their publication. This work was supported in part by PHS Contract N01-CP-61024 of the NCI.

Does PSR0329+54 have companions?

M. Demiański & M. Prószyński

Institute of Theoretical Physics, Warsaw University, 00-681 Warsaw, Hoża 69, Poland

An extensive pulse timing programme has been carried out over the past 10 years for several pulsars[1–5]. The timing observations revealed a wide range of different effects such as glitches, noise in the pulsar rotation and unexpectedly large second time derivatives of the rotation frequency. We suggest here that these unexpectedly large values of $\ddot{\nu}$ may be caused by a binary motion with an orbital period, P_b, longer than the span of timing observations. Even a distant planet of a relatively low mass ($100\,M_\oplus$ for $P_b = 50$ yr) would influence $\ddot{\nu}$. In the case of PSR0329+54, besides a large $\ddot{\nu}$ term, a quasi-sinusoidal modulation shows up in timing residuals. This 3-yr periodicity may be caused by: (1) a change in pulse shape, (2) precession of a magnetic dipole axis, or (3) a small planet ($m = 0.06 - 0.57\,M_\oplus$) orbiting the pulsar.

All known pulsars are slowing down at a rate conveniently described by the braking index $n = \nu\ddot{\nu}/\dot{\nu}^2$, where ν is the pulsar frequency. All models of energy loss proposed so far give $n \sim 3$. Using the observed values of ν and $\dot{\nu}$ and assuming $n = 3$ it is easy to estimate $\ddot{\nu}$. It turns out that $\ddot{\nu}$ should be very small (except for the Crab pulsar) and therefore the pulse number at time t can be approximated by

$$N(t) = N_0 + \nu t + \tfrac{1}{2}\dot{\nu}t^2 \qquad (1)$$

However, unexpectedly large values of $\ddot{\nu}$ have been measured for 11 pulsars observed at Arecibo[1], and Helfand *et al.*[5] have discussed two other pulsars (PSR0611+22, PSR0823+26) belonging to this class. In addition, the residuals $N_{obs} - N(t_{obs})$ shown for PSR0329+54 and PSR1508+55 (refs 5, 6) also indicate the presence of the large $\ddot{\nu}$ term. Table 1 lists all these pulsars. It also includes the Crab pulsar, PSR0531+21, for which $\ddot{\nu}$ is large because of its very rapid slowdown.

Here we discuss some features of the timing data for PSR0329+54. The barycentric arrival times covering 8 yr of pulsar observations[5] at National Radio Astronomy Observatory and Five College Radio Astronomy Observatory were kindly supplied by Dr D. J. Helfand.

To determine $\ddot{\nu}$ we take

$$N(t) = N_0 + \nu t + \tfrac{1}{2}\dot{\nu}t^2 + \tfrac{1}{6}\ddot{\nu}t^3 \qquad (2)$$

The values of $\ddot{\nu}$ calculated from data covering the first 5, 6, 7 and whole 8 yr of observations are respectively $\ddot{\nu} \times 10^{25} = 0.66, 0.64, 0.48$ and $0.55\ \mathrm{s}^{-3}$. For the last 5 and 6 yr one gets $\ddot{\nu} \times 10^{25} = 0.94$ and $0.51\ \mathrm{s}^{-3}$. The value of $\ddot{\nu}$ does not depend strongly on the set of data. As our sets of data overlap, this cannot be treated as proof that the effect is a real one. In fact, it has been suggested[5,7,8] that the observed values of $\ddot{\nu}$ can result from a noise-type variation in the pulsar rotation. A random-walk type phenomenon in the phase, frequency and/or frequency derivative may lead to large values of $\ddot{\nu}$ when the span of timing data has a finite length.

To check the value of $\ddot{\nu}$ and to find whether it is a real effect, it is derived from independent sets of data; noise processes should give a normal distribution around $\ddot{\nu} = 0$. This procedure, however, cannot be applied to PSR0329+54 at present. A ratio of the change in the pulsar phase caused by the $\ddot{\nu}$ term after time Δt, $\Delta N = \ddot{\nu}(\Delta t)^3/6$, to the measurement uncertainty of the phase determination, $\Delta N = 7 \times 10^{-4}$, is poor for short Δt, hence fits over short spans give meaningless values of $\ddot{\nu}$ because an error assigned is of the order of the fitted value. Moreover a periodic component present in residuals (Fig. 1) strongly influences $\ddot{\nu}$ derived from spans shorter than ~5 yr. However, this analysis could be done successfully for pulsars with a larger $\ddot{\nu}$ term such as PSR0823+26. Unfortunately, at present we do not have data for other pulsars with large $\ddot{\nu}$.

If the large value of $\ddot{\nu}$ does represent a real property of some pulsars then one also has to accept large and sometimes negative values of the braking index as a real effect. Therefore, a

* An error quoted corresponds to two standard deviations in $\ddot{\nu}$.

theoretical explanation of this phenomenon is urgently needed.

The large value of $\ddot{\nu}$ derived from the data covering a finite span of time could result from: (1) long time scale irregularities of the pulsar rotation, or (2) from external perturbations such as orbital motion of the pulsar. Irregularities of rotation ('glitches') were observed for several pulsars but their characteristic relaxation times were not longer than a few hundred days. In the models of glitches considered so far it is assumed that the irregularities are caused by a sudden change in the moment of inertia of the neutron star[9,10]. In those models $\ddot{\nu}$ can be large but must be positive during the time of relaxation. Such behaviour was observed for the Vela pulsar after the glitch of September 1975 (ref. 11). For PSR0329+54 the large value of $\ddot{\nu}$ can be explained by this model if the glitch occurred before the discovery of the pulsar and if the relaxation time was longer than the time span of the data. However, it is not possible to say when such a glitch might have occurred. Note that the negative values of $\ddot{\nu}$ observed for some pulsars cannot be explained in this way. Another explanation of this phenomenon is due to Gullahorn and Rankin[12]. They suggest the long time scale (10^2–10^4 yr) variations in the pulsar braking torque. These variations, caused by varying interaction between pulsar and the medium in its vicinity, might give large values of $\ddot{\nu}$ of both signs.

The orbital motion of a pulsar with an orbital period longer than the span of timing observations is very difficult to detect because the effects caused by this motion are masked by the slowdown of the pulsar[13]. Even if ν and $\dot{\nu}$ are strongly influenced by such a motion their analysis cannot show the presence of a binary system unless $\dot{\nu} > 0$ (refs 13, 14).

This orbital motion can be detected more easily, even for a much lighter companion, by looking at higher derivatives of ν which can be drastically influenced by the orbital motion. Let us consider a pulsar moving on a circular orbit. The distance to the pulsar is $d = d_0 + A \sin(\omega t + \phi_0)$ with

$$A = \left[\frac{G}{\omega^2 (M+m)^2}\right]^{1/3} m \sin i,$$

M and m being the mass of the pulsar and its companion respectively. Suppose that during the period of observations $\omega t + \phi_0$ does not change significantly. If $\phi_0 \approx 0$ or π then $d - d_0$ can be approximated by $\pm A(\omega t - \frac{1}{6}\omega^3 t^3)$; if $\varphi_0 \approx \pi/2$ or $3\pi/2$ then $d - d_0 \approx \pm A(1 - \frac{1}{2}\omega^2 t^2)$. Thus, in the most favourable configurations the maximal contributions to ν, $\dot{\nu}$ and $\ddot{\nu}$ are given by $\Delta\nu = \pm\nu A\omega/c$, $\Delta\dot{\nu} = \pm\nu A\omega^2/c$, $\Delta\ddot{\nu} = \pm\nu A\omega^3/c$. If, for example, $P_{\rm orb} = 2\pi/\omega = 50$ yr, $M = 1M_\odot$, $\sin i = 1$ then for $m \ll M$ one gets $A = 6.1\times10^8\ (m/M_\oplus)$ cm, $\Delta\nu/\nu = \pm 8.1\times10^{-11}\ (m/M_\oplus)\ s^{-1}$, $\Delta\dot{\nu}/\nu = \pm 3.2\times10^{-19}(m/M_\oplus)\ s^{-2}$ and $\Delta\ddot{\nu}/\nu = \pm 1.3\times10^{-27}(m/M_\oplus)\ s^{-3}$, where $M_\oplus$ is the mass of the Earth.

Comparing the above values with those in Table 1 we see that the orbital motion of a pulsar caused by a distant planet of a small mass may give large values of $\ddot{\nu}$ but a negligible change in $\dot{\nu}$ (in comparison with typical slowing down rates of pulsars). This shows that a large value of $\ddot{\nu}$ hints that the pulsar may be accompanied by a distant planet and therefore should be closely watched in the future. Unfortunately, the extensive timing project at Arecibo[1] was discontinued in 1976.

Figure 1 shows the residuals $N_{\rm obs} - N(t_{\rm obs})$ for PSR0329+54 with $N(t)$ given by equation (2). There is an apparent periodic component which shows up when we use data covering any period longer than five years. Let us assume that

$$N(t) = N_0 + \nu t + \tfrac{1}{2}\dot{\nu}t^2 + \tfrac{1}{6}\ddot{\nu}t^3 + a \sin\frac{2\pi}{P_{\rm orb}}(t - t_0) \qquad (3)$$

Using the least squares procedure one gets $N_0 = -0.352937 \pm 0.000296$, $\nu = 1.3995435677615 \pm 1.32\times10^{-11}$ s^{-1}, $\dot{\nu} = -4.021220\times10^{-15} \pm 2.56\times10^{-19}\ s^{-2}$, $\ddot{\nu} = 5.553\times10^{-26} \pm 2.05\times10^{-27}\ s^{-3}$, $a = (1.201\pm0.142)\times10^{-3}$, $P_{\rm orb} = 1{,}105.2 \pm 25.2$ d and $t_0 = 518.3 \pm 29.7$ d. All these values refer to the epoch JD 2,440,621.5. The errors assigned to these values are twice the formal standard deviation as derived from the least square fitting process with measurement errors assumed to be 500 μs (ref. 5); $\chi^2 = 315$, the number of degrees of freedom of the fit is $252 - 7 = 245$ and the r.m.s. residual between the fit and the data is 559 μs.

The sinusoidal term corresponds to a displacement with an amplitude of only 257 km over the period of 3 yr! This term

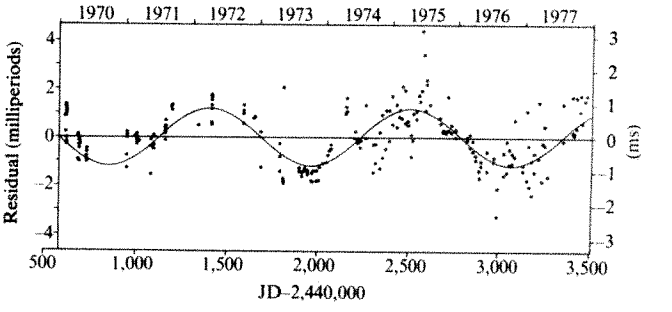

Fig. 1 The residuals for PSR0329+54 after subtraction of a best fitted cubic polynomial. The r.m.s. residual between the fit and the data is 774 μs; $\chi^2 = 603$ for $252 - 4 = 248$ degrees of freedom. The best fitting sinusoid (see equation (3) of text) is also marked.

could result either from a periodic displacement of the emission region in the pulsar magnetosphere caused by precession of the magnetic axis or a very small (858 μs) modulation of the pulsar profile which might have passed unnoticed. A small planet around the pulsar could cause the same effect. The mass function derived from the fitted parameters is $5.57 \times 10^{-19} M_{\odot}$. Masses of neutron stars are believed to be in the range of 0.1–$3 M_{\odot}$ so the lower limits on the mass of a companion ($\sin i = 1$) are correspondingly $0.06\ M_{\oplus}$ and $0.57\ M_{\oplus}$.

We thank Dr D. J. Helfand and his colleagues for the data and Drs J. Cordes, A. Kruszewski, B. Paczyński, J. H. Taylor, S. Tremaine and A. Żytkow for helpful discussions.

VLBI Observations of the double QSO, 0957+561 A, B

R. W. Porcas

Max-Planck-Institüt für Radioastronomie, Auf dem Hugel 69, D-5300 Bonn, FRG

R. S. Booth, I. W. A. Browne, D. Walsh & P. N. Wilkinson

University of Manchester, Nuffield Radio Astronomy Laboratories, Jodrell Bank, Macclesfield, Cheshire, UK

Walsh *et al.*[1] originally suggested that the double QSO 0957+561 A, B might be images of the same object formed by a gravitational lens because of their remarkably similar optical spectra. Additional optical spectral data[2] strengthen the evidence for a gravitational lens. Radio data at 5 GHz have shown a complex structure[3,4]. There are compact (<1 arc s) components closely coincident with the two QSOs; Pooley *et al.*[3] suggested that the one near B may be extended ~1.5 arc s, but the higher resolution data of Roberts *et al.*[4] make it probable that B is, in fact, also compact. In addition, there are at least two extended components, one to the north-east producing more than half the total 5-GHz flux density, and a much weaker one to the west. Pooley *et al.* show that these two extended components have fairly steep spectral indices (−0.65) between 5 GHz and 408 MHz but the components close to the QSOs have relatively flat spectra. We have now tested the gravitational lens hypothesis using the greater resolution obtained by very long baseline interferometer (VLBI) measurements of the QSOs, with the European Network at 1,666 MHz. We have detected two apparently unresolved (≤20 marc s) sources with about the same separation as the optical objects and with flux densities of 44 and 32 mJy. These sources have the same flux density ratio as the small-diameter components detected in lower resolution 5-GHz maps but we see no evidence for the extended features in these maps. Our high resolution results are consistent with the gravitational lens hypothesis.

Our observations of 0957+561 were made at 1,666 MHz using the Max-Planck-Institüt für Radioastronomie (MPIfR) 100-m telescope at Effelsberg, FRG, the Netherlands Foundation for Radio Astronomy 25-m telescope at Dwingeloo, the Netherlands, and the 76-m Mark IA telescope at Jodrell Bank, UK. The data were recorded with a 2-MHz bandwidth using the Mark II VLBI system[5] and processed with the MPIfR VLBI processor in Bonn. A hydrogen maser frequency standard was used at Effelsberg and rubidium standards were used at the other sites. A total of 5 h of observations was obtained during the period 2–4 June 1979. Table 1 summarises the observation periods. Observations of the relatively strong sources BL Lac and 0Q208 showed that the stability of the ionosphere and the local oscillators was sufficient to allow coherent integrations of up to 20 min with only ~5% loss of amplitude.

The longest baseline, Effelsberg–Jodrell, gives lobe spacings of ~55 marc s, almost independent of hour angle during these observations. It is also the most sensitive, with r.m.s. noise of ~6 mJy in a single 20-min coherent integration. With this integration time, the observations of 0957+561 show two well-resolved peaks in the fringe-frequency spectrum. Their separation varies with interferometer hour angle in a way consistent with the separation of the two optical QSOs, A and B. The fringe rate spectrum obtained with a 20-min integration centred at UT 1750, 2 June, is shown in Fig. 1. There is no significant variation in the flux density of A or B with hour angle on 4 June, the individual flux densities being 38 ± 5 mJy and 30 ± 5 mJy, respectively. Note that these errors are a quadratic sum of random noise and an estimated systematic calibration error of 12%. On the Effelsberg–Dwingeloo baseline we have approximately three times less resolution and observations are ~30% less sensitive. Again, there seems to be no variation in the component flux densities with hour angle, the mean values of A and B being 44 ± 6 mJy and 30 ± 6 mJy. From all the 4 June observations we conclude that both components are unresolved. However, for the single half-hour observation on 2 June the flux densities of A and B measured on the Effelsberg–Jodrell baseline are 62 ± 9 mJy and 43 ± 9 mJy. This might be taken as evidence for resolution, variability or even circular polarisation of the components, but we consider that the apparently greater flux densities measured on 2 June can be ascribed to calibration uncertainties. Our best estimates of the flux densities of A and B are therefore the weighted means of these various values; thus, $A = 44 \pm 4$ mJy and $B = 32 \pm 4$ mJy. Some support for the view that the components are unresolved in all the observations comes from the fact that the ratios of flux densities A/B are never significantly different from each other, the mean ratio being 1.38 ± 0.08. The sensitivity of the Dwingeloo–Jodrell baseline is one-third that of Effelsberg–Jodrell, and although we detect the source, we are unable to deduce anything further about its structure.

There is no evidence of any other radio component from our VLBI observations; from the Effelsberg–Jodrell baseline we put an upper limit of 20 mJy on any compact structure associated with the NE and W radio components reported by Pooley *et al.*[3].

It is not possible to obtain useful absolute positions for components A and B from the individual fringe rates. However,

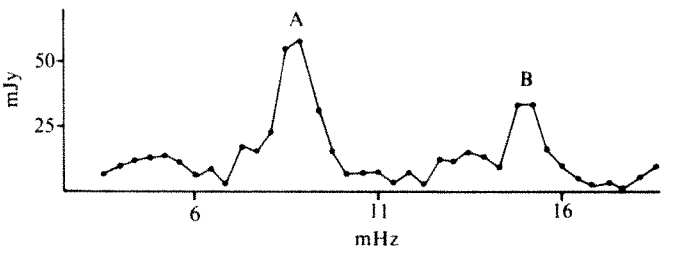

Fig. 1 Residual fringe rate spectrum of 0957+561 A, B after 20 min integration. Effelsberg–Jodrell baseline, 17.50 UT, 2 June.

2 June	17.30–18.00	Right hand circular
4 June	08.40–13.00	Left hand circular

we can determine a very precise relative position from the relative phases by using the fringe rate differences to determine the unknown number of integral turns between the phases of A and B. The relative position and standard deviation, in the sense A minus B, from a least squares fit to the relative phases on both baselines, is $\Delta\alpha(1950.0) = -0.1453 \pm 0.0003$ s, and $\Delta\delta(1950.0) = +6.047 \pm 0.002$ arc s. The separation is 6.175 arc s. These values agree well with the 5-GHz results of Pooley *et al.*—$\Delta\alpha = -0.16$ s, $\Delta\delta = 6.1$ arc s (1950.0), separation 6.25 arc s—but are somewhat greater than the optical separation (5.7 arc s) given by Walsh *et al.* Further optical observations are needed to determine whether this difference is real.

In comparing our VLBI results with previous observations, we note first that the 5-GHz flux densities of Pooley *et al.* for A and B (48 and 37 mJy, respectively, flux ratio, A/B, = 1.30) are somewhat higher than those of Roberts *et al.* (36 and 30 mJy, respectively, flux ratio, A/B, = 1.20). These differences may be within the range of observational error. Our VLBI flux densities at 1,666 MHz (44 and 32 mJy, respectively, flux ratio, A/B, = 1.38) are very similar to the 5-GHz values. At first sight the apparent similarity of the spectral indices is further evidence for the hypothesis that we are seeing two images of the same object via a gravitational lens. However, this apparent similarity must be treated with caution for at least two reasons. (1) The 5-GHz observations refer to angular scales of the order of 1 arc s, whereas the VLBI observations refer only to compact components two orders of magnitude smaller, and we do not know what fraction of the 5-GHz flux is contained in these compact components; (2) if a gravitational lens is operating, and if, as suggested by Pooley *et al.*, the source is radio variable, then, taking into account the relative delay between the two paths, we do not necessarily expect the same spectral index for the two images.

The most important feature of our VLBI data is that we find two unresolved radio components with comparable flux density at 1,666 MHz close to the optical QSOs. As concluded by Pooley *et al.*, this is consistent with the gravitational lens hypothesis but because of the much tighter limits on angular size it is a somewhat more stringent test.

If the radio components are, in fact, images of a single object formed by a lens, our failure to resolve them allows an estimate of an upper limit to the size of the object. Adopting the notation and formulae quoted by Pooley *et al.*, the maximum linear magnifications of the two images (transverse to the direction of the line joining them) are α_1/β and α_2/β, respectively. The values of α_1, α_2 and β can be determined from the flux ratio, which is equal to α_1^2/α_2^2. Unfortunately, the frequency-independent flux ratio inherent in the geometrical optics of the lens is uncertain because of variability, which, as discussed by Pooley *et al.*, seems to be necessary on lens theory. The closer the flux ratio is to unity, the greater the magnification; thus, a reasonable estimate of the upper limit to the intrinsic size of the radio object may be obtained by adopting the largest value of the flux ratio yet proposed. This is the value derived from the optical spectrum by Carswell and D.W. (in preparation), who suggest that after correction for dust close to the QSO, the flux ratio is 1.5 (in the sense B/A). This then yields $\alpha_1 = 3.40$ arc s, $\alpha_2 = 2.78$ arc s, $\beta = 0.62$ arc s and maximum linear magnifications of 5.5 and 4.5 for B and A, respectively. This implies an upper limit of ~4 marc s for the equivalent gaussian diameter of the radio object, and an upper limit to the flux density of ~15 mJy if the lens were absent. Note that the formulae from which this result is obtained are based on the assumption of a point deflecting mass. For the more realistic case of the distributed mass of a galaxy, the precise formulae will depend on the mass distribution, but as long as the flux ratio is not greatly different from unity, the above estimates are probably reasonable.

An upper limit of 20 or even 4 marc s to the diameter of a radio component is quite consistent with that expected for a weak synchrotron source in the nucleus of a QSO, so our size measurements do not provide a definitive test of the lens hypothesis. However, VLBI observations with at least an order of magnitude greater resolution are feasible, and it might then be possible to determine the structures of the two components and so provide a much stronger test of the lens hypothesis.

We thank the staff of the Dwingeloo Observatory for their assistance with these observations and Dr D. A. Graham, Dr K. Weiler and Mr H. Blaschke for their assistance on the MPIfR processor.

Galactic radiation belts

J. G. Luhmann

Space Sciences Laboratory, The Aerospace Corporation, El Segundo, California 90245

Several decades of observations have failed to resolve the problem of the interpretation of extended extragalactic radio sources[1,2]. Most current models invoke the ejection of pairs of plasmoids or relativistic electron beams from the parent elliptical galaxy by various mechanisms[3–5]. As these theories generally predict the relative orientations of the rotation, magnetic and radio source axes, the measurement of position angles provides one test of the proposed models[6,7]. However, position angle studies[6–11] have produced ambiguous and sample-dependent results. While recent analyses[6,7] indicate a preference for radio source alignment along the inferred rotation axes of the optical counterparts, other investigations found random distributions of position angle or bimodal distributions with peaks separated by ~90° (refs 8, 10). One alternative interpretation of extragalactic radio sources that has received little previous consideration, and is considered herein, concerns the possibility that the emission arises from belts of trapped electrons encircling the parent galaxy in the same manner as the Van Allen belts encircle the Earth. This idea seems to have been dismissed primarily because of the absence of ring-shaped or toroidal emission patterns in the radio observations[12]. The morphology of synchrotron emission patterns from these hypothetical structures, however, has never been investigated in detail.

An integral describing the two-dimensional brightness distribution on the plane of the sky from synchrotron-emitting relativistic electrons trapped in a dipolar magnetic-field shell was formulated by Ortwein *et al.*[13] for analysis of the jovian radio emission. These authors derived their results for an arbitrary dipole-axis orientation angle θ_0 with respect to the line of sight and for various degrees of anisotropy of the trapped-electron distribution. The latter was parameterised by the loss-cone angle α_L, which is the smallest populated equatorial pitch angle in the otherwise isotropic particle distribution, and the power law energy spectrum index γ.

While the calculated emission patterns were insensitive to the value of γ, they were strongly dependent on both the aspect

0028–0836/79/470386—03$01.00
© 1979 Macmillan Journals Ltd

angle and the loss-cone angle. The emitting shell of electrons assumed one of six different morphologies for various combinations of θ_0 and α_L: (1) the solid ellipsoid, sometimes showing complex internal structure, (2) the annulus, (3) the limb-brightened, elongated annulus, which approached in appearance (4) the limb-brightened dumbbell shape, with source axis perpendicular to the dipole axis, (5) the separated double source, with source axis parallel to the dipole axis, and finally (6) the invisible source. Figure 1 shows some of these forms.

For the present investigation, the numerical integrations described by Ortwein *et al.*[13] were performed for a large number

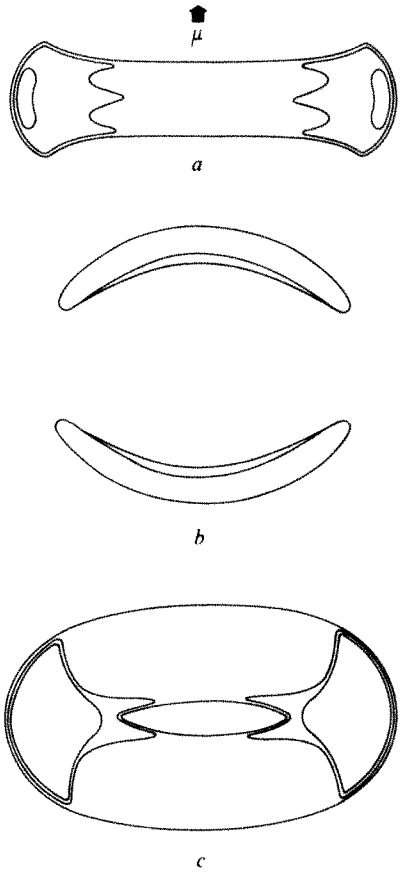

Fig. 1 Examples of the brightness distributions produced by calculations of synchrotron emission from a dipolar shell of trapped electrons using the method described by Ortwein *et al.*[13]. A dumbbell distribution (*a*) with source axis perpendicular to the dipole moment μ is produced when the aspect angle θ_0 is 90° (line of sight perpendicular to the dipole axis) and the loss cone angle is $\alpha_L = \sin^{-1} 0.8$. A double source with source axis parallel to the dipole axis (*b*) is obtained when $\theta_0 = 35°$ and $\sin \alpha_L = 0.8$. The limb-brightened, flattened annulus or torus (*c*) results from the parameters $\theta_0 = 60°$ and $\sin \alpha_L = 0.6$. The contour interval is variable. Numerical results can be found in the work of Ortwein *et al.*[13].

of aspect angles θ_0 between 0 and 90° and loss cone angles α_L between 0 and 90°. Five-degree intervals were taken in aspect angle θ_0 and $\sin \alpha_L$ was incremented by 0.05. The electron spectral index γ was set equal to the nominal value of 1.5, which is the galactic cosmic-ray index[14]. Two-dimensional plots of the intensity were generated for each case. These were then categorised according to morphological class as defined by the six types described above.

Figure 2 shows how the morphology of the brightness pattern varies as a function of aspect angle and electron pitch angle anisotropy. In nature, the dipole axes will be isotropically distributed. However, all loss-cone angles may not occur. In particular, the results given in Fig. 2 indicate that if large loss cones ($\sin \alpha_L > 0.8$) are prevalent, the observed distribution of

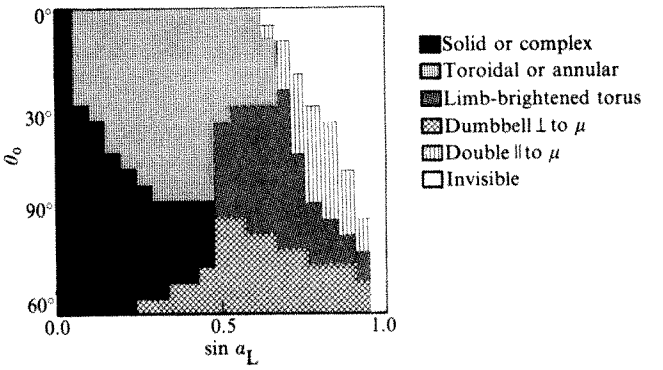

Fig. 2 Distribution of source morphologies for all values of aspect angles θ_0 and loss-cone angle α_L.

source morphologies will be practically equivalent to what has been found in some of the data analyses. These thin disk-like populations of gyrating electrons produce emission patterns that are virtually undetectable or double with the radio source axis either parallel or perpendicular to the dipole axis of the parent galaxy. (The limb-brightened annuli are likely to appear as doubles connected by 'bridges' of emission.)

Of course, actual galactic radiation belts would be composed of a distribution of non-uniformly emitting shells, thus altering the emission patterns somewhat. For example, it would not be surprising to find (under circumstances of non-uniform sources, sinks and field geometry) cases of multiple belts which appear as nearly co-linear paired sources. Also, galaxies with minimum-*B*

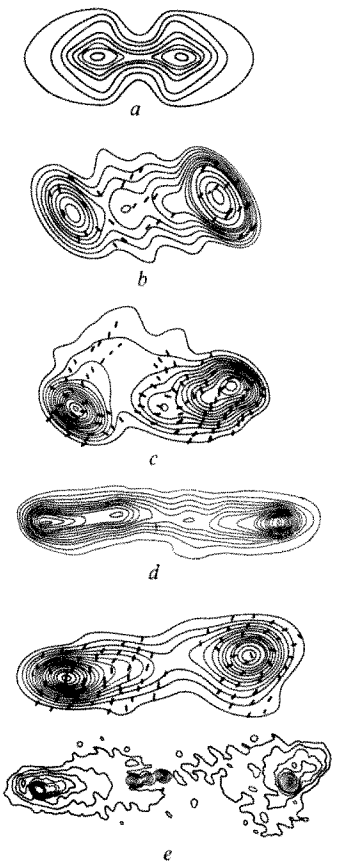

Fig. 3 A selection of observed radio-source brightness distributions at various resolutions: *a*, Jupiter[17] at 10.4-cm wavelength; *b*, 3C234 (ref. 16) at 1.4 GHz (21 cm); *c*, 3C382 (ref. 16) at 1.4 GHz; *d*, 3C452 (ref. 1) at 1.4 GHz; *e*, 3C219 (ref. 16) at 1.4 GHz (top) and at 2.7 GHz (bottom). The dashes show the direction of the magnetic field in the sources as inferred from polarisation measurements.

surfaces that are warped by non-dipolar field components[15] may show an anomalous displacement between the rotation and magnetic axes, as well as asymmetric trapping regions. Moreover, a galactic wind[24] or local intergalactic material can further distort the configuration of trapped electrons. Figure 3, which compares the brightness distributions and inferred magnetic field geometries of several extragalactic radio sources[16] with the jovian radiation-belt source[17], suggests an intriguing similarity.

The related questions of why galactic radiation belts should exist at all and why they would be populated by electrons with such a highly anisotropic pitch angle distribution lead to several speculations. Parker[18] demonstrated that the magnetic field of our own galaxy could be attributed to dynamo activity. Dipolar components are preferentially excited in dynamos and dominate the field at large distances from the dynamo centre[19]. Also galaxies contain sources of energetic particles, the cosmic rays. Various scattering mechanisms and propagation effects[20,21] can cause particles originating in the galaxy to become trapped in a surrounding dipolar field which is effectively a highly organised cosmic-ray halo. In fact, the cosmic ray spectrum observed in Earth's vicinity could produce the observed radio source spectra[22]. Finally, Schulz[23] pointed out that both synchrotron losses and radial diffusion processes in radiation belt configurations naturally lead to pitch angle distributions that are strongly peaked at an equatorial pitch angle of 90°.

Many peripheral points of interest can be found in analogies with other radiation belts in nature[23,25]. The perpendicular sources may show evidence of the gradient-curvature drift of the trapped particles around the parent galaxy. This azimuthal drift would cause opposite Doppler shifts of the synchrotron radiation from the two extremities of the source. Magnetic storms, analogous to those which accelerate particles in Earth's environment[26], may have their counterparts in galactic magnetospheres. The variation of the radio sources with time will be determined by the competition between particle sources and synchrotron losses, and also by changes in magnetic field geometry. Some 'tailed' radio sources have already been compared with the Earth's magnetosphere[27,28].

These speculations notwithstanding, the calculations described above suggest that electrons trapped in a dipolar magnetic field can reproduce some of the observed distributions of emission from extended extragalactic radio sources, including the absence of toroidal configurations, if the electron pitch angle distributions are sufficiently anisotropic.

This work was supported by US Air Force SAMSO contract F04701-75-C-0079. I thank M. Schulz and J. B. Blake for reading the original manuscript.

Numerous theoretical calculations[1,2] have been made of the effect of an increased carbon dioxide concentration in the atmosphere on the surface temperature of the Earth. Estimates of the increase in the surface temperature of the Earth caused by a doubling of the carbon dioxide content of the atmosphere generally range from ~0.7 to 2.9 °C. For a 10% increase in carbon dioxide, the corresponding temperature increases range from 0.096 to 0.40 °C. All these results are calculated from theoretical models which range in complexity from one-dimensional planetary radiation budget studies to three-dimensional general circulation models. Here a new approach to this problem is described which allows an empirical determination of the heating of the surface of the Earth by the carbon dioxide greenhouse effect to be calculated. This technique indicates that the heating of the Earth over the period 1880–1970 was 0.40 °C or less.

Consider that climatic fluctuations have three components: (1) natural climatic changes caused by external forcing such as variations in solar luminosity; (2) natural climatic fluctuations caused by year-to-year stochastic variations in sea-surface temperature, snow and ice cover, cloud cover, and so forth; and (3) man-induced climatic variations caused predominantly by increased carbon dioxide in the atmosphere. Here most of the observed trends in the Earth surface temperature over the last century are hypothesised to have been caused by external forcing, namely by changes in solar luminosity. Once we know the history of this forcing function, the forcing of climate caused by the carbon dioxide greenhouse effect can be determined. If changes in volcanic activity contribute significantly to long-term trends in climate, then the estimate for the carbon dioxide warming will need to be altered. The results of an earlier study[3] are now reviewed so that we can reconstruct the solar luminosity variations over the last century.

Sunspots are dark regions on the Sun which vary in number with an 11-year cycle. Nearly all sunspots have a dark central region (umbra) and a less dark surrounding region (penumbra). The areas of these regions have been measured by the Royal Greenwich Observatory since 1874[4]. The ratio of the areas of the umbrae to that of the penumbrae may be used to characterise sunspot structure. The umbral/penumbral ratio varies not only from sunspot to sunspot but also has marked year-to-year variations and shows long-term secular changes (Fig. 1).

The umbral/penumbral ratio may be a measure of the amount of convective energy transport in the photosphere of the Sun[3,5–7]. Facular activity is more intense when the umbral/penumbral ratio is high[5], indicating that the umbral/penumbral ratio is directly proportional to the solar convective flux. Deszo[8] indicates that the manner in which sunspots decay in time also implies that the umbral/penumbral ratio is a measure of solar convective flux. For periods of more active convective motions, the penumbrae tend to be destroyed more readily than the umbrae hence increasing the umbral/penumbral ratio.

If the umbral/penumbral ratio is a measure of convective flux in the Sun, it must also be a measure of radiant flux from the Sun. During periods of more intense convective flux, warmer gases from inside the Sun will rise to the surface and the Sun will be brighter. An earlier study[3], using the mixing length theory of convection and available sunspot models, showed that the observed changes in the umbral/penumbral ratio were

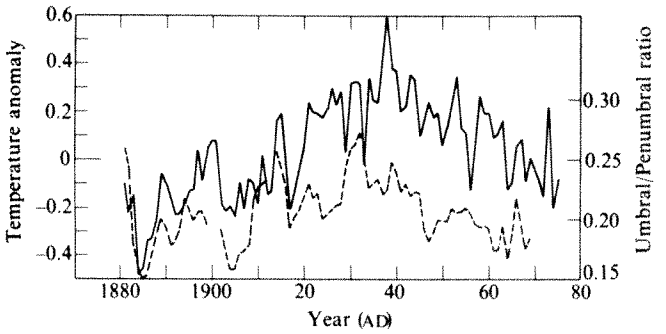

Fig. 1 The solid curve shows the Northern Hemisphere temperature anomalies from Budyko (1881–1957), Reitan (1958–1968) and Angell and Korshover (1969–1975). The dashed curve illustrates the umbral/penumbral ratio from the Royal Greenwich Observatory measurements 1881–1969. Note the general similarity, particularly for the earlier years.

equivalent to a change on the solar constant of about 0.4% over the last century.

A consequence of the above is that the climate of the Earth will vary in a parallel manner with variations of the umbral/penumbral ratio. The higher the umbral/penumbral ratio, the greater will be the solar constant and the warmer the Earth. Figure 1 compares the temperature anomalies of the Northern Hemisphere[9-11] and the umbral/penumbral ratio. The cross-correlation of these two time series is 0.53 ± 0.13 which is significant at better than the 1% level. The uncertainty of this correlation has been increased[12] to correct for the autocorrelation in the two time series. The umbral/penumbral time series has been corrected for the years 1900, 1901 and 1913 as suggested earlier[3], although using years with few sunspots causes the correlation to be less than it would be otherwise. Using only those years for which the penumbra covers more than 100 millionths of the solar disk gives a cross-correlation of 0.57. The probability of such a high cross-correlation occurring by chance is < 1 in 10^2. Furthermore, when both series are detrended by fitting parabolas to each and subtracting them from the observed time series, the cross-correlation of the residuals equals 0.46. It is the common year-to-year variations in the two time series that gives rise to their correlation rather than their common long-term trends.

Although the umbral/penumbral ratio successfully accounts for ~28% of the total variance in the observed temperature records, the crucial test of this mechanism for climatic change is that solar constant variations be proportional to the umbral/penumbral ratio. The predictive capability of the model as it stands supports its validity. In particular, it has successfully predicted the following: (1) the umbral/penumbral ratio should be small during the Maunder Minimum of the late 1600s (ref. 13). A preliminary qualitative check of available sunspot drawings agrees with this prediction[3]. (2) Because of the need for energy balance in the solar convective zone, the solar rotation rate should have increased in recent years: Measurements by Livingston and Duvall[14] confirm this prediction. (3) Correspondingly the solar rotation rate before 1930 when the Earth was warming should have decreased to a minimum about this time: measurements by Eddy[15] apparently confirm this prediction. (4) Because of a 20-yr cycle in the umbral/penumbral ratio[3], there should be a 20–22-yr cycle in certain meteorological parameters. The best documented such variation concerns the 22-yr cycle of droughts in the western US[16]. The umbral/penumbral ratio has peaked 0–4 yr before each drought over the past century[3] and strongly suggests a physical connection. (5) The thermal time constant of the Earth–ocean–atmosphere system should be ~4–5 yr based on calculations using a simple energy balance climate model. Others[17-18] have estimated this time constant to be ~6.5–6.9 yr. Further information on this hypothesis for climatic change is given elsewhere[3].

The proposed hypothesis should also allow a successful prediction of the warming of the Earth by the carbon dioxide greenhouse effect. Only three basic assumptions are needed (1) the umbral/penumbral ratio and surface temperature of the Earth are correlated and proportional to one another. Although for physical reasons the umbral/penumbral ratio is believed to provide a measure of the solar constant whose variations in turn cause climatic change, another physical mechanism could be invoked without upsetting the above assumption. The record for the surface temperature of the Northern Hemisphere is taken to be representative of the whole Earth[19] although doubts have been expressed about the parallelism of the temperature records of the two hemispheres[20]. (2) The carbon dioxide content of the atmosphere has been increasing exponentially since 1880 (refs 21, 22) and consequently the temperature of the Earth has been increasing approximately exponentially with time[1]. (3) Earth surface temperatures have long-term secular variations over the past 100 yr forced predominantly by variations in solar luminosity and carbon dioxide increases. Long-term trends in atmospheric transmission attributable to anthropogenic or volcanic aerosols reported by Budyko[9] as a possible cause of climatic change have not been supported by many subsequent studies[29-33]. Volcanic activity or natural variations may contribute to the trend in temperature but for the first estimate of the carbon dioxide warming these effects are neglected.

The trends in the observed temperature record[9-11] (Fig. 1) with the above assumptions consist of a natural variation caused largely by solar variations and anthropogenic portion caused by increased carbon dioxide. The anthropogenic portion is analytically represented in two models by a linear and exponential increase of temperature with time. Subtracting various hypothetical anthropogenic temperature increases from the observed temperature records allows natural temperature variations to be deduced. The highest cross-correlation of a calculated natural temperature variation versus the umbral/penumbral ratio is 0.63 and occurs for an assumed linear anthropogenic temperature increase of 0.40 °C over the period 1880–1970 (Fig. 2) or assumed exponential increase of 0.3 °C to 0.4 °C. The deduced increase in temperature caused by anthropogenic carbon dioxide should be interpreted as an upper limit to the actual warming because the presumed cooling in the late 1880s caused by volcanic eruptions[23] will tend to be interpreted as a natural climatic variation. Hence, the warming after the volcanic eruptions will give a higher value for the calculated carbon dioxide warming than it should. A more detailed climate model should help resolve the magnitude of this overestimation. The location of temperature measurements near urban areas may also give the appearance of a long-term warming of the Earth because of the increasing effects of urban heat islands[19]. The observed and expected natural temperature variations in the absence of mankind are shown in Fig. 3.

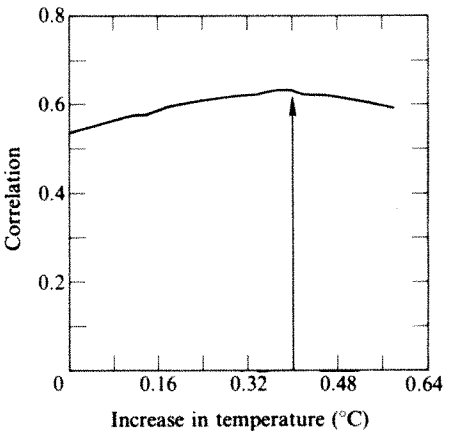

Fig. 2 The correlation of the natural temperature anomalies compared with the umbral/penumbral ratio for various assumed linear temperature increases caused by the carbon dioxide greenhouse effect during 1880–1970. The best correlation occurs for a linear temperature rise of 0.4 °C. A similar plot for a more realistic exponential temperature rise gives a best correlation for 0.3–0.4 °C.

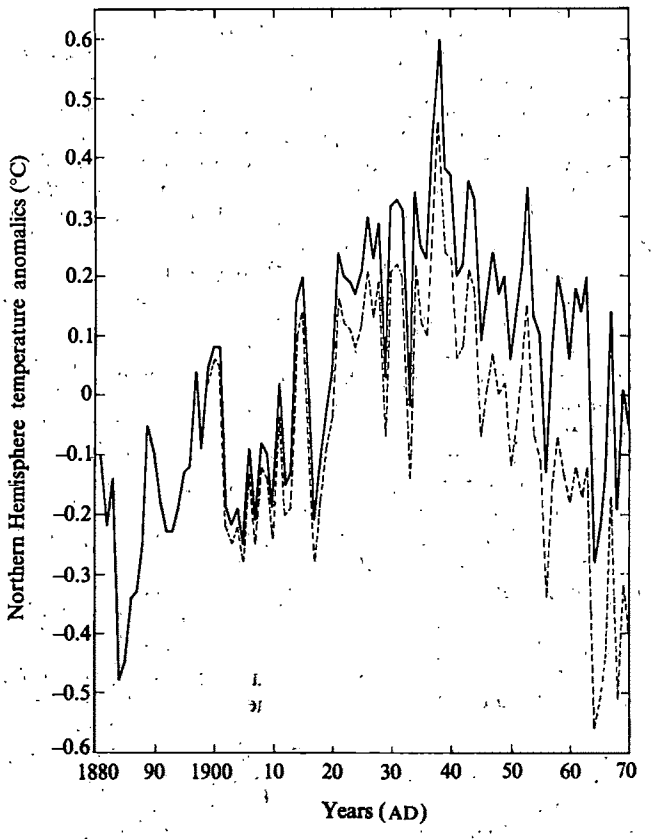

Fig. 3 The solid curve gives the observed Northern Hemisphere temperature anomalies and the dashed curve gives the natural unperturbed Northern Hemisphere temperature anomalies. The increasing exponential separation of the two curves is caused by the increased (anthropogenically produced) carbon dioxide.

Although the 0.30–0.40 °C warming due to the carbon dioxide greenhouse effect is the present best estimate of this quantity based on techniques used here, there is considerable uncertainty in the statistical significance of this result. The cross-correlation between the calculated externally driven natural temperature variation and the umbral/penumbral ratio is 0.63 ± 0.13. The cross-correlation between the observed temperature variation and ratio is 0.53 ± 0.13. As only 90 yr of data are used in calculating these correlations, the significance of the difference between the correlations is only 16% (ref. 24). Although this technique does not prove that the Earth is warmer because of the presence of added carbon dioxide in the atmosphere, it supports this hypothesis.

Estimates of the carbon dioxide content in the atmosphere in 1880 range from 280 (ref. 21) to 293 p.p.m. (refs 23, 25). If during 1970 the concentration was 320 p.p.m. (ref. 26) the total increase in carbon dioxide from 1880 to 1970 was 9–14% of the original amount. The 0.40 °C temperature increase therefore implies that doubling the amount of carbon dioxide would result in warming in the range 2.0–3.1 °C. Manabe and Wetherald[27,28] estimate a 2.4 and 2.9 °C temperature increase respectively for the same conditions. The Manabe and Wetherald models imply that for a 9–14% increase in carbon dioxide, the Earth's surface temperature increases by 0.30–0.55 °C which bracket the present 0.3–0.4 °C empirical prediction. The present results further predict that a continued exponential increase in carbon dioxide content of the atmosphere, will warm the Earth by an additional ~0.3–0.4 °C by the year 2000.

Evidence for quasi-periodic July drought in the Hudson Valley, New York

Edward R. Cook & Gordon C. Jacoby Jr

Lamont-Doherty Geological Observatory, Palisades, New York 10964

July Palmer Drought Severity Indices[1] (PDSI) have been reconstructed[2] for the Hudson Valley region of New York State from the annual ring-width variations of local old trees. Using additional, subsequently developed tree-ring chronologies, we have developed a new July drought reconstruction that extends back to 1694. Variance spectra of the new PDSI series reveal statistically significant quasi-periodicities of 11.4 and 26 yr.

The July PDSI reconstruction was developed using six tree-ring chronologies from sites in the Hudson Valley. Each chronology is represented by only one tree species and is a mean-value function of 30–40 ring-width series from individual trees on a site. Five tree species are represented in the six chronologies: eastern hemlock (*Tsuga candensis* Carr.), pitch pine (*Pinus rigida* Mill.), eastern white pine (*P. strobus* L), chestnut oak (*Quercus prinus* L.) and white oak (*Q. alba* L.). Using several species and sites practically eliminates the possibility that insect infestations or other non-climatic disturbances have created the fluctuations found in the drought reconstruction. The reconstruction was developed using a combination of principal components analysis and multiple regression to compute prediction equations for estimating past climate[3,4].

Figure 1 shows the tree-ring PDSI estimates (*a*) plotted against the actual Hudson Valley regional July PDSIs (*b*). The latter series was used as the dependent variable to develop the multiple regression calibration equation for reconstructing drought. The estimates reduce 54% of the variance in Fig. 1*b* adjusted for degrees of freedom[5]. This is statistically significant well below the 1% level. The July PDSIs in Fig. 1*c* were computed from monthly temperature and precipitation data of the Mohonk Lake, New York cooperative meteorological substation which is near some of the tree-ring sites. The 1896–1930 interval is independent of the calibration period and, thus, can be used to test and verify the accuracy of the regression estimates. Three tests of verification were used: the sign test, the product means test[3] and the degree of cross-correlation. The sign test (30 agreements, 5 disagreements) and the correlation coefficient ($r = 0.60$; d.f. = 33) pass the 1% significance level. The product means test ($t = 2.21$; d.f. = 33) passes the 2.5% significance level.

To test the frequency-domain fidelity of the reconstruction, we computed spectral and cross-spectral estimates[6] of the

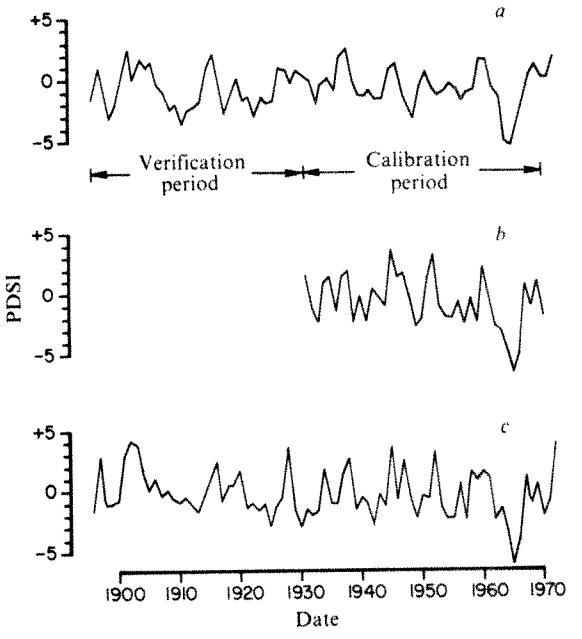

Fig. 1 Tree-ring reconstructed July PDSI (*a*), Hudson Valley Division July PDSI (*b*) used to calibrate the multiple regression equation for estimating PDSI from tree growth, and Mohonk Lake, New York. July PDSI (*c*) used to verify the tree-ring PDSI estimates.

Mohonk Lake and reconstructed PDSI series. For this test we used all of the common data (1896–1972) to provide better low-frequency resolution. The two series are no longer independent because the Mohonk Lake data are highly correlated with the divisional data used in the 1931–70 calibration period. But as the 1896–1972 common interval is almost twice the calibration period, we still expect a reasonably rigorous depiction of the frequency-domain fidelity of the PDSI reconstruction.

Figure 2 shows the variance spectra (*a*) and the squared coherency spectrum (*b*) of the two series. The similarity of the variance spectra illustrates the good fidelity of the drought signal recorded by tree rings. The loss of variance in the higher frequencies of the reconstruction is partly a function of the unexplained variance of the regression equation used for prediction. Note that both spectra have a broad-based peak centred at a period of 12.6 yr.

The coherency spectrum provides an estimate of the common per cent variance between two series at each frequency. This spectrum indicates that 60–80% of the climatic signal in the bandwidth accounting for periods of 7–30 yr is common to both series. Other frequencies show poor to good coherence. The phase spectrum is not shown because the two series are in phase for almost all frequencies.

Figure 3 shows the complete July PDSI reconstruction and a low-pass filtered version that passes all variance at frequencies of once in 10 yr or less. Judging from the coherency spectrum, the filtered PDSI series shows the most reliable drought information. It clearly shows a strong low-frequency rhythm of wetness and dryness that is suggested in Fig. 2.

Using the 1700–1972 period of the unfiltered series, we computed a high-resolution variance spectrum from the autocovariance function of $N/3$ or 91 lags. The Hamming window was used for smoothing the spectrum. Figure 4*a* shows two very strong peaks of variance at periods of 11.4 and 26 yr. The general shape of the spectrum is characteristic of a time series containing 'red noise' or persistence which inflates the low-frequency variance. Significance tests of such spectra must be computed either from a null spectrum of an empirically determined low-order Markov process[7] or after prewhitening to reduce the original data to residual 'white noise'. We use both approaches with an *a priori* hypothesis test, but compute the confidence levels from somewhat different null models.

The null spectrum of the unwhitened PDSI data was computed from the autocovariance function of 14 lags which produces a very low resolution spectrum. In this case, we want the null spectrum to be arbitrarily smooth without defining the stochastic process it represents. Using a one-tailed χ^2 test, the significance levels are computed as

$$\mathrm{CL} = \frac{\Gamma(\omega)\cdot\chi^2}{\nu} \qquad (1)$$

where $\Gamma(\omega)$ is the null spectrum estimate for frequency ω and χ^2 is the χ^2 value for a given confidence level (CL) with ν degrees of freedom. In Fig. 4*a*, the 95 and 97.5% confidence levels are plotted with the high and low resolution spectra. Both the 11.4- and 26-yr peaks exceed the 97.5% level of significance.

In Fig. 4*b*, the high-resolution spectrum was computed after the PDSI series was prewhitened using the difference equation of the second-order autoregressive (AR) process

$$Y_t = A_t + 0.827\,Y_{t-1} - 0.293\,Y_{t-2} \qquad (2)$$

The order of the process was selected using the Akaike final-prediction-error criterion[8] which is an unbiased estimator of the order of an AR process[9]. Although the drought series may be more complex than an AR (2) process, the cumulative periodogram of the prewhitened series did not show any systematic departure from a white noise null continuum. For white noise

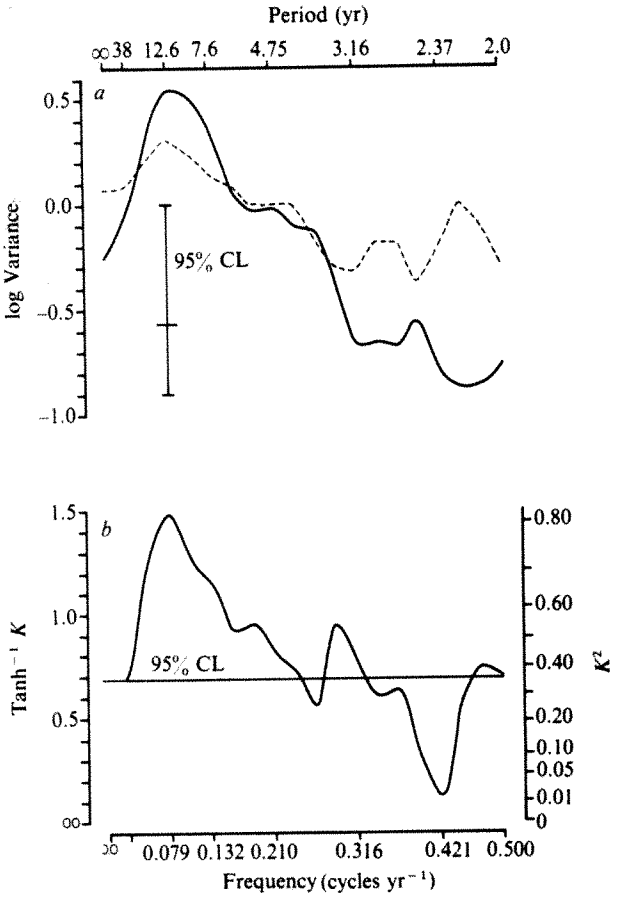

Fig. 2 Variance spectra of Mohonk Lake and tree-ring reconstructed July PDSI and the squared coherency (K^2) spectrum of the two series. Data shown in Fig. 1*a* and *c* were used to compute the spectra. The confidence interval of each variance spectrum is the same. $N = 77$; d.f. = 10; bandwidth = 0.066. Dashed line indicates Mohonk Lake, New York, July PDSI.

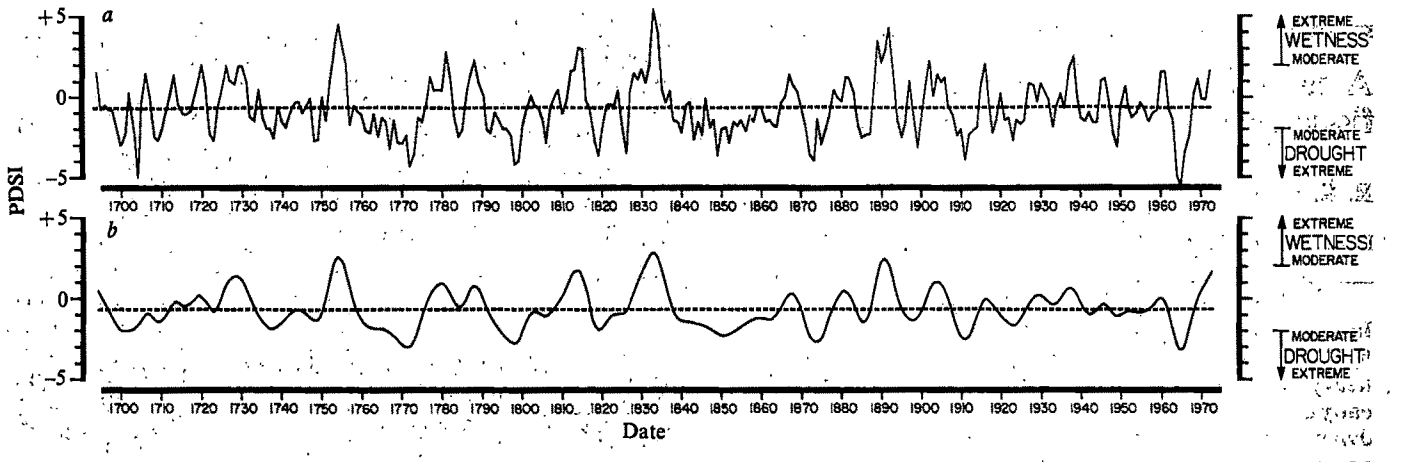

Fig. 3 Tree-ring reconstructed July PDSI from 1694 to 1972. *a*, The unsmoothed estimates. *b*, A low-pass filtered version of the unsmoothed series that emphasises frequencies of once in 10 yr or less.

processes, the expected relative variance of the null spectrum at each frequency is

$$\Gamma(\omega) = 1.0/m \qquad (3)$$

where m is the number of spectral estimates. $\Gamma(\omega) = 0.011$ for all ω in our case and the confidence levels are computed using equation (1). Again the 11.4- and 26-yr peaks are significant at the 97.5% confidence level.

We conclude that low-frequency fluctuations of past drought in the Hudson Valley are partly quasi-periodic. These periods may be identified with the 11-yr sunspot cycle[10] and a 27-yr cycle of soli-lunar tidal influence on zonal westerly flow[11]. An unsmoothed periodogram of the drought series indicates that ~20% of the variance is accounted for by these harmonics. Although this percentage suggests that these harmonics may have some practical predictive use, the nature and cause of these signals must first be understood. We strongly discourage any idea that drought in the Hudson Valley can be operationally predicted from the present results.

The belief that influences outside the Earth's atmosphere could significantly modulate climate is gaining credibility. A rigorous statistical analysis has convincingly linked the 22-yr midwestern US drought rhythm with the Hale sunspot cycle and its envelope, the Gleissberg cycle[12].

A highly coherent spatial pattern of inferred solar cycle signal (~10.7 yr) has also been detected in surface–air temperature data over North America[13]. It is particularly interesting that the presence of that signal is apparently limited to the region north of 35° N latitude and east of the Rocky Mountains divide. The Hudson Valley is within this region.

We do not yet know if there are consistent relationships between our drought series and such external forcing functions of climate. However, the 11.4- and 27-yr quasi-periodic drought rhythms are sufficiently near the soli-lunar tidal and sunspot periodicities to warrant a statistical inquiry into these possible relationships. Even if these harmonics are eventually regarded as part of an ensemble of internal stochastic mechanisms[14] of the ocean–atmosphere–cryosphere system, they represent an important aspect of climatic variability that is still poorly understood.

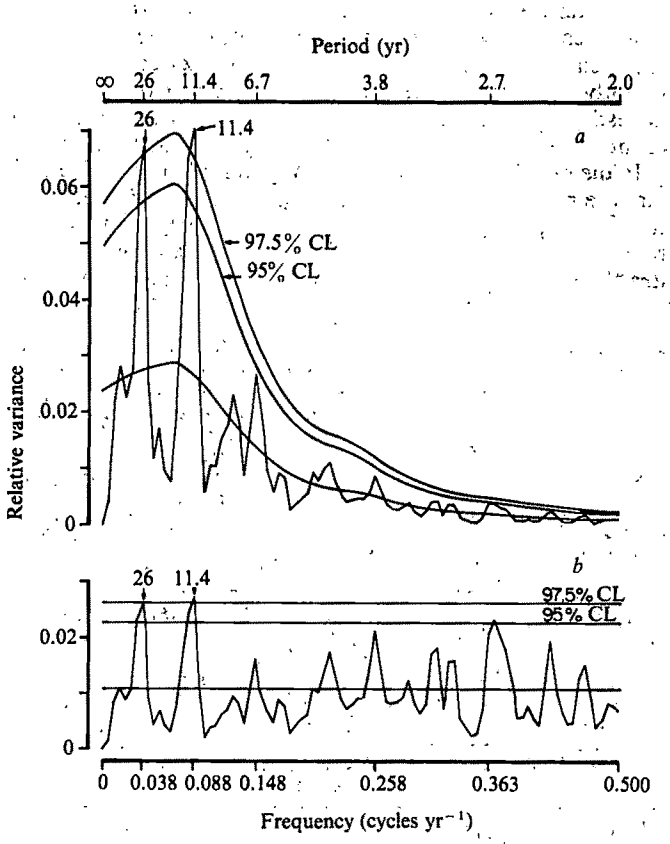

Fig. 4 Variance spectra of the unsmoothed July PDSI reconstruction (*a*) and the same series after prewhitening (*b*) using equation (2). An appropriate null continuum and its 95% and 97.5% confidence levels (CL) are superimposed on each spectrum. The bandwidth = 0.0138 and d.f. = 6 are the same in each case. $N = 273$.

A search for superheavy-element fission-tracks in iron meteorites

R. K. Bull

Department of Physics, University of Birmingham, Birmingham, UK

In a series of recent papers Runcorn and coworkers[1-3] have hypothesised that the radioactive decay of siderophile superheavy elements (SHE) provided the heat source which produced early melting of the Moon and which drove an ancient lunar core dynamo. If such elements had a half life of $\sim 10^8$ yr then this provides a natural explanation for the decay of the postulated lunar core dynamo and the associated magnetic field on a time scale of this order. It would be surprising if these SHE had accreted into the early Moon and not into the parent bodies of the iron meteorites. Libby *et al.*[4] have suggested that the iron meteorites did accrete SHE, and have argued that SHE fission has produced the observed peaks in the trace element abudances in iron meteorites at charge number $Z \sim 40$, 50 and 80. Libby *et al.*[4] claim that these abundances are well above those which may be expected on the basis of a simple calculation of the solubilities in Fe of these elements. These peak trace element abundances are ~10 p.p.m. by weight and assuming an element at the peak corresponds to a fission yield of 5% then the original abundance of SHE in the metal must have been in the region of 2×10^{-4} kg kg^{-1}. Such high concentrations of fissioning elements should produce a number of observable effects, one of which is the production of very large numbers of radiation damage tracks in the borders of silicate grains along the boundary with metal regions. This boundary contribution falls to zero at a distance within the silicate crystal equal to one fission fragment range (~5–10 μm). We report here a search for fissioning species in the metal phases of IA iron meteorites and a pallasite. No excesses of tracks in these boundary regions have been found and an upper limit of $\sim 10^{-12}$ kg kg^{-1} can be placed on the concentration of fissioning superheavy elements in the metal of the Odessa IA iron at the time when fission track retention began.

We have examined the silicate portions of two group IA iron meteorites and of the Brenham pallasite. In the case of the iron meteorites Odessa and Landes, slices were cut and the metal–silicate boundaries examined. A large Brenham olivine inclusion was extracted cleanly from the metallic matrix and mounted with the interface surface uppermost. One slice of Brenham was also studied.

Track densities near to the centre of each grain and along a strip ≈10 μm wide immediately adjacent to the metal contact were measured. In addition track densities on the interface surface of one olivine grain were also measured. The track densities are displayed in Table 1. Also given are the probable sources of the tracks in the central regions of the crystals.

Various criteria for deciding on the principal sources of tracks in any given meteorite crystal have been enumerated by Fleischer *et al.*[6]. In Brenham olivine, orthopyroxene from Landes and feldspar from the Odessa meteorite the tracks are observed to have anisotropic angular distributions and track length distributions dominated by short (<5 μm) tracks. These tracks would seem to result from slowed-down heavy cosmic-ray primaries. Track densities encountered in Odessa diopside are considerably higher than those in nearby feldspar crystals. The angular distribution of the tracks is isotropic and the length distribution fairly flat up to track lengths of ~12 μm (ref. 7). These characteristics all indicate a fission origin for these tracks[6] and previous work[7] has established that the majority are most probably formed by the spontaneous fission of ^{244}Pu.

These assignments of track origin are important because they determine the density of tracks to be expected in the boundary regions. For an external source such as cosmic r
track density measured in a 10-μm wide strip a

with the observations provided that we accept a somewhat contrived model, namely that the silicates and metal were not placed into intimate contact until $\sim 10^9$ yr ago. Radiometric ages for the silicate inclusions in irons are generally $\sim 4.6 \times 10^9$ yr (ref. 10) and none is yet known to be younger than 3.8×10^9 yr. Such an emplacement event therefore would have to be such that the Rb–Sr, K–Ar ages were not reset.

Taking as a generous estimate for the upper limit to the boundary track excess the actual measured boundary track densities of Table 1, column 5, then the corresponding upper limits to the concentration of fissioning SHEs become $\sim 2 \times 10^{-15}$ kg kg^{-1} for the metal phase of Brenham (from the density of deep etch pits) and $\sim 10^{-12}$ kg kg^{-1} for metal adjacent to Odessa diopside. These figures apply to the time at which quantitative retention of fission tracks began in the silicates. This is probably not later than $\sim 4.2 \times 10^9$ yr ago in the case of Odessa diopside but this is not known with any certainty for the case of Brenham olivine. Of course, the presence of α-decaying superheavy elements is not precluded by these data but if α-decay is the predominant mode of decay for the SHE then the similarity between trace element abundance peaks and fission product abundance curves pointed out by Libby *et al.*[4] must be purely fortuitous.

I thank Drs D. W. Sears and P. F. Green for useful discussions and Dr S. A. Durrani for his interest. I acknowledge the financial support of the SRC.

Amino acids in the Yamato carbonaceous chondrite from Antarctica

Akira Shimoyama & Cyril Ponnamperuma

Laboratory of Chemical Evolution, Department of Chemistry, University of Maryland, College Park, Maryland 20742

Keizo Yanai

National Institute of Polar Research, Kaga 1-chome, Itabashi-ku, Tokyo 173, Japan

More than one thousand pieces of meteorites have been discovered recently in Antarctica[1–4] which were preserved in the Antarctic Ice Sheet since their fall and were brought out on to the surface of the bare ice. They are likely to have the least possible terrestrial contamination, thus providing a new opportunity for the study of primordial organic synthesis in the early solar nebula[5] and of chemical evolution before the emergence of life[6,7]. Organic compounds of extraterrestrial origin were first detected in the form of protein and non-protein amino acids with an equal abundance of their D- and L-enantiomers in the Murchison carbonaceous chondrite[8,9]. This ratio of enantiomers has been used as a criterion for the meteoritic origin of the amino acids detected subsequently in other meteorites[10–13]. We present here detailed evidence for the presence of amino acids of extraterrestrial origin in our Antarctic carbonaceous chondrite[14].

© 1979 Macmillan Journals Ltd

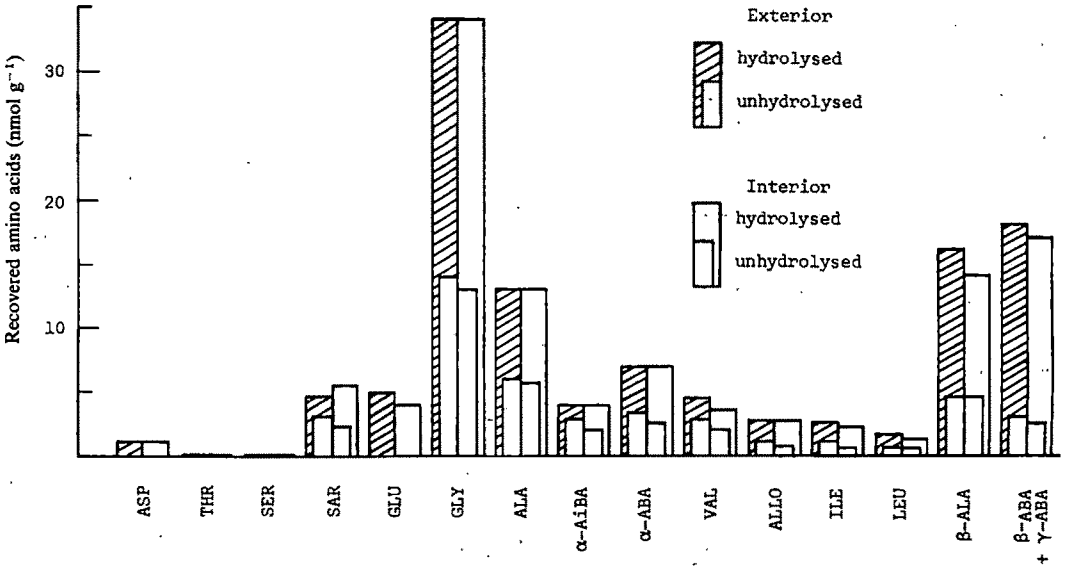

Fig. 1 Amino acids recovered from the Yamato meteorite 74662. The quantities were estimated by the amino acid analyser. The amount of β-ABA + γ-ADA consists mostly of γ-ABA by the gas chromatographic study.

A ~5-g fragment of the original 150-g meteorite was separated into exterior, middle, and interior portions. These portions were pulverised and nearly 1 g of the exterior and interior was individually extracted with water at 105 °C for 24 h. The water extracts were centrifuged and the supernatants were recovered. The residues were rinsed twice with water and combined with the corresponding supernatants. Half of each resulting solution was further halved into two aliquots. One of the aliquots was reduced to an appropriate volume and analysed by a Durrum 500 amino acid analyser. The other aliquot was dried under an IR lamp and derivatised, first, with isopropyl alcohol, 1.5 M HCl, and, then, TFAA-CH_2Cl_2 (1 : 2 by volume). The N-TFA-isopropyl-derivatives of amino acids were analysed by a gas chromatograph (GC) equipped with a Chirasil Val glass capillary column (25 m) using a nitrogen detector. The other half of the resultant solution was evaporated and was hydrolysed with 6 M HCl at 105 °C for 24 h. The hydrolysed solution was divided into two equal portions which were dried completely under the IR lamp. One of the dried samples was redissolved with an appropriate volume of water and analysed by the amino acid analyser. The other dried sample was subjected to the derivatisation for the enantiomer study by GC. All analytical preparations were conducted in a class 100 clean room.

Fifteen amino acids were detected in the Yamato meteorite: of these, nine are protein and six are non-protein amino acids. The individual amino acids have abundances between 34 and <1 nmol per g meteorite. Figure 1 compares the exterior versus interior and the unhydrolysed versus hydrolysed portions. The abundances in the exterior and interior are similar. The yields of amino acids increase two to three times after the acid hydrolysis.

The gas chromatogram obtained with the nitrogen detector shows a complex mixture. However, the D- and L-enantiomers of alanine, aspartic acid, and glutamic acid have nearly equal abundance. If other overlapping peaks around the baseline level are subtracted this fact might become even more evident (Fig. 2). The nearly equal abundance was observed in all the unhydrolysed and hydrolysed portions of the exterior and interior of the meteorite.

The amino acid assemblage, their concentrations and the enantiomeric ratios found are indicative of amino acids of abiotic origin and, therefore, extraterrestrial in nature. It may be argued that the observed DL ratios were produced during the preservation of the meteorite after contamination with terrestrial biological material at the time of fall. Unlike relatively recent falls of the Murchison (1969), Murray (1950), Orgueil (1864) and Mighei (1889) that exclude a pronounced racemisation during the terrestrial age, Antarctic meteorites might have enough time for an extensive racemisation. The age of the present bare ice surface of the Yamato Mountains may be 240,000 yr (ref. 2). However, as these meteorites fell on, and were subsequently preserved in, the Antarctic ice the terrestrial contamination would be insignificant and the racemisation process must have been exceedingly slow. The presence of non-protein amino acids also clearly indicates prebiotic synthesis. Further, the remarkable similarity in the amino acid abundance of the exterior and interior suggests that the terrestrial organic contamination was minimal.

More confirmation is provided by the equal abundance of D- and L-enantiomers of protein amino acids such as alanine, aspartic acid and glutamic acid in both the exterior and the interior. A similar study of the Mighei meteorite showed a striking L-enantiomer predominance of protein amino acids in its exterior portion, which diminished towards the interior of the

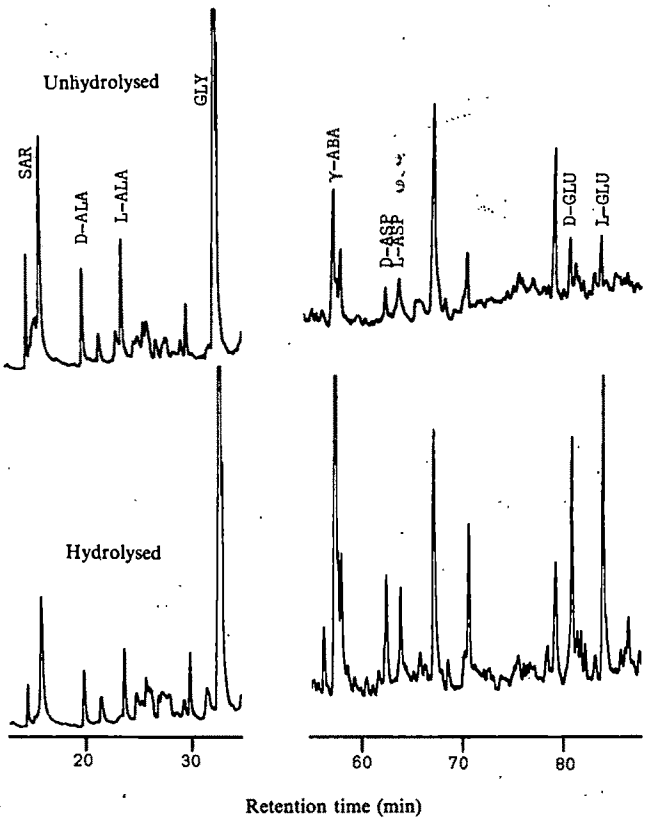

Fig. 2 Gas chromatograms of amino acids (N-TFA-isopropyl esters) of the interior portion of the Yamato meteorite 74662.

meteorite. The non-protein amino acids, however, did not show a difference throughout the exterior to interior portions[15].

The Yamato meteorite contains amino acids similar to those in the Murchison and Murray meteorites. All three are type II carbonaceous chondrites. The abundance of amino acids are also of the same order of magnitude. Glycine, the most abundant amino acid, is 34 nm in the Yamato, 81 nm in the Murchison[8,10,11], and 40 nm in the Murray[11]. Another common feature is the marked increase in the yields of aspartic acid and glutamic acid (both dicarboxylic amino acids) after acid hydrolysis. The Murchison and Murray meteorite also have aspartic acid and glutamic acid in very small quantities in the unhydrolysed portion[11]. This resemblance minimises the possibility that these amino acids in the unhydrolysed portion of the Yamato meteorite had been washed out by water on the surface of bare ice because dicarboxylic amino acids are anionic under a neutral *p*H. The observation of the recovered body of the Yamato meteorite indicated that about half of the fusion crust was lost by weathering[14]. Nevertheless, the metoerite does not seem to have been significantly altered by weathering. It seems that only the portion of the crust, physically broken from the parent body, was lost during its period on Earth.

The Allan Hills carbonaceous chondrite, also from Antarctica, exhibits an equal abundance of the D- and L-enantiomers in the exterior and interior[16]. Although the amino acid concentration was much lower in the Allan Hills meteorite than in the Yamato meteorite, these two Antarctic carbonaceous chondrites seem to be the least contaminated of the meteorites we have examined so far.

Since the fall of the Murchison meteorite, information on organic compounds indigenous to carbonaceous chondrites has revealed the processes of primordial organic synthesis. Studies of Antarctic carbonaceous chondrites, such as the Yamato 74662 which contains organic material of nearly the same concentration level as that of the Murchison meteorite, provide additional information useful for the understanding of extraterrestrial organic material.

We thank Dr T. Nagata, Director of the National Institute of Polar Research of Japan for permission to examine the Yamato meteorite and Dr P. E. Hare, Carnegie Institution of Washington for technical assistance. This research was supported by NASA grant NGR-21-00-317.

Quantification of monocarboxylic acids in the Murchison carbonaceous meteorite

James G. Lawless

Extraterrestrial Research Division, Ames Research Center, NASA, Moffett Field, California 94035

George U. Yuen

Department of Chemistry, Arizona State University, Tempe, Arizona 85281

Although the nature and origin of carbon and its compounds in meteorites have been reviewed by Hayes[1] and Nagy[2], much of our understanding of carbon and its compounds in carbonaceous chondrites remains speculative. Evidence for the extraterrestrial nature of the solvent-soluble organic matter was first found in the Murchison carbonaceous chondrite[3]; this material in the Murchison meteorite and in other meteorites has been identified as amino acids and precursors[3–10], monocarboxylic acids[11], dicarboxylic acids[12], hydrocarbons[6,13,14], amines[15], and other organic compounds[16–20]. The data suggest a chemical synthesis from simple precursors. Although the mechanisms by which these organic compounds were formed are unknown, theories (such as Fischer-Tropsch Type (FTT)[21] and discharge reactions[22]) have been proposed to account for their presence. Knowledge of the distribution of isomers in these chondrites is essential for understanding the mechanism of synthesis, and we report here the quantification of some of the branched- and straight-chain isomers of the monocarboxylic acids extracted from the Murchison meteorite.

The successful use of deuterated analogues for the quantification of amino acids[23] led to the selection of this approach for the quantification of the monocarboxylic acids. The deuterated and undeuterated monocarboxylic acid solutions for calibration and spiking purposes consisted of the 11 acids listed in Table 1. The deuterated analogues were prepared by the method of Pfeffer and Silbert[24].

A 1.084-g sample of finely crushed Murchison (interior) was refluxed for 3 h in a KOH–methanol solution (0.5g : 8 ml). After cooling to room temperature, the methanolic solution with some suspended solids was decanted into a Teflon test tube and the residue was washed twice with 5-ml portions of distilled water. After the combined solutions had been centrifuged, the supernatant was transferred to a 25-ml round-bottomed flask and the solvents were removed under reduced pressure. The resulting residue was acidified to *p*H 1 by adding concentrated hydrochloric acid dropwise, while cooling the flask in an ice-water bath. The aqueous mixture was filtered to remove inorganic salts and the filtrate collected in a screw-cap vial. The inorganic salts were rinsed with 3.0 ml of diethyl ether and collected in the same vial that contained the aqueous acid solution. After shaking for 1 min, a sample of the ether phase was analysed by gas chromatography using a 46-m-long stainless steel column with an i.d. of 0.05 cm; the column was coated with UCON 550-H_3PO_4. Comparison of this gas chromatogram with that of a standard solution of deuterated carboxylic acids prescribed the quantity of the deuterated solution to be added to the meteorite extract in order to have approximately a 1 : 1 correspondence in molar concentration between the carboxylic acids in the meteorite sample and their deuterated analogues. After adding the solution of deuterated acids and intimate mixing, the ether layer was separated from the aqueous phase and the latter was extracted three times with 1-ml portions of diethyl ether. The combined ether extracts were dried over sodium sulphate, filtered and concentrated to a small volume (~50 μl) for analysis by combined gas chromatograph–mass spectrometry (GC–MS).

Table 1 Monocarboxylic acids in Murchison meteorite

Compound	Abundance (μmol g^{-1})	$N/\Sigma Br$
Ethanoic	1.03 ± 0.06	—
Propanoic	1.83 ± 0.03	—
2-Methylpropanoic	0.50 ± 0.06	0.76
Butanoic	0.38 ± 0.02	
3-Methylbutanoic	0.09 ± 0.02	
2-Methylbutanoic	0.12 ± 0.02	0.57
Pentanoic	0.12 ± 0.03	
4-Methylpentanoic	0.07 ± 0.02	0.86
Hexanoic	0.06 ± 0.01	
Heptanoic	0.03 ± 0.01	
Octanoic	0.01 ± 0.002	

To determine the effectiveness of this procedure to extract the monocarboxylic acids from the sample, the solid meteorite residue was again pulverised and re-extracted by the procedure described. No monocarboxylic acids were found in the second extract, which strongly suggests that the first extraction process had completely removed these acids from the sample. Therefore, the values for the monocarboxylic acids (Table 1) are good estimates of the abundance of these compounds in this sample of the Murchison meteorite. Satisfactory procedural blanks accompanied all the experiments.

An area of concern is the possible degradation of these saturated monocarboxylic acids during extraction. However, the potassium hydroxide and refluxing methanol involved, are also used in a procedure to identity these acids[25] and are not known to degrade them[26]. It is reasonable to assume that the saturated monocarboxylic acids should survive a similar treatment.

Our procedure was similar to that used previously but with slight modification[23]. Mass spectra were acquired every 4.2 s over the mass range 12–400 throughout the GC run. Identity of the individual components was established by evaluation of the mass spectra obtained for each component eluting from the GC. Quantification was accomplished by selection of mass spectral ions of the corresponding deuterated and undeuterated analogues of each monocarboxylic acid and measurement of the area ratio of each m/e pair within a given gas chromatographic peak. The results of this measurement from the deuterium-spiked Murchison meteorite extract were then compared with standard calibration curves obtained in an analogous fashion from standard mixtures. The quantification data for the monocarboxylic acids reported in Table 1 were obtained in this way.

As an extraterrestrial chemical synthesis seems to be responsible for the presence of the monocarboxylic acids in the Murchison meteorite, a similar distribution of decreasing concentration with increasing molecular weight would be expected to that found for the amino acids[9]. Such a distribution for the monocarboxylic acids was not obvious from the data previously reported[11]. In that study, the GC peak heights (and area) for propanoic and hexanoic acids appeared to be equal, suggesting equal concentrations of these two compounds. In reality, propanoic acid is 30 times more abundant than hexanoic acid (Table 1). Gas chromatogram peak areas do not adequately reflect the distribution of components, as these results could be an artefact of the analytical procedure used. For example, the distribution of the acids previously observed could have been skewed by the differences in partition coefficients of these acids in the solvents utilised. Thus, the quantification data presented in Table 1 reflect more accurately the monocarboxylic acid distribution in that the deuterated analogues added to the meteorite extract during the isolation procedure would be subjected to the same analytical skewing.

The monocarboxylic acids are present in the Murchison meteorite in higher concentration than are the amino acids, which are the only other group of compounds that have been rigorously quantified[5,10,23]. The concentration of propanoic acid (1.83 μmol per g of meteorite), the most abundant monocarboxylic acid, is ~58 times greater than the most abundant amino acid, glycine (0.041 μmol g^{-1})[23] found in aqueous extracts of the Murchison meteorite. We also note a general decrease in concentration of the monocarboxylic acids as the number of carbon atoms in these acids increased, a trend similar to that previously noted for the amino acids[9]. This supports the hypothesis that monocarboxylic acids, like amino acids, are present as the result of an extraterrestrial abiotic synthesis. Table 1 shows that nearly equal concentrations of each branched- and straight-chain isomer with the same carbon number are present in the sample.

Miller[27] showed that formic, acetic and propanoic acids could be synthesised when a primitive-Earth-type reducing atmosphere was subjected to a spark discharge. Similarly, C_2–C_{12} monocarboxylic acids have been produced when a methane–water mixture was exposed to a semicorona discharge[28]. In the discharge experiment monocarboxylic acids with carbon numbers less than six were present both as straight- and branched-chain isomers, but for those acids with carbon numbers of six or greater, only the branched-chain isomers were observed[28]. Since the Murchison meteorite contains straight-chain monocarboxylic acids with carbon numbers greater than five (hexanoic, heptanoic and octanoic acids) a re-evaluation of the laboratory simulation experiment is warranted. An alternative mechanism (FTT) has been proposed as the possible pathway to the organic compounds in meteorites[21]. Theoretical consideration of the proposed mechanism for the FTT process predicts a high concentration of straight-chain isomers, with $N/\Sigma Br > 1$, for any given carbon number (N, straight-chain isomer concentration; Br, branched-chain isomer concentration). Recent FTT experimental studies in which monocarboxylic acids were synthesised[29] support this prediction.

Although Leach *et al.*[29] were not able to quantify the C_2–C_6 monocarboxylic acids which would have allowed a direct comparison of their results with those reported in Table 1, they did report quantification of the C_7–C_{18} monocarboxylic acids that were synthesised by the FTT process. Straight-chain isomers were observed to predominate over the branched with $N/\Sigma Br$ ratio falling between 1.7 and 5.

In contrast, the predominance of straight- over branched-chain isomers is not observed for the isomeric monocarboxylic acids found in the meteorite extract ($N/\Sigma Br < 1$, Table 1). Moreover, this study and previous work[11] indicate that other branched-chain isomers are present. If these were included in the quantification, the value of $N/\Sigma Br$ would be further decreased. Thus, if the monocarboxylic acids present in the Murchison meteorite are the original, unchanged, extraterrestrially synthesised compounds, its isomer distribution is not consistent with that of the FTT process. Thus the FTT process, conducted in reported experimental conditions[29], is not apparently singly responsible for the formation of the acids found in the Murchison meteorite. If a two-step mechanism is envisaged, a primary FTT reaction followed by a secondary partial equilibration[21], then the effect of the equilibration step on product distribution deserves careful examination. It has been predicted on theoretical grounds[30] that there would be little difference in concentration between straight- and branched-chain isomers of the short-chain (C_2–C_8) monocarboxylic acids formed inorganically in equilibrium conditions. The meteorite results reported here apparently support this prediction with regard to isomer distribution. Our results are consistent with the production of the monocarboxylic acids by a naturally occurring chemical synthesis and support the chemical evolution theory.

Experimental evidence of rare earth element immobility in greenstones

Martin Menzies & William Seyfried Jr

Department of Geology and Geophysics, 108 Pillsbury Hall, University of Minnesota, Minneapolis, Minnesota 55455

Douglas Blanchard

Significant petrogenetic importance has recently been placed on the Nd isotopic composition and variable rare earth element (REE) content of basalts, although the effect of alteration on the REE has not been fully investigated. REE analyses of oceanic[1–6] and ophiolitic basalts[7,8] suggest that the light REE (La, Ce, Nd, Sm, Eu) are mobile during basalt–seawater interaction at relatively low temperatures. However, the behaviour of the trace and rare earth elements during greenstone formation at higher temperatures is less well understood[9–15], primarily because of uncertainties regarding the composition of the unaltered precursor, temperature, pressure and effective water/rock ratio. In an attempt to overcome these uncertainties we have analysed basalt glass subjected to 10 individual basalt–seawater interaction experiments. In all these experiments the REE are found to be immobile at temperatures of 150–350 °C even when the basalt is totally altered to clay. Furthermore the data suggest that the minor fluctuations observed in the light REE content of some greenstones[9,10] may result from a low temperature overprint due to retrograding of the greenschist facies basalts.

Details of the experimental, analytical and sampling procedures used in this study have been described elsewhere[8,15,16]. Briefly, experiments were performed at temperatures from 150 to 350 °C, 500 bar and water/rock mass ratios of 10–125 using Dickson hydrothermal equipment[16], and REE were analysed by instrumental neutron activation analysis (INAA). Figure 1 shows the REE composition of the fresh basalt glass (*a*) and experimental alteration products relative to chondrite (*b–e*).

The glassy tholeiite (that is, unaltered precursor) has a light REE depleted profile with a detectable Eu anomaly—features characteristic of many ocean-floor basalts. All of the experimentally altered basalts have similar REE profiles, although

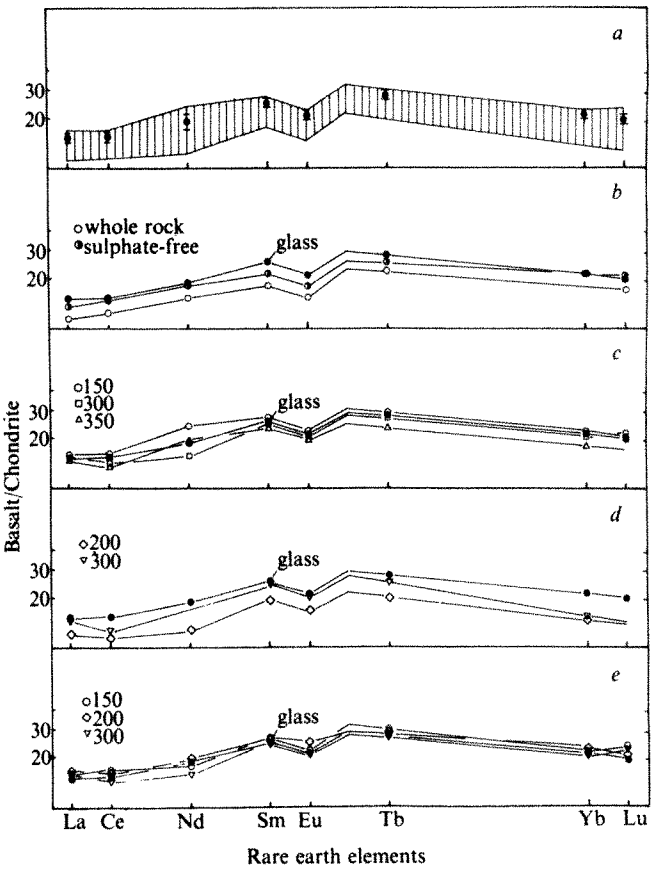

Fig. 1 Chondrite normalised REE patterns of experimentally altered basalt and the unaltered precursor. The figure includes the REE abundance profile of *a*, the fresh glass (●) with error bars and the total range in REE produced by alteration of this glass at 150–350 °C and a water rock ratio (W/R) of 10–125; *b*, the whole rock altered at 300°C and a W/R 125 before and after correction for 20% modal anhydrite; *c*, the whole rock altered at 150–350 °C and a low W/R of 10; *d*, the whole rock altered at 200–300°C and a higher W/R ratio; and *e*, the silicate fraction (chlorite + smectite) altered at 150–300 °C and a W/R of 62 (anhydrite was removed by repeated washings in deionised water[15]).

they differ in their absolute REE content. We believe this to be a dilution effect caused by the presence of anhydrite, a phase ($CaSO_4$) which precipitated during the experiments[15]. For example, anhydrite constituted approximately 20% of the 'bulk' alteration from interaction at 300°C and a water/rock ratio of 125. Anhydrite contains an insignificant amount of REE, so its presence simply and effectively dilutes the REE abundances of the alteration products as a whole. Thus correcting for the presence of anhydrite, a REE profile develops which is identical to that of the unaltered basalt (Fig. 1*b*). This is highly significant since the basalt was entirely transformed to a mixed layer chlorite–smectite phase. This was the case for all silicate fractions (altered basalt minus anhydrite)[15] separated from the altered solids from each experiment. Thus, for the duration of these experiments, REE were conserved and in general revealed a solubility similar to previously defined conservative species, such as Co, Cr, Ni, Al, V and Ti (W.S. and M.J. Mottl, unpublished).

Hydrothermal alteration of the oceanic crust and greenstone formation apparently occurs at temperatures, pressures, and water/rock ratios analogous to those used in these experiments. The immobility of REE in greenstones from the Point Sal[8] and Troodos[11,19,20] ophiolites, and the Mid-Atlantic[10] Ridge compares favourably with the data presented here. Similarly, amphibolites[21] and chlorites[22] from the seafloor exhibit REE abundances typical of oceanic basalts. In the case of the chlorites

0028-0836/79/470398—02$01.00

it was proposed that they represent disrupted fragments of submarine greenstones[22]. This conclusion is certainly compatible with the results of the present investigation which confirm the relative immobility of REE during hydrothermal processes (Fig. 1), hence, their use as a 'fingerprinting' tool to deciphor origins of recent and Archean[9,23] greenstones.

However, it is difficult to reconcile the fluctuations in light REE content of some greenstones with the experimental data. Because the light REE are more mobile at low temperatures than at 150–350°C the apparent mobility of the light REE in rocks with greenschist facies mineralogy may partly reflect retrograde reactions. Such reactions would superimpose a low temperature overprint on the greenstone thus modifying the mineralogy and chemistry of the rock.

Massive volumes of seawater must be involved in retrograde processes if these events are to substantially modify the REE content of basalt. Furthermore, that LREE are specifically enriched during this event suggests ionic size–charge relationships may be important if not restrictive to secondary REE enrichment. Certainly this is true for post-greenstone enrichment of K and Rb. These species are apparently incorporated in cation exchange sites of clay minerals (smectite, mixed layer chlorite–smectite, chlorite) in greenstones. Sediments found within the Troodos ophiolite have a La, Ce, and Nd content 10–100 times that of basalt[7]. Similarly, clay rich umbers[7] (ferromanganoan oxyhydroxides and silicates) concentrate the light REE (except Ce) relative to basalt. Thus the light REE can be enriched in clay minerals within greenstones provided adequate exposure to seawater is maintained for prolonged periods of time (>1 Myr). This is particularly noticeable in basalts found within or adjacent to the discharge zones of the Troodos submarine geothermal system[7]. The basalts are characterised by pronounced negative Ce anomalies and enhanced La and Nd contents, whereas, zeolite and greenschist facies[11,20] basalts isolated from abundant seawater show no such REE mobility.

The effect of availability and accessibility of seawater and REE mobility is also amply illustrated in the Point Sal[8] ophiolite, Caifornia. At Point Sal the upper smectite bearing lavas have been exposed to seawater for ~15 Myr before deposition of a sedimentary horizon primarily consisting of chert[26]. Thus, these volcanic flows were actively and effectively altered by seawater for approximately 15 Myr before being isolated. The light REE in these lavas were mobilised and are now characterised by negative Ce anomalies[8]. Similar anomalies have been observed in seawater[27], marine precipitates[7,27], and basalts[2,4,7] exposed to low temperature alteration or retrograde reactions. However, at a stratigraphically lower level in the Point Sal ophiolite, greenstones show little or no change in REE abundance even though these rocks are thoroughly altered and characterised by abundant epidote and quartz (epidosite)[8]. We believe that the apparent absence of REE mobility during greenschist facies metamorphism results from limited exposure of these rocks to fluids (seawater) at low temperatures. Vein mineralisation during incipient alteration may have effectively reduced the permeability of these rocks to the point of not permitting access of seawater subsequent to the primary alteration event.

Variations in the light REE content of greenstones relative to an inferred unaltered precursor have been noted[9,10,24]. These changes may in part reflect alteration effects subsequent to the metamorphic event which initially transposed the basalt to greenstone. The suggestion that greenstones are modified chemically subsequent to their formation is supported by the light REE enrichment noted and the trace element abundances reported for these rocks. It has been shown experimentally that K is leached from basalt[15] reacted with seawater at temperatures ≥150°C; whereas, at lower temperatures the reverse is true, that is, K is removed from seawater and enriched in the altered basalt[25].

The above discussion emphasises that metamorphic minerals produced during greenstone formation immobilise the REE and that changes in the light REE may result from retrograde effects. There remains the problem of spilites and greenstones with modified ΣREE contents. The origin of these rocks is clearly complex, although Sun and Nesbitt[9] and Hellman and Henderson[13] attribute the consistent change in REE profile to alteration processes. However, the REE content of an altered rock is influenced by, (1) the chemistry of the unaltered precursor, (2) the extent of igneous fractionation[28], and apparently (3) the degree of retrograde reactions. Thus the REE chemistry of these rocks[9,13] probably represents a complex interplay of primary and secondary processes, and their origin is at best equivocal.

The experimental work was performed in the hydrothermal labs at Stanford University and the USGS, under NSF grant IDO-74-12880. We thank Mike Mottl for his paticipation in these experiments. The analytical work was completed at the Planetary and Earth Sciences Division of the Johnson Space Center, Houston, Texas. This work was supported by NSF grant EAR 7-75-14806 (to V. R. Murthy), and Sandia Laboratories, contract 13-4009 (to W. E. S. Jr).

A new date for *Ramapithecus*

Lisa Tauxe

Department of Geological Sciences, Columbia University, Lamont-Doherty Geological Observatory, Palisades, New York 10964

Recent work in the Middle Siwalik rocks of the Potwar Plateau in northern Pakistan is doing much to further our understanding of Miocene mammalian evolution, in particular the evolution of *Ramapithecus* and *Sivapithecus*, hominoids considered important for human ancestry[1]. It is crucial to the understanding of hominoid evolution to place the fossils in as precise a chronologic framework as possible. As there is a lack of material suitable for radiometric dating, it is necessary to rely on the correlation of the magnetic stratigraphy associated with the Siwalik faunas to the calibrated magnetic polarity time scale (MPTS). Initial age estimates by Barndt *et al.*[2] were based on reconnaissance level palaeomagnetic sampling. The more detailed sampling presented here suggests a revised correlation of the local magnetic stratigraphy to the time scale and hence a revised age estimate for *Ramapithecus*: 8 Myr now seems more likely than the previous estimate of 9 Myr.

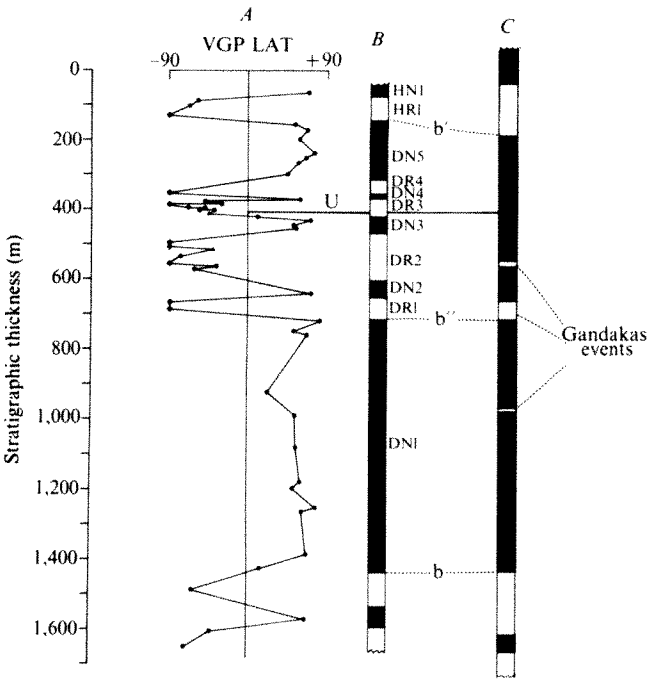

Fig. 1 Column *A*, VGP latitudes calculated from site means of the Ratha Kas section[1]. Class A, B and C data (see text) are denoted by circles, triangles and diamonds respectively. Column *B*, Block diagram of section in (*A*), black is normal polarity, white is reversed. Magnetozones D and H stand for Dhurnal and Hasal chronostratigraphic units[12]. N and R stand for normal and reversed respectively. Column *C*, Part of the magnetic stratigraphy of Barndt *et al.*[2] correlated to section shown in (*A*) and (*B*) by means of stratigraphic marked bed U.

Barndt *et al.*[2] established a local magnetic stratigraphy which was correlated to the MPTS based on various faunal constraints and later showed it to be consistent with a dated bentonite[3]. The bulk of the hominoid material was thus estimated to be around 9 Myr old. In the work described here, part of the magnetic stratigraphy of Barndt *et al.*[2] was examined in great detail, originally to precisely define an isochron within the sediments that could be used for lateral correlation of hominoid levels. However, as a result of this more detailed work it became clear that the original identification of the magnetic reversal sequence needed revision.

The location, geological setting and stratigraphy are described in detail elsewhere[4]. Briefly, the strata exposed on the northern flank of the Soan Synclinorium are cut by rivers flowing approximately perpendicular to strike. The sampling technique used was similar to that described by Johnson *et al.*[5] which is ideally suited for Siwalik sediments. Sampling of river channel exposures resulted in the section shown in Fig. 1. Each site consists of three to five samples and the sites were placed in a stratigraphic section constructed by members of the joint GSP–Yale University field party. The section presented in Fig. 1 consists of 81 sites in 1,600 m for an average site density of about 1 in 20 m. The actual site density is dependent on the relative abundance of sandstone (unsuitable for palaeomagnetic purposes) and the finer grained units, and thus varies over the thickness of the section. The maximum separation is estimated to be about 100 m and the minimum separation is about 1.5 m.

To allow unambiguous correlation of the magnetostratigraphic section of the Khaur area, a major sandstone unit, referred to here as the 'U' sandstone, was carefully traced in the field from section to section. The magnetic stratigraphy presented here can thus be precisely correlated to the sections of Barndt *et al.*[2].

An extensive study of the magnetic mineralogy of Middle Siwalik rocks has been completed, including a conglomerate test coupled with rock magnetic studies which will be presented elsewhere. It is reasonable to assume that the primary remanence of the rocks is carried by haematite, was acquired during or soon after deposition, and can be isolated by thermal demagnetisation. After thermal demagnetisation at 550 °C, site means were calculated using Fisher statistics[5]. Sites found to be statistically significant by Watson's test for randomness[7] (for a mean of three sample directions of unit length, the resultant vector length must be ≥ 2.62) after thermal cleaning are designated Class A. Statistically significant sites after a.f. demagnetisation at peaks of 300 Oe are Class B, useful primarily when the specimens disintegrate on heating. Class C are sites with two specimens showing reversed directions in good agreement where the third is either lost, crumbled or widely deviant. Class D are samples showing a strung distribution to the South and are thought to be possibly reversed. Only Class A, B and C data are used here. Class A and B site means were converted to virtual geomagnetic pole (VGP) latitudes.

In Fig. 1, Classes A, B and C are represented by circles, triangles and diamonds, respectively. In some cases sites showing a statistically significant normal cluster after a.f. treatment became reversed after thermal cleaning. To ensure the best quality palaeomagnetic data, only Class A data are used for normal polarity information as there is mounting evidence to indicate that a.f. demagnetised specimens have not been properly cleaned. Each labelled magnetozone of Fig. 1 has been substantiated in at least three stratigraphically correlatable sections in the Khaur area, strengthening the assumption that they represent palaeomagnetic field behaviour.

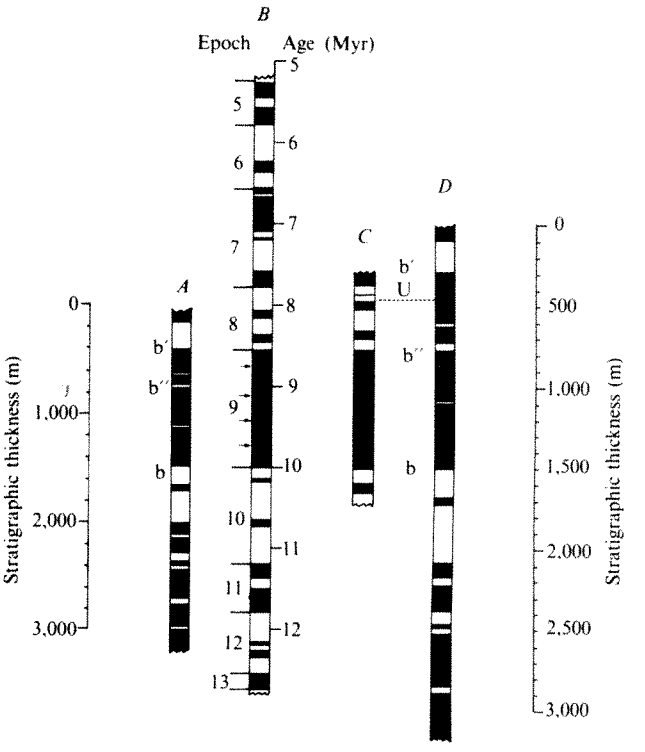

Fig. 2 Correlation of the magnetic stratigraphy to the magnetic polarity time scale. Column *A*, Previous correlation to the time scale of the Barndt *et al.*[2] section. Column *B*, The revised dates given by Mankinen and Dalrymple[13] for the time scale of LaBrecque *et al*[14]. Column *C*, The section presented in this paper drawn to scale at right assuming DN1 (see Fig. 1) is Epoch 9 of the time scale. Column *D*, The section in (*A*) redrawn at the same scale as the section in (*C*). The stratigraphic marker bed U allows unambiguous stratigraphic correlation of the Barndt *et al*[2]. section in (*D*) and the more densely sampled section of (*C*). The bulk of the primate material has been found in close association with the U marker bed and thus is about 8 Myr old.

The magnetic stratigraphy of Barndt *et al.*[2] established the existence of a long zone of dominantly normal polarity (b to b′ of column *C* of Fig. 1) which was apparently punctuated by several reversed events known as the 'Gandakas Events'. The Barndt *et al.*[2] section was correlated to the MPTS as shown in Fig. 2*A* based on faunal constraints and visual correlation. The magnetic stratigraphy in Fig. 1 represents a more densely sampled section of the same strata and it is clear that the Gandakas Events represent more reversed time that was previously supposed.

Several assumptions must be made to make a useful correlation of the magnetic polarity stratigraphy to the MPTS. These include: (1) an estimate of the range of ages that the section could encompass; (2) that for a given lithofacies, when averaged over a large stratigraphic thickness, thickness is linearly proportional to time; (3) the section is densely sampled enough to assume that it approximates field behaviour; and (4) the magnetic remanence of the rock was acquired shortly after deposition and represents a record of the magnetic field at the time of formation of the rock. These assumptions are not always valid and great care must be taken to substantiate them whenever possible.

Both Barndt *et al.*[2] and the magnetic stratigraphy of this paper are bounded by the following palaeontological criteria. A maximum age for the bottom of the section is given by the sudden appearance of the extinct equid, *Hipparion*, within the Khaur normal zone (DN1 of Fig. 1). The earliest Old World *Hipparion* has been dated[8] at 12.5 Myr, and the Indian *Hipparion* is probably younger (B. MacFadden, personal communication). A minimum age for the top of the section is given by the conspicuous absence of hippopotamus, *Hexaprotodon*, which occurs suddenly and abundantly in the Upper Siwaliks. The oldest hippopotamus in the Siwaliks is found in the Rhotas section at the Gilbert/Epoch 5 boundary. The absence of *Hexaprotodon* (John Barry, personal communication) in the section presented here and in that of Barndt *et al.*[2] therefore suggests that the top of the section is probably older than about 5 Myr.

Based on the more detailed section presented here it seems unlikely that the Gandakas Events (Fig. 1*C*) are all within Epoch 9 because (1) in the more detailed section shown in Fig. 1, the reversed zones represent a large stratigraphic thickness and it is unlikely that such long reversed zones would be unresolvable in the seafloor spreading record, and (2) the four events or intensity fluctuations discussed by Blakely[10] and Cande and Labrecque[11] are evenly spaced within anomaly 5 (Epoch 9) and the reversed zones in Fig. 1 are tightly grouped. A better correlation of the magnetic stratigraphy of the Khaur area, based on the work presented here, is shown in Fig. 2*C* where the vertical scale is expanded by assuming the two upper Gandakas Events to comprise Epoch 8. Epoch 9 is thus b to b″ of Fig. 2. Figure 2*D* shows the Barndt section redrawn to the same scale as Fig. 2*C*. Clearly the overall correlation is much improved and there is now a reasonable fit to the time scale from the top of Epoch 8 to the bottom of Epoch 11. Below Epoch 11 there seems to be a dominance of normal polarity which seems to correlate with an increase in red pigmentation. Recent efforts using thermal demagnetisation techniques have improved the fit below Epoch 11 dramatically (to be presented elsewhere).

Fig. 1 suggests three short normal subzones, DN2-DN4, within the dominantly reversed zone. Since the normal subzones occur in correlated sections of different rock types and persist after thermal demagnetisation, these are thought to be real. The uppermost zone, DN4, was ignored in the correlation process because in most sections it is represented by only one site, even when sampled at 1.5 m intervals and is therefore likely to be genuinely short and thus undetectable from the seafloor spreading record. Accepting that the long normal DN1 is Epoch 9, and that thickness is approximately linearly related to time over this interval, then the best match to the time scale (that requiring the least condensing or stretching of the section) is that adopted in Fig. 2*C*. Thus the youngest of the three normal subzones DN4 within the reversed zone seems to be a previously undetected normal event within Epoch 8.

The results presented here emphasise the importance of adequate specimen demagnetisation and sampling density. Based on the previous reconnaissance level work the correlation appeared quite reasonable, but this detailed work has revised the age scale significantly. The bulk of the hominoid localities in the Khaur region fall within a narrow band associated with the U stratigraphic marked bed and a date of 8 Myr is apparently much more reasonable than the previous 9 Myr.

Even with adequate sampling density, palaeomagnetic stratigraphy in Middle Siwalik rocks is more uncertain than in rocks younger than about 5 Myr because (1) the time scale itself is less well defined and (2) the rocks have undergone prolonged diagenetic alterations (such as red pigment formation) which often obscures the original magnetisation of the rock. For these reasons, work is in progress to extend the magnetic stratigraphy pattern into younger rocks in order to increase the reliability of the correlation and the inferred ages.

I thank Neil Opdyke, David Pilbeam and Bruce MacFadden for their time spent as faculty and research advisors. I also thank Dennis Kent and Neil Opdyke for helpful criticisms, and John Barry, Kay Behrensmeyer and Geof King for helpful suggestions. Involvement of hydrogen sulphide in the degradation of parathion in flooded acid sulphate soil

P. A. Wahid & N. Sethunathan

Laboratory of Soil Microbiology, Central Rice Research Institute, Cuttack-753006, India

There is increasing evidence that certain pesticides, resistant to degradation in aerobic systems, undergo fairly rapid degradation in anaerobic ecosystems such as flooded soil[1,2]. After flooding, the soil components NO_3^-, Fe^{3+}, Mn^{4+} and SO_4^{2-} are reduced almost in a thermodynamic sequence with a corresponding shift in favour of anaerobic microorganisms[3]. Although anaerobic microorganisms have been implicated directly in the degradation of some pesticides in anaerobic environments[1,2], there is circumstantial evidence for chemically catalysed reactions, involving, for example, the iron redox system[4] or reduced iron porphyrins[5]. However, the importance of this and other dominant redox reactions in the behaviour of pesticides in a flooded soil is not well understood. We report here the involvement of hydrogen sulphide, the end product of sulphate reduction, in the degradation of parathion in a flooded acid sulphate soil.

Portions (10 g) of laterite (*p*H, 6.3; organic matter, 2.88%; S, 0.01–0.03%) and acid sulphate (*p*H, 5.2; organic matter, 5.52%; S, 0.2%; known as pokkali) soils were reduced by flooding with 10 ml of distilled water for 60 d in screw-capped glass tubes (30×120 mm, 30 ml capacity). The 60-d flooded soils were shaken with 160 μg of parathion in acetone for 30 min. The soils, flooded immediately before equilibration with parathion, served as oxidised soils. After 30 min of equilibration, the residues of parathion and its metabolites were extracted from the soils with acetone–sodium sulphate–hexane and the hexane layer was analysed by gas-liquid chromatography using a phosphorus-specific photometric detector. To measure soil reduction due to flooding, the 60-d flooded soil sample in each tube was transferred to a beaker and redox potentials were assayed immediately with a compound platinum–calomel electrode as described before[6]. The variations in soil potential in five replicates were less than 5% by this method. Redox potentials decreased from +260 to −140 mV in laterite soil and from +200 to −200 mV in acid sulphate soil after 60 d of flooding, confirming the reduction of the soil.

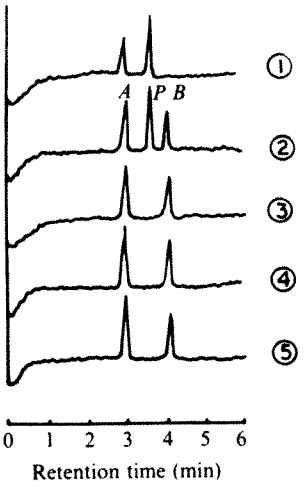

Fig. 1 Gas chromatograms of the products of reactions between: 1, parathion and prereduced laterite soil; 2, parathion and prereduced acid sulphate (pokkali) soil; 3, aminoparathion and prereduced pokkali soil; 4, aminoparathion and sodium iodide; 5, aminoparathion and hydrogen sulphide. *A*, aminoparathion; *P*, parathion; *B*, desethyl aminoparathion. The soils were prereduced by flooding for 60 d before equilibration with parathion (1 and 2) and aminoparathion (3).

After 30 min of equilibration with 60-d flooded soils, the concentration of parathion decreased to 13.8% of the original level in the acid sulphate soil and to 52.1% in the laterite soil. During the same period, 92–95% of added parathion was recovered from the oxidised soils. The gas chromatograms of the residues (Fig. 1) showed that the rapid destruction of parathion in equilibration with reduced soils led to the formation of one compound (peak *A*) in laterite soil and two compounds (peaks *A* and *B*) in acid sulphate soil. Based on chromatographic characteristics (retention time, 2.9 min; R_F, 0.35) and its positive reaction to palladium chloride spray, compound *A* was identified as aminoparathion, a major product of parathion metabolism in soils and in microbial cultures[7].

To characterise compound *B*, authentic aminoparathion was equilibrated with 60-d flooded pokkali soil for 30 min. A gas chromatogram of the residues showed the formation of a compound with the same retention time as that of compound *B* (Fig. 1), which we therefore presume was formed after aminoparathion.

We investigated whether compound *B* was a dealkylation product of aminoparathion as follows. Desethyl aminoparathion was prepared by a reaction between aminoparathion and sodium iodide, essentially as described by Miyamoto *et al.*[8]. Portions of 20 ml each of 0.05 M solutions of aminoparathion and sodium iodide in acetone were refluxed at 65±1 °C in a water bath for 3 h. This chemical reaction produced only desethyl aminoparathion, which had characteristics (retention time, 4 min; R_F, 0.47; positive reaction to palladium chloride spray) identical to those of compound *B*. Thus compound *B* was identified as desethyl aminoparathion. This is the first report of the formation of a dealkylation product in the degradation of parathion in soils. There is evidence that the degradation of related organophosphates, methyl parathion and fenitrothion, by *Bacillus subtilis* leads to the formation of their respective amino analogues and dealkylation products, desmethyl aminoparathion and desmethyl aminofenitrothion[8].

It is interesting that desethyl aminoparathion was generated from added parathion or aminoparathion only by reduced pokkali soil and not by laterite soil. Unlike laterite soil, pokkali soil is rich in organic matter and sulphate and is classified as acid sulphate soil[9]. Sulphate reduction leading to the formation of hydrogen sulphide is important in flooded soils, especially rich in organic matter and sulphate[3]. Studies in our laboratory (R. C. Ray, unpublished results) showed that after the redox potential of the flooded pokkali soil had dropped to −160 mV—a potential favourable for sulphate reduction[10]—there was significant production of hydrogen sulphide and decrease in sulphate content. In contrast, the formation of sulphide in laterite soil was negligible. These results confirmed the substantial formation of sulphide in pokkali soil when it is flooded.

To investigate the involvement of hydrogen sulphide in the dealkylation of aminoparathion, hydrogen sulphide evolved by reaction between sodium sulphide and dilute hydrochloric acid was bubbled through a solution containing 1,000 μg of aminoparathion in 2 ml of acetone and 25 ml of distilled water. The product of the reaction was extracted with acetone–sodium sulphate–hexane and analysed by gas-liquid chromatography. Only one product was detected and that had a retention time similar to that of desethyl aminoparathion and compound *B* formed by the reaction of parathion and aminoparathion with reduced pokkali soil (Fig. 1). When parathion was treated similarly with hydrogen sulphide, aminoparathion and desethyl aminoparathion were not formed. This implies that hydrogen sulphide formed readily in flooded pokkali soil was, at least in part, responsible for the formation of the dealkylation product from parathion through aminoparathion. These findings indicate that chemical degradation of pesticides mediated by the products of anaerobic decomposition of inorganic and organic soil components can be more common and widespread in anaerobic ecosystems than hitherto believed.

Intermodal matching by human neonates

Andrew N. Meltzoff & Richard W. Borton

Child Development and Mental Retardation Center, and Department of Psychiatry and Behavioral Sciences, University of Washington, Seattle, Washington 98195

Normal human adults judge two identical objects to have the same shape even when they are perceived through different modalities, such as touch and vision. The ontogenesis of man's capacity to recognise such intermodal matches has long been debated. One hypothesis is that humans begin life with independent sense modalities and that simultaneous tactual and visual exploration of shapes is needed to learn to correlate the separate tactual and visual sense impressions of them[1-3]. A second hypothesis is that the detection of shape invariants across different modalities is a fundamental characteristic of man's perceptual-cognitive system, available without the need for learned correlations[4-7]. Recent research has shown that 6-12-month-old infants can recognise certain tactual-visual matches[8-11]. However, such data cannot help resolve the classic theoretical debate. Infants of this age repeatedly reach out and touch objects they see, and such simultaneous bimodal exploration presumably offers ample opportunity for learning to correlate tactual and visual sense impressions. The experiments reported here show that humans can recognise intermodal matches without the benefit of months of experience in simultaneous tactual-visual exploration. We demonstrate that 29-day-old infants can recognise which of two visually perceived shapes matches one they previously explored tactually, thus supporting the second hypothesis listed above.

For our assessment of intermodal matching, we adapted a paradigm used to test infant memory[12]. We began with a brief familiarisation period during which the infant tactually explored an object. Next, the infant was shown a pair of visual shapes, only one of which matched the tactual stimulus. Visual fixation to the matching versus non-matching shape was then recorded. Three experimenters were used to ensure objectivity of the results. One experimenter selected the tactual shape and the left-right positioning of the visual shapes. This experimenter was not involved with testing the infant. A second experimenter administered the tactual stimulus. He was not informed about the left-right positioning of the visual shapes. A third experimenter observed the infant's visual fixations through a 0.64-cm peephole in the centre of the rear wall of the testing chamber. He was unaware of both the tactual shape used and the left-right positioning of the visual shapes. Corneal reflections of the test objects were visible to this scorer, but the shapes of the objects were not resolvable. He scored the infant as fixating the left object when the left reflection was visible in either of the infant's pupils, and as fixating the right object when the right reflection was visible[13]. These fixations were recorded on a Rustrack event recorder. Inter-observer agreement was high when assessed in both experiments (0.93, experiment 1; 0.98, experiment 2).

Thirty-two full-term infants ranging from 26 to 33 days old (mean 29.4 d) served as subjects in experiment 1. As infants of this age will not explore objects manually, the tactual stimuli were constructed by modifying pacifiers so that small, hard-rubber shapes could be mounted on them (Fig. 1). The matching shapes used for the visual test were constructed from dense Styrofoam and painted bright orange (diameter 6.4 cm). The experiment started with a 90-s tactual familiarisation period during which infants orally explored one of the tactual stimuli. This stimulus was then removed and the infant presented with both visual shapes for a 20-s visual test. Care was taken to ensure that the tactual stimulus was administered and removed without the infant seeing it. The shape used for tactual familiarisation, the left-right positioning of the visual objects, and the sex of the infants were counterbalanced. Thus, half the infants were tactually familiarised with the sphere and half with the sphere-with-nubs; half the infants in each of these groups were shown the familiar shape on the left and half on the right; half the infants within each of these subgroups were male and half female.

The results clearly demonstrate that infants under 1 month of age are capable of intermodal matching (Table 1). Of the 32 infants, 24 fixated the shape matching the tactual stimulus longer than the non-matching shape. These results were significantly different from chance ($P < 0.01$; binomial test). The mean per cent of total fixation time directed to the matching shape was 71.8%, as compared with the chance level of 50% ($t = 3.07$; $P < 0.01$). There were no significant differences due to sex of the infant, familiarisation object or method of feeding (breast or bottle), nor were there significant preferences for fixating the right versus left side or for fixating the sphere versus sphere-with-nubs.

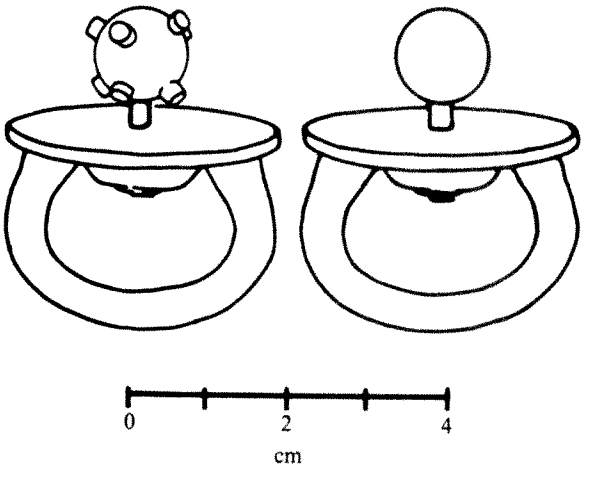

Fig. 1 The tactual objects. The tactual shapes were 1.2 cm in diameter. They were moulded from G.E. RTV-620A silicone rubber and fixed to a threaded nylon rod (6–32) that was bolted to the pacifier backing. The sphere-with-nubs was administered so that four of the nubs were orientated towards the base of the infant's mouth and four towards the roof. The nubs on the sphere were 2 mm high × 3 mm wide. The tactual stimuli were administered while the infant sat in an infant chair with his back to the visual objects. They were administered without the infant seeing them by having the experimenter hide them in his cupped hand while he was bringing the objects to and from the infant's mouth. The tactual familiarisation period started as soon as the infant began sucking on the tactual shape. Ten seconds before the end of the familiarisation period, the room lights were extinguished and the infant's seat was swivelled around so that he faced the visual objects. When the familiarisation period ended, the experimenter removed the tactual object, centred the infant's head midway between the visual objects, and only then switched on the light illuminating the visual objects. As soon as the infant made his first fixation to either object, the visual test period began, and the experimenter removed his hands from the infant. The centres of the visual objects were 28 cm apart and 32 cm from the infant's eyes. They were displayed in a three-sided black cardboard chamber 71 cm high × 112 cm wide × 52 cm deep, and each suspended from the ceiling of this chamber by a thin black rod (diameter 0.64 cm). Illumination for the visual objects was provided by an incandescent bulb directly above and behind the infant's head, yielding a luminance of approximately 0.86 log cd m^{-2} at the objects and −0.14 log cd m^{-2} at the background midway between the objects. The visual sphere-with-nubs was orientated so that four of the nubs directly faced the infant. Each nub on the visual object was 1.1 cm long and 1.2 cm in diameter and fashioned from a section of wooden doweling with the edge rounded.

Table 1 Numbers of infants who looked longer at the object matching one they had explored tactually, compared with those who looked longer at the non-matching object

	n	Looked longer at matching shape	Looked longer at non-matching shape	P (binomial test, two-tailed)
Expt 1	32	24	8	0.01
Expt 2	32	22	10	0.05

Studies using paired-comparison paradigms usually report a preference for the novel stimulus. The present findings are not incompatible with this, as there are several important procedural differences between the present experiments and those previously reported. For example, the present experiments (1) used infants younger than typically tested with the paired-comparison technique, (2) assessed tactual–visual rather than visual–visual matching, (3) used three-dimensional forms rather than two-dimensional patterns, (4) used a 90-s tactual familiarisation period. These differences may interact to influence the direction of infant visual preference.

A second experiment checked whether different experimenters using a different sample of infants could replicate the previous effects. A new group of 32 full-term infants 27–31 days old (mean 29.4 d) served as subjects. The procedure was identical to that used in experiment 1 and the effects were replicated (Table 1). Of the 32 infants, 22 fixated the matching shape longer than the non-matching one ($P = 0.05$). The mean per cent of total fixation time directed to the matching shape was 67.1% ($t = 2.14$; $P < 0.05$).

These experiments used a successive, intermodal matching task. The tactual object was no longer in the perceptual world at the time the infants were presented with the visual test. Positive results from such a task indicate that neonates can (1) tactually discriminate between the shapes presented, (2) visually discriminate between them, (3) store some representation of the tactually perceived shape, and (4) relate a subsequent visual perception to the stored representation of the tactually perceived shape. The last point has implications for our current theories of infancy.

A basic assumption of piagetian theory[3] is that infants begin life with independent sense modalities that gradually become intercoordinated with development. Our findings, however, show that neonates are already able to detect tactual–visual correspondences, thereby demonstrating an impressive degree of intermodal unity. Thus, whatever develops in the first year of life, it is apparently not the *de novo* coordination of functionally independent sense modalities. A more general implication of the present research is that human neonates are not limited to processing bits of sense-specific information such as retinal images or tactual sensations. If neonates were restricted to registering such sensory elements they could not succeed on these intermodal matching tasks. Obviously, these initial experiments do not isolate the exact nature of the information perceived as invariant across the different modalities. However, they suggest that neonates are capable of using and storing surprisingly abstract information about objects in their world. This information must be abstract enough, at least, to allow recognition of objects across changes in size and modality of perception.

Is there a 'consolidation' effect for monocular deprivation?

R. D. Freeman* & C. R. Olson†

School of Optometry, University of California, Berkeley, California 94720

During a time of high vulnerability early in a kitten's postnatal life, a few days of monocular vision can result in the control of most striate cortical neurones exclusively by the open eye[1–5]. Although the general consequences of this procedure have been known for some time[6], the mechanisms remain unknown. Because they develop rapidly[3,4], it has been suggested that the processes involved are similar to those of memory and learning. One aspect of this analogy is that memory is thought to be 'consolidated' from a weak to a stable form and that the process can be disrupted by the administration of drugs, electroconvulsive shock or physical trauma[7]. The connection with plasticity in the visual cortex has been suggested by studies in which kittens were first bilaterally deprived and then briefly exposed either monocularly or binocularly[3,4,8]. The effects of exposure were reported to be greatest if there was a delay between exposure and physiological study. Although this has been referred to as a 'consolidation' effect[3,4,5,8], it was a delay process rather than a process of stabilisation that was investigated. Furthermore, even though the evidence for this effect is not compelling, it has been assumed that the consequences of monocular deprivation in kittens with prior normal rearing also are consolidated, that is, they become accentuated if the unilateral occlusion is followed by a period without vision[5]. We tested directly the notion that short-term monocular deprivation effects are more extensive if, after unilateral exposure, a period is imposed before physiological study during which kittens are kept in darkness. We report here that the consolidation idea is not supported by our results. On the contrary, the post-monocular period spent in darkness actually diminished the consequences of the deprivation, allowing some functional recovery of binocular connections.

Kittens were reared normally until postnatal day 29, when susceptibility to deprivation effects is very high[1]. Vision through one eye was then blocked for 24 h using a large opaque contact lens. In one group of animals, study of cortical cells was begun immediately after the occlusion period. A second group was placed in a darkroom for 48 h before recording. Because 4-week-old kittens sleep a great deal, it was necessary to keep them awake during as much of the monocular exposure period as possible. All kittens were watched during most of their exposure sessions and they were periodically isolated from their mothers so that their attention could be maintained. The recording sessions were arranged so that cats were studied in pairs, one by each of us in separate laboratories. Findings were not compared until the studies were completed.

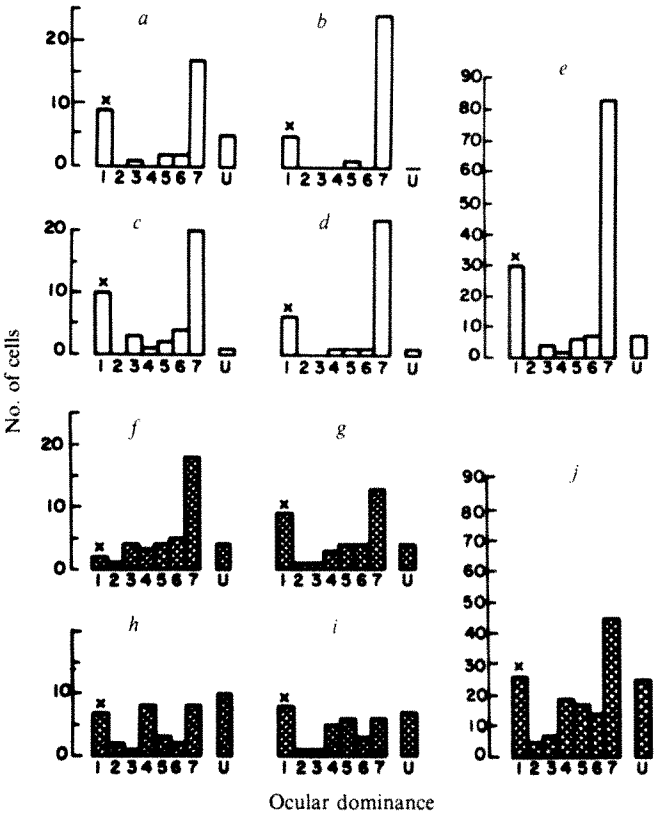

Fig. 1 Ocular dominance histograms are shown for experimental animals. The numbers on the abscissae represent subjectively determined classifications of the degree to which the two eyes influence a given cortical cell. Binocular neurones are designated by groups 2–6 and monocular cells by groups 1 and 7. Groups 1–3 (or 5–7) represent cells dominated by the eye contralateral (or ipsilateral, respectively) to the hemisphere from which electrode recordings were made. Visually unresponsive cells are indicated by the category 'U'. After 4 weeks of normal postnatal rearing, eight kittens were unilaterally occluded with large opaque contact lenses worn in their left eyes for 24 h. Half were studied physiologically immediately after occlusion (*a–d*) and the other half spent 48 h in darkness before recording (*f–i*). Summary histograms are shown for each group in *e* and *j*. × Indicates the occluded eye, which, in all cases, was contralateral to the hemisphere that contained the electrode.

Standard physiological recording techniques were used[9,10]. Halothane was used while a vein was cannulated, and anaesthesia was continued with Brevital while a tracheal tube was positioned and an electrode placed. Animals were then paralysed and artificially respirated; CO_2, electroencephalogram, electrocardiogram and temperature were monitored. Spikes isolated from individual neurones by means of tungsten-in-glass microelectrodes were amplified and displayed. As a conservative procedure, electrodes were always placed in the hemisphere contralateral to the deprived eye because, in the normal cat, the contralateral eye tends to predominate[9].

Receptive fields were determined for each responsive unit. Optimal stimuli were found for each eye and cells were classified into types using standard criteria[1,2,9,10]. We paid particular attention to subjectively determined estimates of absolute response strength and to the relative strength of responses elicited through each eye (ocular dominance). Response strength classifications used were: unresponsive, weak, fair, good and vigorous. Relative strength was categorised into seven ocular dominance groups, as defined in Fig. 1 legend.

In normal cats and kittens, most cells in the visual cortex are binocular[1,9]. Ten days of monocular occlusion in a 4-week-old kitten results in the open eye gaining control over nearly all cortical cells[2]. One day of this procedure is sufficient to produce a marked effect, as shown in Fig. 1. Ocular dominance histograms *a–d* are for kittens studied immediately after 24 h of monocular deprivation. A summary of these results is given in *e*. Two marked effects are evident. First, very few binocular cells were found; second, considerably fewer cells were controlled by the deprived eye in all cases (27% of the total are contralateral, that is, fall into groups 1–3). Most cells were highly responsive to optimal stimuli and, as shown in the histograms, very few were visually unresponsive. Data from the animals placed in darkness for 48 h following 24 h of monocular exposure are shown in Fig. 1*f–i*, with a summary in *j*. Once again, there is a clear reduction of binocularity, but it is noticeably less than in the first group (binocular cells constitute 14% in the first group *e* and 47% in the second *j*). The findings for the group which was studied after a delay also indicate a predominance of ipsilateral (groups 5–7) cells (64%). Although this is less than the proportion observed in the group recorded immediately after monocular exposure (73%), the difference is not statistically significant (χ^2 test). The summary histograms (Fig. 1*e*, *j*) show one other prominent difference between the two groups. Visually unresponsive cells comprise only 5% (7 cells) of the total in the first group *e*, but 16% (25 cells) in the second group. In addition to the higher proportion of unresponsive cells, the imposition of 48 h of darkness (second group) seemed, in general, to cause a noticeably reduced strength of visual responsiveness even when cells were driven through the eye that had not been deprived. More units habituated, had bursting responses, exhibited high spontaneous activity and seemed generally variable than in the other group. As a consequence, more cells were classified as weak or fair. Apparently, the relatively short period with no visual input was sufficient to cause some degenerative changes in cortical connections.

The results presented in Fig. 1 clearly show that the period spent in darkness following 24 h of monocular exposure does not produce a consolidation of the unilateral deprivation effect. On the contrary, a substantial increase occurs in the proportion of cells that can be driven through both eyes. However, the conclusion that a consolidation period does not accentuate the effects of monocular deprivation is limited to the time courses we chose for unilateral exposure and for the post-exposure period. It is possible that a consolidation effect occurs, but over a different time course. The loss of binocularity for the animals recorded after 24 h of unilateral deprivation was so marked that a greater effect would be difficult to discern.

We decided, therefore, to examine two other groups of kittens with a shortened time course of monocular exposure. In the first, animals were unilaterally occluded for 8 h on postnatal day 29 and then studied physiologically. The second group was similarly exposed monocularly, but recording was delayed for an additional 8 h during which the kittens were kept in darkness. Because of the very brief time, animals were exposed in a slowly rotating clear chamber to ensure that they were alert during most of the period. Once again, analysis of a sample of cortical cells showed that binocularity was severely reduced for both groups of cats, although not as much as for those shown in Fig. 1. In three cats recorded immediately after monocular deprivation, 36% of all cells were binocular, compared with 51% in three others recorded after 8 h of darkness. In addition, the ipsilateral eye (non-deprived) predominated in both cases, but controlled 70% of the sample from the first group and 58% from the second which had an 8-h interval between exposure and physiological study. As in the case of 24-h monocular deprivation, these findings do not support the notion of consolidation. The degree of binocularity is once again actually higher when a period intervenes between exposure and recording. Therefore, we conclude that for this condition also, there is no consolidation effect.

We have shown that periods as short as 8 h of monocular deprivation can cause functional disruption of binocular cortical connections. This finding is distinct from that of previous studies in which short periods of monocular exposure were preceded by binocular deprivation[4,11]. In that case, the physiological effects

observed reflect a unilateral recovery of visual function and the mechanisms could be different from those of monocular deprivation. The fact that the effects we have found are so much greater than those previously reported[5] may be due in part to the procedures we used to ensure maximum exposure during the monocular rearing periods. However, the major difference is probably attributable to use, in the previous study, of a post-monocular period of binocular deprivation.

In the conditions of our study, we conclude that the effects of short-term monocular deprivation do not become consolidated during a post-exposure period spent in darkness. The inactivation of pathways from a deprived eye must require some time, but it must be much shorter than the period of deprivation required to produce an effect detectable by our methods. We have not tested 'consolidation' in the original sense[12,13], because our study did not attempt to look at the issue of conversion of a deprivation effect from an unstable to a stable form. To do this, one might administer, for example, electroconvulsive shock or a protein synthesis inhibitor like puromycin, to kittens immediately after a period of monocular exposure to see if these agents interfered with the effects of the deprivation.

The analysis of sound by the sprat ear

E. J. Denton & J. A. B. Gray

Marine Biological Association of the United Kingdom, The Laboratory, Citadel Hill, Plymouth, UK

In the acoustico-lateralis systems of vertebrates the individual hair cells are usually polarised in their responses to displacements of the liquid in which they lie, and are often arranged in back-to-back pairs or groups with different polarities. A simple example to investigate, mechanically as well as electrically, is the utriculus of the sprat (*Clupea sprattus L.*). The acoustico-lateralis system of the sprat and other clupeids has two partly gas-filled bony bullae which transform pressure changes into liquid displacements capable of stimulating the sense organs of the ear and lateral line[1–3]. With its related structures the utriculus is a very sensitive sound pressure detector which has one population of receptors that respond to the compressions and another that respond to the decompressions of a sound wave. We now give additional evidence that this type of organisation is unlike that of the mammalian cochlea in being specialised more for the detection of phase/time relationships than for frequency analysis.

Popper and Platt[4] have described the distribution and orientation of hair cells in the three maculae of the herring utriculus[5]. In each macula the hair cells have their kinocilia on the side closest to a line running down the middle of the long axis. One of us (J.A.B.G.), with A. C. G. Best, has independently made similar observations on the sprat utriculus. This is like that of the herring except that the hair cells of the posterior macula are orientated along, rather than across, its length. The anterior and middle maculae are suspended along their long edges (Fig. 1). Each sprat utriculus has about 13,000 hair cells, about 60% on the middle macula and slightly more than 20% on the anterior macula.

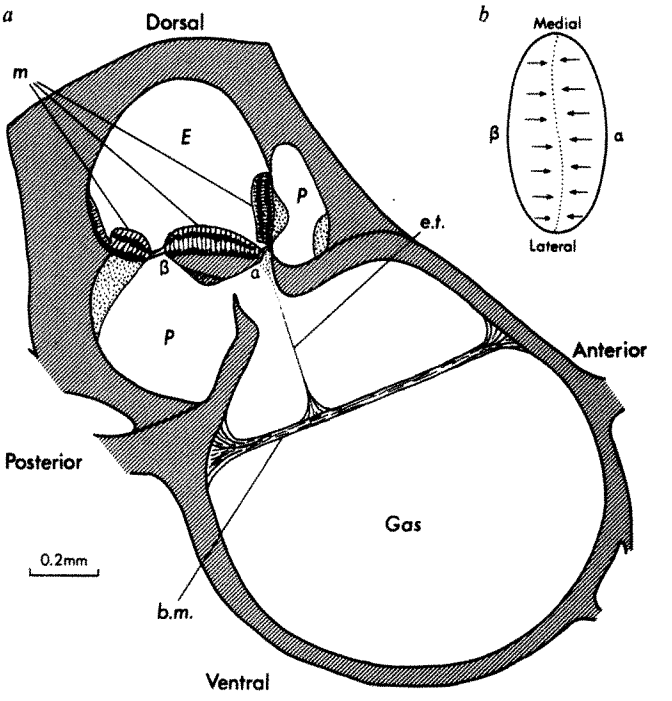

Fig. 1 *a*, Sagittal section through part of the auditory system of the sprat. Pressure vibrations cause vibrations of the bulla membrane (b.m.) which set up vibrations of the utricular maculae (m). The long axis of the middle macula is at right angles to the line $\alpha\beta$. The hatched areas are tough collagenous or calcified tissue. Nerves are stippled. The maculae are shown as cells but the 'hairs', cupulae and the utricular otolith are not shown. A thin elastic thread (e.t.) connects the bulla membrane to the base of the utriculus (out of the plane of this drawing). It seems possible that this thread is associated with the detection of slow, large pressure changes. E is endolymph, P perilymph. Displacements of liquid are possible because the system communicates with the lateral line. *b*, Plan view from above of the middle macula of the utriculus. It is divided into two areas in which the hair cells are orientated in opposite directions. The arrows point to the sides of the hair cells on which the kinocilia lie.

As an electrode is introduced into the utricular endolymph a positive d.c. potential step of 10–14 mV is observed. On stimulation with sinusoidal pressure waves microphonic potentials of double frequency[6,7] are recorded. The potentials consist of two sets of negative peaks, one associated with compressions, the other with decompressions (Fig. 2*a*). Because in fish, hair cells are preferentially excited when their ciliary processes are displaced towards their kinocilia[8], it seems almost certain that the two sets of peaks correspond to the excitation of the two major populations of oppositely orientated hair cells in the two larger maculae. These responses do not change significantly in shape over a frequency band of at least 5–880 Hz. The two sets of peaks are similar in the way they change when the electrode is moved in and out of the endolymph, in the way they decline with anoxia and in the time intervals between the peaks of each set and the corresponding compressions or decompressions. The recorded responses to a pressure of 1 N m^{-2} are of a few tens of microvolts and attain about half a millivolt at pressures around 100 N m^{-2}. We shall call the responses to compression c-responses (from c-receptors) and the responses to decompression d-responses (from d-receptors). The pressure required to give a particular response of either group changed very little between about 40 and 700 Hz. Below about 20 Hz sensitivity declined sharply.

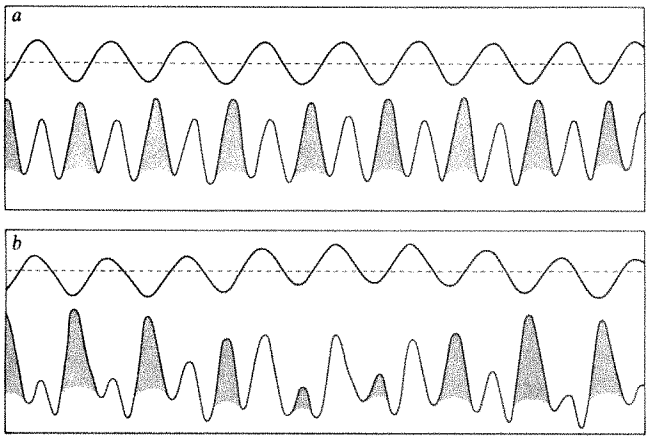

Fig. 2 *a*, Upper trace: stimulus, a sinusoidal pressure wave of 200 Hz; mean pressure shown by dashed line, compressions upwards; peak to peak pressure 12.5 N m^{-2}. Lower trace: potentials in the endolymph of the utriculus; *d*-responses are stippled. *b*, Like *a* but the stimulus pressure obtained by mixing frequencies of 200 Hz (as in *a*) and 30 Hz.

Two frequencies of pressure stimulation can be combined (see ref. 7) as, for example, in Fig. 2*b*, where 200 and 30 Hz waves are mixed. The d-responses to the 200-Hz component (stippled) are larger during the decompression phase of the slower wave and smaller during the compression phase. The c-responses behave in the reverse way. In Fig. 2 the envelopes enclosing both the c- and d-responses correspond to the lower frequency. The two frequencies and their phase relationship are much clearer in the responses of the receptors than in the pressure record. The responses of the two different receptor populations result from pressure excursions either above or below the mean pressure and their timing can be predicted from the form of the pressure wave. The sizes of the responses increase with the extent of the compression or decompression, but this relationship is not the same as that of the d-response to simple sine wave stimulation, for the slope of the log response/log pressure curve is much steeper.

The phenomena described above also produce potential patterns which are very sensitive to phase between harmonics. Figure 3 shows utricular responses to changes of phase between a pressure wave of 62.5 Hz and its second harmonic.

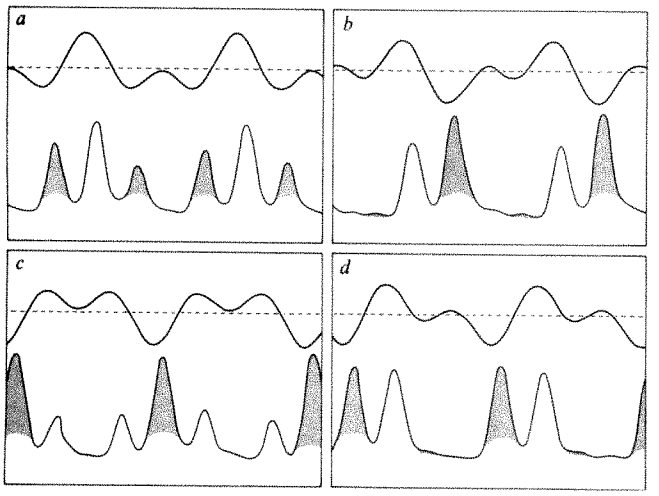

Fig. 3 To show that phase changes greatly affect the pattern of the responses given by the utriculus. *a*, Upper trace: stimulus pressures obtained by mixing frequencies of 125 Hz and 62.5 Hz of approximately equal amplitudes (~15 N m^{-2}); mean pressure shown by dashed line, compression upwards. Lower trace: potentials in the endolymph of the utriculus; the d-responses are stippled. *b*, *c*, *d*, Like *a* but with the higher frequency delayed by 2, 4 and 6 ms, respectively (respective delays in phase 90°, 180° and 270°).

These results give information on the representation of amplitude and timing in the activity of the utriculus. As a considerable proportion of the 13,000 cells is likely to be available, it seems probable that amplitude can be coded accurately and quickly by the number of active units in the population of nerve fibres. The intervals between compressions or decompressions or between a compression and a decompression are clearly represented even in a complex wave by the activities of the two populations of receptors. The system should allow interactions which diminish noise and blurring. The striking changes in the relative amplitudes of the c- and d-responses which immediately follow changes in the pressure wave strongly suggest that the system is organised to facilitate the detection of time/phase differences and provide rapid answers to rapid events, that is, to noises or transients given, for example, by a sharp change of direction of a neighbouring fish[9]. It also provides a 'standard' based on pressure against which the activity of the various neuromasts of the lateral line can be compared, thus enabling estimates of distance and direction to be made[3,10].

As so much is known about hearing in mammals, it is interesting to contrast the behaviour of the clupeid utriculus with that of the mammalian cochlea. Microphonics recorded from the latter are very different from those described above; there is no frequency doubling and the response to a sinusoidal stimulus is an almost perfectly sinusoidal wave of the same frequency (see for example, ref. 11).

Helmholtz and others have shown that, with trivial exceptions, man is insensitive to phase relationships of tones[12,13]. Results like those of Figs 2 and 3 support the view that this may not be true for animals in which the receptors are organised in the same general way as the sprat utriculus.

Met- and Leu-enkephalin immunoreactivity in separate neurones

Lars-Inge Larsson*, Steven Childers & Solomon H. Snyder

Institute of Medical Biochemistry, University of Aarhus, DK-8000 Aarhus C, Denmark
and Department of Pharmacology and Experimental Therapeutics, Johns Hopkins School of Medicine, Baltimore, Maryland 21205

A pair of pentapeptides, Met- and Leu-enkephalin were recently isolated from brain tissue[1,2]. The two peptides seem to represent endogenous opiate receptor ligands and have by immunocytochemical and radioimmunoassay studies been shown to occur in an extensive system of cerebral and peripheral nerves[3–8]. The relative proportions between Met- and Leu-enkephalin varies between different brain regions and also between different species, suggesting the existence of separate populations of Met- and Leu-enkephalin nerves[9–12]. Until now, however, immunocytochemistry has given no support for this notion. We report here evidence of separate populations of Met- and Leu-enkephalin nerves.

Table 1 Properties of enkephalin antisera determined by radioimmunoassay

Serum	Dilution	IC_{50} (pmol of peptide) Met-enk	Leu-enk	β-endorphin
anti-Met-enk M12	1:250	40	4,500	>25,000
anti-Met-enk M14	1:250	25	2,000	>25,000
anti-Leu-enk L2	1:500	500	3	>25,000

Radioimmunoassays were performed as previously described[21], using a dilution of serum which bound 30–40% of ^{3}H-enkephalin in the absence of unlabelled peptide. Results of competitive binding experiments are expressed as the IC_{50} values of the amounts of peptides required to displace 50% of bound ^{3}H-enkephalin in the radioimmunoassay. The incubation volume was 0.25 ml. The data were obtained from typical experiments performed in triplicate and repeated at least twice.

Met- and Leu-enkephalin differ only in that their COOH-terminal residue is either methionine or leucine. Furthermore, Met-enkephalin is identical to the NH_2-terminal pentapeptide of the long-chain opioid peptide, β-endorphin. So far, however, there is no evidence for a biosynthetic relationship between these two peptides. Furthermore, immunocytochemistry has demonstrated that enkephalin-immunoreactive nerves show a distribution distinct from that of nerves containing β-endorphin, β-lipotropin (β-LPH) and adrenocorticotropic hormone (ACTH)[6,13,14]. The similarities in amino acid sequences may, however, cause significant problems of cross-reactivity between different opioid peptides. In several previous studies, radioimmunoassay data have been obtained indicating only small degrees of cross-reactivity between the two enkephalins[11,12]. Such data cannot, however, be taken as proof for immunocytochemical specificity[15,16]. Thus, of numerous reports on enkephalin immunocytochemistry[3–8,17] to our knowledge, only one, dealing with Met-enkephalin localisation[5], seems to have fully documented lack of cross-reactivity.

We have examined a number of antisera to Met- and Leu-enkephalin in immunocytochemical models and have obtained evidence for considerable cross-reactivity. With selective absorptions as well as by oxidative destruction of the methionine residue of Met-enkephalin we have been able to develop methods, selectively demonstrating either Met- or Leu-enkephalin. When applied to tissue sections, these selective techniques reveal that the two enkephalins are localised in two distinct systems of nerves.

Three antisera were used (Table 1). In radioimmunassay both Met-enkephalin antisera, M12 and M14, displayed approximately 100-fold greater selectivity for Met-enkephalin than Leu-enkephalin. The Leu-enkephalin antiserum L2 had over 150 times more affinity for Leu-enkephalin than Met-enkephalin. None of the three antisera exhibited any cross-reactivity with concentrations of β-endorphin as high as 10^5 pmol ml^{-1}.

Cytochemical models consisted of Sepharose 4B beads, to which was coupled either synthetic Met-enkephalin, Leu-enkephalin or β-endorphin. Treated beads were attached to glass slides by the technique of Streefkerk *et al.*[18] and subjected to immunocytochemical staining (peroxidase–antiperoxidase, PAP procedure). L2, M12 and M14 antisera were all found to react with beads to which Met- and Leu-enkephalin was coupled, whereas, at all concentrations tested (1:200–1:40,000), they failed to react with the β-endorphin beads. In accord with this observation, pre-adsorptions of the three antisera with β-, α-, and γ-endorphin, ACTH or other unrelated peptides (see Fig. 1) failed to affect staining of the Met- and Leu-enkephalin beads. Pre-adsorption of all three antisera with Met-enkephalin (2–100 μg ml^{-1}) resulted in complete inactivation of staining of both Met- and Leu-enkephalin beads. In contrast, pre-adsorption of antisera M12 and M14 with

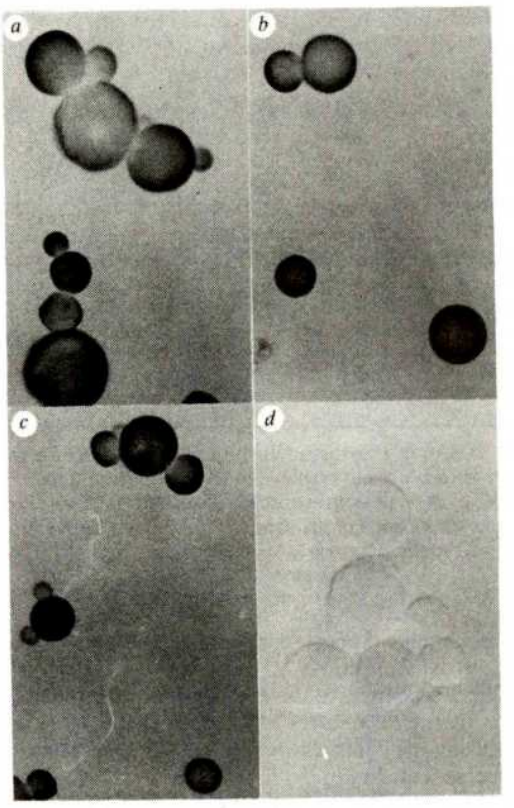

Fig. 1 Sepharose beads to which Leu-enkephalin (*a*, *b*) or Met-enkephalin (*c*, *d*) has been coupled. The beads shown in *a* and *c* have been reacted with Leu-enkephalin antiserum (L2; PAP technique) without pretreatment, whereas the beads in *b* and *d* have been pre-oxidised with acidic permanganate before staining with antiserum L2. Note that this antiserum reacts as readily with Met- as with Leu-enkephalin (*a*, *c*) and that oxidation with acidic permanganate eliminates staining of Met- (*d*) but not of Leu-enkephalin (*b*). Thus, following this type of pre-oxidation, antiserum L2 is fully specific for Leu-enkephalin. Similar model staining experiments confirmed that Leu-enkephalin-adsorbed antisera M12 and M14 were fully specific for Met-enkephalin. Cytochemical models were prepared by coupling synthetic Met-enkephalin, Leu-enkephalin or β-endorphin (Bioproducts Peptide and Peninsula Labs) to CnBr-activated Sepharose 4B beads (Pharmacia). In general, 1 mg of peptide was coupled to 2 ml swollen beads according to the manufacturers manual. Prepared beads were mounted as monolayers on glass slides according to Streefkerk *et al.*[18] and subjected to various treatments before immunocytochemical staining. Such treatments included exposure to solutions used for preparing the tissue material (compare with Fig. 2) and excluded deleterious influences of these procedures on the Met- or Leu-enkephalin immunoreactivity. In addition, the beads were treated with solutions of potassium permanganate in dilute sulphuric acid. The best formula agreed with that for antibody elution suggested by Tramu *et al.*[19], and consisted of 0.15 M $KMnO_4$ and 0.02 M H_2SO_4. Treatment of beads (or cryostat sections) with this solution for 2 min was sufficient to completely block Met-enkephalin immunoreactivity, whereas even a 10-min exposure left Leu-enkephalin immunoreactivity unaffected (as tested by antiserum L2). Oxidised and non-oxidised beads were allowed to react with either unpretreated, Leu-enkephalin-pretreated or Met-enkephalin-pretreated antisera to Met-enkephalin (M12, M14) or Leu-enkephalin (L2). Antisera were produced in rabbits by immunisation with the enkephalins coupled by carbodiimide and glutaraldehyde to keyhole limpet haemocyanin, as previously described[21]. The site of antigen–antibody reaction was revealed by either PAP or immunofluorescence[22]. Controls for immunocytochemical specificity were made by pretreating antisera with varying amounts of Leu- or Met-enkephalin (2–100 μg ml diluted antiserum) as well as with excess amounts of α-, β- and γ-endorphins, ACTH (Ferring) and synthetic human gastrin I (ICI). Of these peptides, only the enkephalins affected staining and additional controls including conventional staining controls[22], gave negative results.

Leu-enkephalin (5–100 μg ml^{-1}) failed to abolish staining of the Met-enkephalin beads, whereas it abolished staining of the Leu-enkephalin beads. On the basis of these results we conclude that the Met-enkephalin antisera M12 and M14 contain two antibody populations: one specific for Met-enkephalin and one reacting with both Met- and Leu-enkephalin. The latter antibody population could be inactivated by pretreating the antisera with as little as 5 μg of Leu-enkephalin, but in all subsequent studies this antiserum was used routinely with 100 μg Leu-enkephalin added per ml of a 1 : 1,600 dilution. In these conditions, both antiserum M12 and M14 are fully specific for Met-enkephalin.

We noted that even mild oxidative treatment (by acidic permanganate or cyanogen bromide) completely abolished immunoreactivity of the Met-enkephalin beads, whereas that of Leu-enkephalin beads was left unaffected. This effect can be explained by destruction of the methionine residue of Met-enkephalin and has previously been exploited in bioactivity studies[9,10]. Thus, following such oxidative treatment our cross-reactive antiserum L2 produced strong staining of Leu-enkephalin beads but left Met-enkephalin beads unstained (Fig. 1).

On the basis of such model experiments we examined the tissue distribution of Met-enkephalin by using Leu-enkephalin-absorbed antiserum M14 or M12, and of Leu-enkephalin by treating tissue sections with oxidising agents (usually acidic permanganate solutions), before staining with Leu-enkephalin antiserum L2. Immunocytochemical specificity was proved by adsorbing antisera against the enkephalins, endorphins, ACTH and other peptides (compare Fig. 1). As precursors to the enkephalins have not yet been identified it is impossible to assess whether our antisera would also react with such molecules. Note, however, that although β-endorphin contains the entire sequence of Met-enkephalin, none of the antisera used reacts with this long-chain opioid peptide. Even if our enkephalin antisera did react with enkephalin precursors, however, our results make it reasonable to assume that oxidation plus staining with antiserum L2 demonstrates only Leu-enkephalin-related molecules and that Leu-enkephalin-pre-adsorbed antiserum M12 and M14 react only with Met-enkephalin-related molecules.

Both techniques demonstrated numerous immunoreactive nerves in both the gastrointestinal tract of cats and guinea pigs and in brains of guinea pigs. In most regions studied, the number of Met-enkephalin nerves exceeded that of Leu-enkephalin nerves. The two types of nerves showed roughly the same distribution, which agreed with previous data on the distribution of enkephalin immunoreactivity in brain and gut[3–8,17]. In the cat gastrointestinal tract, occasional ganglia of the myenteric plexus seemed to contain predominantly Leu- or Met-enkephalin nerves (Fig. 2). Most areas examined, including the myenteric plexus showed, however, great parallelism in the distribution of the two types of nerves. To prove that the two peptides did occur in distinct populations of nerves, double-staining immunocytochemistry was carried out. Met-enkephalin immunoreactivity was first demonstrated by Leu-enkephalin-pre-adsorbed antiserum M12 or M14 with the peroxidase–antiperoxidase (PAP) procedure. Following demonstration of peroxidase activity with 3,3′-diaminobenzidine, which produced a brown reaction product, antibodies were eluted from the sections by the method of Tramu *et al.*[19]. This technique uses an acidic permanganate solution, which also destroys Met-enkephalin immunoreactivity. Following successful elution and simultaneous destruction of Met-enkephalin immunoreactivity, the sections were restained with antiserum L2, now able to react only with Leu-enkephalin present in the sections. The PAP technique was used again, but peroxidase activity was now demonstrated with 4-Cl-1-naphtol, yielding a blue reaction product[19]. Thus Met-enkephalin-containing nerves are stained brown and Leu-enkephalin-containing nerves are stained blue.

Alternatively, the site of reaction between the L2 antiserum and the tissue was shown by indirect immunofluorescence. In this case, brown-stained Met-enkephalin and immunofluorescent Leu-enkephalin nerves were visualised (Fig. 3). The success of the antibody elution was verified by the fact that the Met-enkephalin nerves did not restain in the second step of the double-staining procedures as well as by controls involving use of antisera pre-adsorbed with either Met- or Leu-enkephalin in both steps of the procedures and, finally, also by the substitution of the enkephalin antisera by unrelated immune sera. All these controls confirmed the specificity of the immunolocalisations and also documented the completeness of the antibody elution technique as well as its ability to destroy Met-enkephalin reactivity to antiserum L2. The double staining techniques were successful in demonstrating distinct populations of Met- and Leu-enkephalin nerves in the nucleus caudatus-putamen and globus pallidus of the guinea pig brain and in the gastrointestinal tract. Interestingly, both types of nerves showed a very similar distribution, with Leu-enkephalin nerves being about one-quarter to one-fifth as numerous as Met-enkephalin fibres. A full description of the extent and distribution of the two types of nerves will be published elsewhere.

Our data demonstrate that Leu- and Met-enkephalin occur in two distinct populations of nerves. The occurrence of two distinct types of enkephalin nerves is of considerable interest, partly because both types seem to show at least partially overlapping distributions. This distribution also agrees with that of

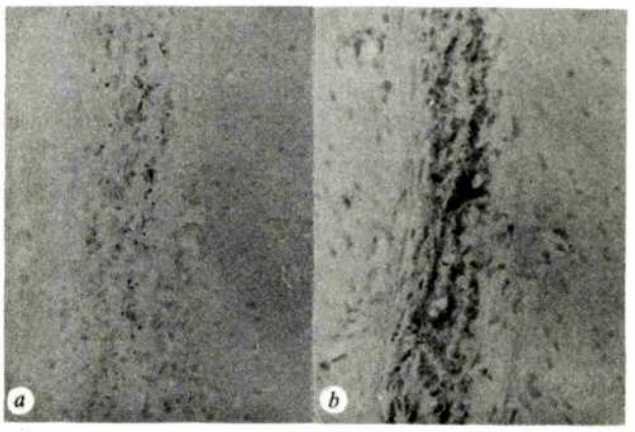

Fig. 2 Adjacent sections showing Auerbach's plexus of cat ileum. *a*, This section has been stained with Leu-enkephalin-adsorbed antiserum M14 (PAP technique), whereas *b* has been pre-oxidised with acidic permanganate and then stained with antiserum L2 (compare with Fig. 1). Thus, in *a* Met-enkephalin immunoreactive nerves and in *b* Leu-enkephalin immunoreactive nerves are shown. Note that in this particular ganglion the Leu-enkephalin nerves are more numerous than the Met-enkephalin nerves and that also a Leu-enkephalin immunoreactive cell body can be seen. Similar experiments, involving staining of the same section for the two types of immunoreactivity in contrasting colours (compare with Fig. 3), showed that the Leu- and Met-enkephalin immunoreactivity resided in separate nerve populations. Guinea pigs ($n = 10$) and cats ($n = 5$) were anaesthesised with diethyl ether or mebumal chloralose, respectively, and perfused via the heart with cold (4 °C) saline followed by a 4% paraformaldehyde solution in 0.1 M sodium phosphate buffer *p*H 7.3. Specimens from the gastrointestinal tract of both species as well as frontal brain slices from guinea pigs were postfixed in the paraformaldehyde solution for 15–30 min, soaked in 20% sucrose solution in the phosphate buffer overnight and frozen on cryostat chucks in melting Freon-22. Cryostat sections, cut at 3–10 μm, were subjected to immunocytochemical staining for Met- and Leu-enkephalin immunoreactivity, as described in Fig. 1 legend. Controls were also identical. Occasionally, sections stained for Met-enkephalin immunoreactivity were submitted to antibody elution according to Tramu *et al.*[19] and poststained with a cross-reacting Leu-enkephalin antiserum (L2). This elution technique is identical with that used for destroying Met-enkephalin immunoreactivity. Met- and Leu-enkephalin nerves could be demonstrated in contrasting colours, using the PAP technique. The efficiency of antibody elution was shown by the fact that separate nerves were stained, and by the controls, suggested by Tramu *et al.*[19].

brain opiate receptors[4]. As previously pointed out, nerves containing other putative ligands for opiate receptors, like β-endorphin and ACTH, show only a partially overlapping distribution with enkephalin nerves[6,13,14]. These data should be viewed in the light of the previously suggested existence of separate types of opiate receptors[20] and should initiate studies of differential release of the two endogenous opiate ligands.

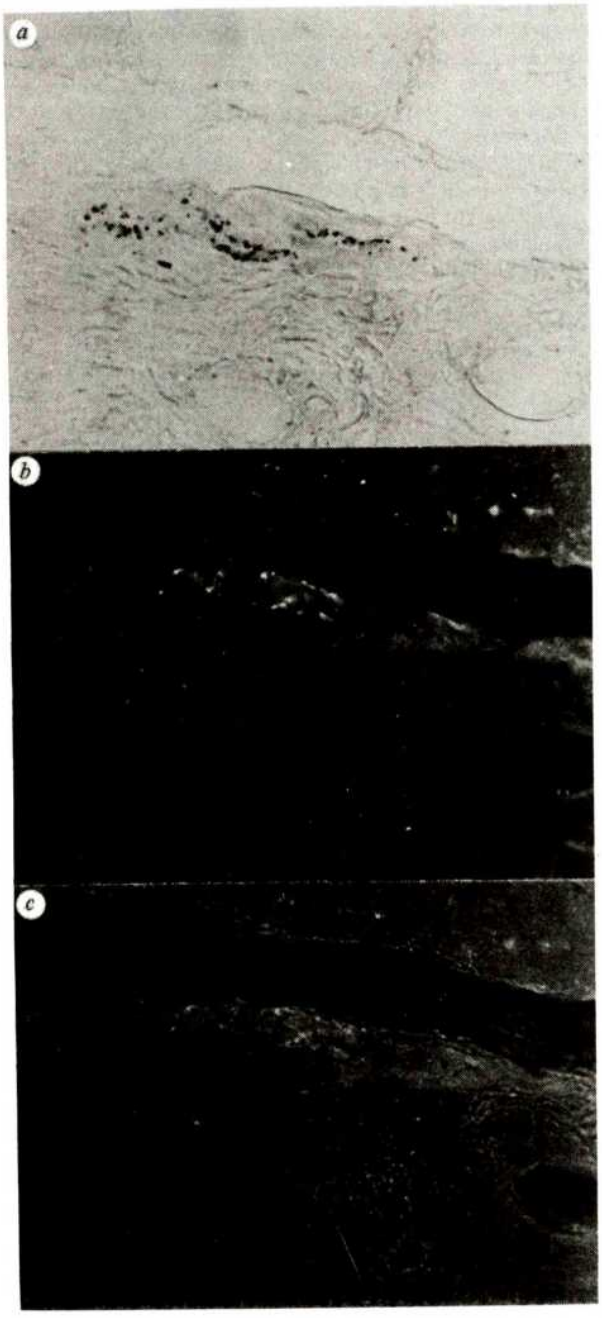

Fig. 3 Section of submucous (Meissner's) ganglion of cat small intestine. The section was first stained with Leu-enkephalin-adsorbed antiserum M14 using the PAP procedure (top) resulting in dark-stained Met-enkephalin nerves. Subsequently, antibodies were eluted and Met-enkephalin immunoreactivity destroyed by acidic permanganate treatment, whereafter the section was restained with antiserum L2, now able to show only Leu-enkephalin immunoreactivity (compare with text and Fig. 2). The site of reaction with the L2 antiserum was revealed by indirect immunofluorescence, using fluorescein isothiocyanate-labelled goat antirabbit IgG (centre). Bottom, the same section is viewed in combined blue light (490 nm) and in ordinary light, showing that the black-stained Met-enkephalin nerves are distinct from the immunofluorescent Leu-enkephalin nerves. ×370.

We thank Mrs B. Blankenberg-Serup, Mrs J. B. Lauridsen and Mrs E. Petersen for technical assistance. The studies were supported by the Danish MRC.

A novel analgesic dipeptide from bovine brain is a possible Met-enkephalin releaser

Hiroshi Takagi, Hirohito Shiomi, Hiroshi Ueda & Hiro Amano

Department of Pharmacology, Faculty of Pharmaceutical Sciences, Kyoto University, Kyoto 606, Japan

It is generally accepted that morphine exerts its analgesic effect by binding to specific opiate receptors in the brain and spinal cord[1]. Since Hughes *et al.*[2] isolated and identified two endogenous pentapeptides, Met- and Leu-enkephalin, from the brain and found that they acted as agonists at opiate receptors, α-, β- and γ-endorphins, larger peptides than enkephalins and having morphine-like activity, have been identified in either the brain or pituitary of various species[1]. Several studies have demonstrated that enkephalins possess analgesic properties and that they are distributed in the pain-mediated pathways in the central nervous system. These findings suggest that enkephalins are important neurotransmitters or neuromodulators regulating pain transmission. We now report the isolation of a novel substance which has a Met-enkephalin releasing action. Our findings suggest the possibility of a regulating mechanism for the release of endogenous opioid peptides, especially Met-enkephalin.

During purification, bovine brain extracts were injected intracisternally into unanaesthetised mice, using a J-shaped needle[3], and analgesia was evaluated by the tail-pinch test using an artery clip (2 mm wide) with a constant pressure of 200 g (ref. 4). All the materials tested were dissolved in distilled water and administered into the cisterna magna, in a volume of 10 μl. Eight mice were used for each experiment. The specificity of morphine-like activity was confirmed using the narcotic antagonist naloxone.

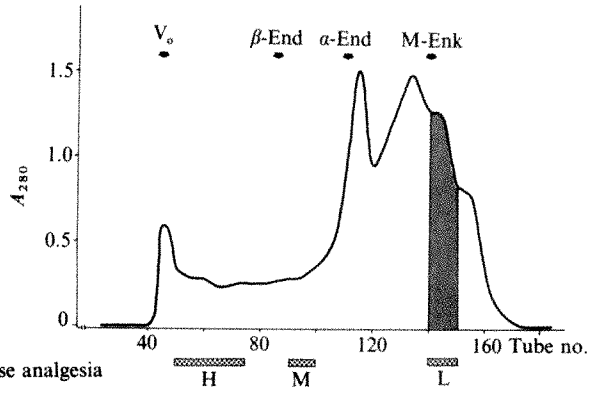

Fig. 1 Gel filtration chromatography of 3 g of 0.5 M acetic acid extract on a Sephadex G-50 column (90 × 5 cm). Elution was carried out with 0.5 M acetic acid, the rate of flow was 1 ml min^{-1}, and 15-ml fractions were collected. The elution pattern was monitored by UV absorbance at 280 nm. The analgesic activities were found in three fractions, H, M and L, indicated by the horizontal bars. The approximate elution positions of some endorphins are indicated by the arrows. V_0, void volume; β-End, β-endorphin; α-End, α-endorphin; M-Enk, Met-enkephalin.

Isolation of the substance was as follows. Fresh frozen bovine brains minus cerebella were crushed and homogenised in 5 volumes of acetone with a Polytron homogeniser at −10 °C. The homogenate was filtered and the acetone powder obtained was stirred for 12 h with 10 volumes of 0.5 M acetic acid at 4 °C. After centrifugation, the supernatant was lyophilised, redissolved in a small volume of 0.5 M acetic acid and applied to a Sephadex G-50 column. As shown in Fig. 1, analgesic activities measured as described above were found in three fractions, designated H (molecular weight ~ 10,000), M (MW ~ 3,000) and L (MW ~ 1,000). As the naloxone-induced reversibility of fraction L was more clear-cut than that of the other two fractions, this fraction was run in a Dowex 50W-X2 column to separate the peptides further. The column was eluted with a linear *p*H gradient of 0.2 M pyridine–acetate buffer, *p*H 3.1, and 1 M pyridine–acetate buffer, *p*H 7.0, and successively with 0.01 M NH_4OH, 1 M NH_4OH and 2 M NaOH. Analgesic activities were found in three fractions, L1, L2 and L3. The peptides of fraction L3 were found to be basic, as they could be eluted with 1 M NH_4OH. Fraction L3, which consisted of three peaks, could be further broken down into three fractions, L3a, L3b and L3c (see Fig. 2). In these five fractions (L1, L2, L3a–c), the most potent analgesic activity was found in fraction L3b, which showed a 38-fold enrichment in analgesic activity compared with the original L fraction. Fraction L3b was then applied to a BioGel P-2 column (Fig. 3), and the L3b′ fraction obtained showed an analgesic activity 1.5-fold greater than that of fraction L3b. The analgesic effect of intracisternally injected L3b′ peptide (12 μg per mouse) was maximal (about 55%) within 5 min, terminated 30 min after administration and was completely suppressed by pretreatment with naloxone (0.5 mg per kg, subcutaneously (s.c.)). The elution position of fraction L3b′ did not correspond with the positions of α-endorphin or glycine, and showed that this substance had a relatively small MW. With high-voltage paper electrophoresis (HVPE) at 33 V cm^{-1} for 90 min at *p*H 3.6 (pyridine/acetic acid/H_2O; 1 : 10 : 289) fraction L3b′ showed a single spot with ninhydrin reagent. The relative mobility value of peptide L3b′ was 0.75 using arginine as a standard, and its amino acid composition, after hydrolysis with 6 M HCl at 110°C for 18 h, was tyrosine 0.90 and arginine 1.00. Tryptophan was not detected with Ehrlich reagent on TLC of peptide L3b′. Moreover, dansylation and HCl hydrolysis of the peptide resulted in a single spot on the polyamine sheet corresponding to *bis*-tyrosine, and thus indicating that the single N-terminal amino acid was indeed tyrosine. In view of these results and the elution position on the BioGel P-2 column, tyrosyl-arginine is proposed as the amino acid sequence of peptide L3b′.

In comparative studies, synthetic dipeptide Tyr-Arg and the endogenous peptide L3b′ had an identical R_F value (R_F 0.18) on TLC (*n*-butanol/pyridine/acetic acid/H_2O; 4 : 1 : 1 : 2), showed only a single spot on co-chromatography, and had a corresponding retention time on HPLC. Similar results were obtained in the HVPE in the above conditions (R_F 0.75 using arginine as a standard). Finally, intracisternally administered synthetic Tyr-Arg and endogenous peptide L3b′ had equipotent analgesic effects. These findings confirm that the endogenous analgesic compound, peptide L-3b′, is a dipeptide of amino acid sequence Tyr-Arg. In preliminary experiments, Tyr-Arg could also be isolated from the 0.4 M perchloric acid extract of the mouse brain, by which the proteolytic enzymes are denatured. It is interesting that the Tyr-Arg sequence is present in some hypothalamic hormones—residues 74–75 and 79–80 in human thyroid stimulating hormone, residues 78–79 in human luteinising hormone, and residues 5–6 in human, but not bovine,

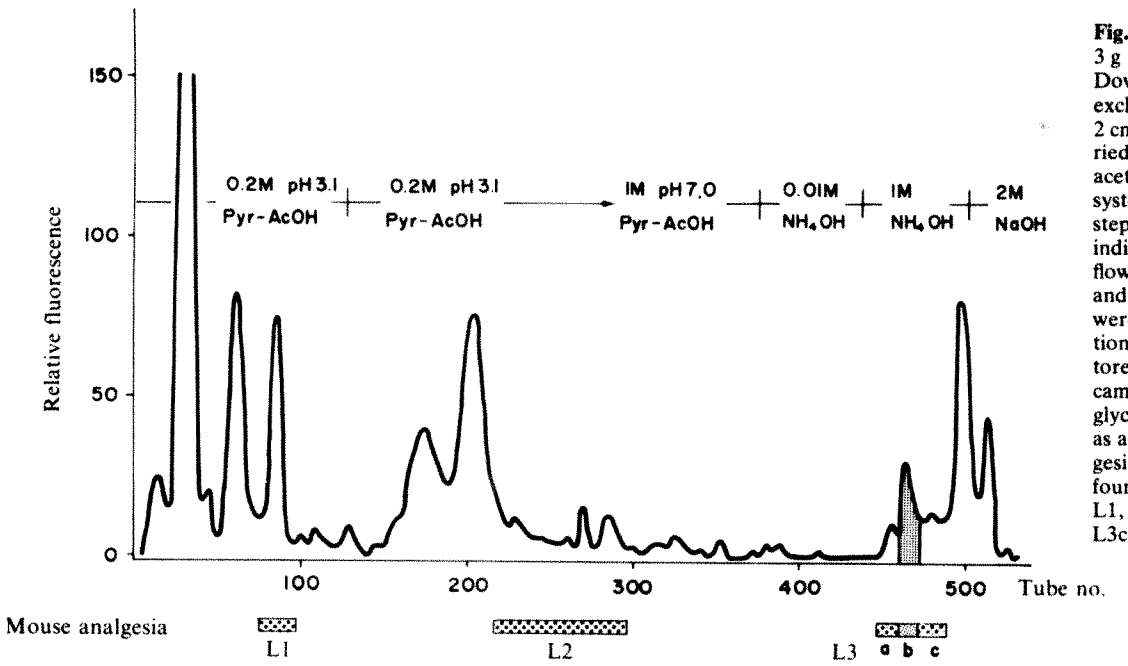

Fig. 2 Fractionation of 3 g of fraction L on a Dowex 50W-X2 cation exchange column (80 × 2 cm). Elution was carried out with a pyridine–acetate linear gradient system and using a stepwise system, as indicated. The rate of flow was 0.3 ml min^{-1}, and 15-ml fractions were collected. The elution pattern was monitored by the fluorescamine method with glycine (10^{-8} M = 100) as a standard. The analgesic activities were found in five fractions; L1, L2, L3a, L3b and L3c, as indicated by the horizontal bars.

β-melanotropin. It remains to be determined whether these hypothalamic peptides are precursors of the newly identified dipeptide.

When injected intracisternally, the analgesic effect of synthetic Tyr-Arg was dose dependent and was completely abolished by pretreatment with naloxone (0.1 mg per kg, s.c.). The ED_{50} value tested by the tail-pinch method was 34.7 nmol per mouse (11.7 μg per mouse) with 95% confidence limits of 22.0–54.9 nmol. Although the analgesic potency of Tyr-Arg was about 60 times less than that of morphine (ED_{50} 0.61 nmol per mouse), it was about 4.2 times higher than that of Met-enkephalin (ED_{50} 146 nmol per mouse). In addition, the analgesic effect of Tyr-Arg lasted longer (for 30 min at ED_{50} dose) than that of Met-enkephalin (disappeared within 15 min at ED_{50} dose). Tyr-Arg-induced analgesia was also demonstrated by the hot-plate method of Loh *et al.*[5], giving an ED_{50} of 15.7 nmol per mouse. Furthermore, Tyr-Arg showed analgesic activity in the rat when given into the nucleus reticularis gigantocellularis, an area of the brain which is highly sensitive to morphine analgesia[6].

Nevertheless, Tyr-Arg was only weakly inhibitory towards electrically induced contraction of longitudinal muscle of the guinea pig ileum (18.8% inhibition at 360 μM), suggesting that this compound does not interact with opiate receptors. We therefore studied the binding affinity of Tyr-Arg to specific opiate receptors. The binding assay, using the rat brain membrane preparation, was as described by Simantov *et al.*[7]. Tyr-Arg was only weakly inhibitory towards ^{3}H-dihydromorphine (24.9% inhibition at 100 μM) and ^{3}H-naloxone (22.7% inhibition at 100 μM), indicating that the dipeptide does not bind with the specific opiate receptors. This strongly suggests that the naloxone-reversible analgesic effect of Tyr-Arg is mediated by enkephalins or β-endorphin. Therefore, Tyr-Arg acts either as an enkephalin- or β-endorphin-releasing factor or as an inhibitor of the degradation enzymes of enkephalins, such as aminopeptidase and enkephalinase[8].

Met-enkephalin release was studied using the method described by Henderson *et al.*[9]. Its release from guinea pig striatal slices (four striata from two animals weighing ~600 mg) was detected by an opiate receptor binding assay after purification of the Met-enkephalin using HPLC as described by Meek and Bohan[10]. The basal release of Met-enkephalin in the superfusate (15-min collection period) was 16–17 ng. During 15 min of high-potassium ion (50 mM) stimulation, Met-enkephalin release increased to levels about four times higher than in the preceding spontaneous release samples. After 15 min exposure to a Tyr-Arg-containing medium (10^{-5} or 10^{-6} M) the output of Met-enkephalin increased to 2.3 times that of the preceding basal release (see Fig. 4).

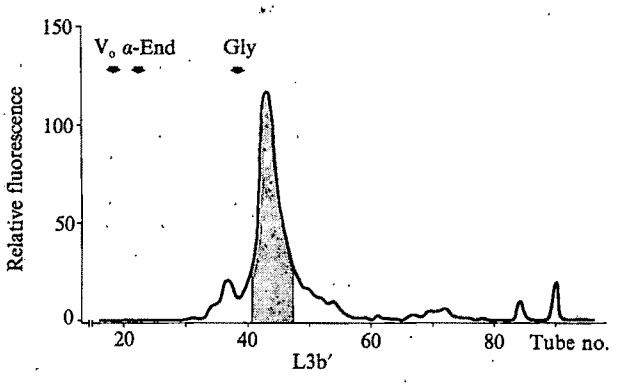

Fig. 3 Gel filtration chromatography of 8 mg of fraction L3b on a BioGel P-2 column (100 × 1 cm). Elution was carried out with 1 M acetic acid, the rate of flow was 0.2 ml min^{-1}, and 1.5-ml fractions were collected. The elution pattern was monitored by the fluorescamine method with glycine (10^{-8} M = 100) as a standard. The approximate elution positions of α-endorphin (α-End) and glycine (Gly) are indicated by the arrows. V_0 shows void volume.

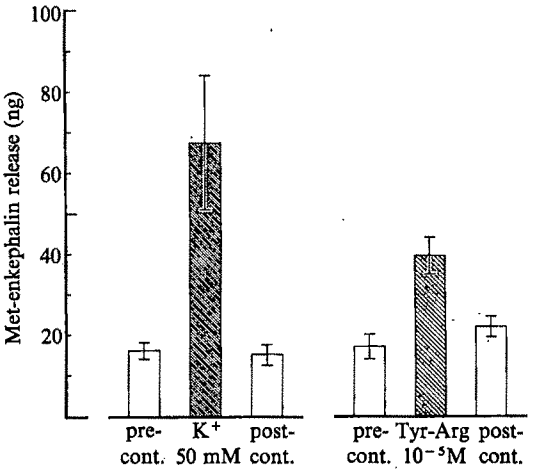

Fig. 4 Met-enkephalin release from rat striatal slices. Guinea pig striatal slices (500 μm thick, sagittal section) from four striata taken from two animals weighing ~600 mg were used in each experiment. The slices were superfused at a rate of 1 ml min^{-1} with a Krebs–bicarbonate medium at 37 °C, containing the dipeptides, Leu–Leu, Leu–Gly, Tyr-Tyr and Gly-Phe (each 1 mM) to protect against loss of released enkephalin by metabolism, and gassed with 95% O_2 and 5% CO_2. After an initial wash period of 15 min, superfusate samples were collected at 15-min intervals. For the first collection period, slices were superfused with normal medium containing the dipeptides (precontrol release). On the second collection period, slices were exposed to a high K^+ (50 mM) or Tyr-Arg (10^{-5} M)-containing medium (stimulated output) and the medium was replaced with normal solution for a 15-min period (post-control release). For the determination of the released Met-enkephalin, the method described by Meek and Bohan[10] was used. Final recovery of Met-enkephalin with this method was approximately 94%. The results are means ± s.e.m. for three or four experiments, as the absolute value of output from each striatal preparation.

In preliminary experiments, Tyr-Arg inhibited the enkephalin degradation enzymes in mouse brain homogenate preparations. However, its effect was weaker than that of bacitracin (less than 1/5th–1/10th, on a molar basis), which is a potent enkephalin degradation blocker. In addition, bacitracin did not produce analgesia even with intracisternal administration in a dose of 100 μg per mouse (71 nmol per mouse).

Thus, the analgesic effect of Tyr-Arg is interpreted as follows. Tyr-Arg itself does not bind with the opiate receptors but acts to release Met-enkephalin, which does bind with opiate receptors effectively, and consequently produces a potent analgesia. The relatively long-lasting analgesia induced by Tyr-Arg may be attributed to a stabilising effect on the released Met-enkephalin because Tyr-Arg weakly inhibits enkephalin degradation enzymes. Thus, Tyr-Arg seems to be a Met-enkephalin releasing factor, and its presence suggests the existence of a regulating mechanism for the release of Met-enkephalin. A preliminary report of a part of this work has been made elsewhere[11].

We thank Drs H. Yajima and K. Hayashi for advice, M. Ohara for assistance with the manuscript, and Dr H. Yajima for synthetic Tyr-Arg.

Stimulation of the pituitary-adrenocortical axis by nerve growth factor

U. Otten

Department of Endocrinology, University Children's Hospital, CH-4058 Basel

J. B. Baumann & J. Girard

Department of Pharmacology, Biocentre of the University, CH-4056 Basel, Switzerland

Nerve growth factor (NGF) is a protein essential for the development and maintenance of the peripheral sympathetic nervous system[1,2], causing responsive neurones to increase in size and to extend neurites. Biochemically, the selective induction of tyrosine hydroxylase (TH) and dopamine β-hydroxylase[3,4] key enzymes in catecholamine biosynthesis, is one of its most characteristic effects. Both the morphological[5] and biochemical[6] effects are modulated by glucocorticoids, suggesting a close relationship between specific effects of NGF and hormone action. NGF has been shown to induce an increase in adrenal cyclic AMP in intact but not in hypophysectomised rats[7], and so we have looked directly at the effect of systemic administration of NGF on the hypothalamo-pituitary-adrenal axis. We report here that NGF induced an enhanced secretion of adrenocorticotropin (ACTH) and a prolonged increase in plasma glucocorticoid concentration after intravenous (i.v.) injection. Such effects could have important implications for the biological activity of NGF.

NGF was prepared from submaxillary glands of adult male mice by the method of Bocchini and Angeletti[8], as the 2.5S subunit, with the modifications of Suda *et al.*[9]. The purity of NGF was controlled by SDS gel electrophoresis and its biological activity was determined as described by Fenton[10]. The biological activity of our NGF preparation was 250 biological units per μg of protein. Biologically inactive NGF was prepared by oxidation of the tryptophan residues with *N*-bromosuccinimide as described by Frazier *et al.*[11]. Adult male Sprague–Dawley rats of 100–120 g body weight were maintained at 24 °C, five per cage, with lights on at 0700 h and off at 1900 h. Food and water were provided *ad libitum*. For hormone studies they were injected in the tail vein with NGF at between 0700 h and 0900 h. They were killed by decapitation and trunk blood was collected at intervals of 5–720 min. Plasma ACTH and corticosterone were determined by radioimmunoassay as previously described[12]. The ACTH antibody used cross-reacts completely on a molar basis with $ACTH_{1-24}$ but not (cross-reaction <0.005%) with α-melanocyte-stimulating hormone (α-MSH), β-MSH, $ACTH_{17-39}$ or β-endorphin. There was no cross-reactivity with NGF. TH activity was determined according to Mueller *et al.*[13].

Table 1 Specificity of NGF for hormonal changes in rat plasma

	ACTH (pg per ml)	Corticosterone (μg per 100 ml)
Controls	576 ± 110	3.5 ± 1.1
Saline	609 ± 142	4.1 ± 1.2
NGF	1,223 ± 113*	17.5 ± 1.8*
Cytochrome *c*	582 ± 138	4.7 ± 1.6
Inactive NGF	343 ± 145	3.1 ± 1.1

Groups of five rats were injected i.v. with saline or equimolar concentrations (10 pmol per g BW) of various proteins. Rats were killed 90 min later and plasma ACTH and corticosterone were measured[12]. Results are mean ± s.e.m.

* $P < 0.005$, compared with controls (saline or cytochrome *c*) or with inactive NGF.

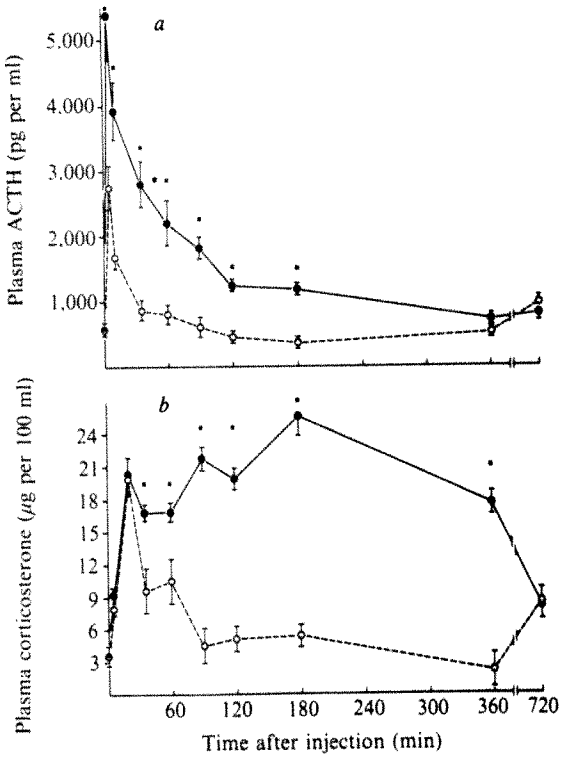

Fig. 1 Stimulation of the pituitary-adrenocortical axis by NGF. Groups of 5–10 rats were injected i.v. with 100 pmol per g NGF (●) or equimolar amounts of cytochrome *c* (○). They were killed at the times indicated and plasma was assayed for ACTH (*a*) and corticosterone (*b*) by radioimmunoassay[12]. Values represent the mean ± s.e.m.

* $P < 0.0025$, compared with cytochrome *c* controls.

A single i.v. injection of NGF (100 pmol per g) produced a prolonged stimulation of the adrenocortical system (Fig. 1). NGF increased plasma ACTH levels from 576 ± 110 pg ml^{-1} in controls to 5,380 ± 690 pg ml^{-1} ($n = 10$) at 5 min. ACTH did not return to resting levels within 180 min. Plasma corticosterone levels continued to increase for 20 min and remained at a high plateau of 20–24 μg per 100 ml for at least 6 h. The specificity of the response to NGF was confirmed by injecting control animals with equimolar concentrations of cytochrome *c*, a protein similar to NGF in molecular weight and isoelectric point. The

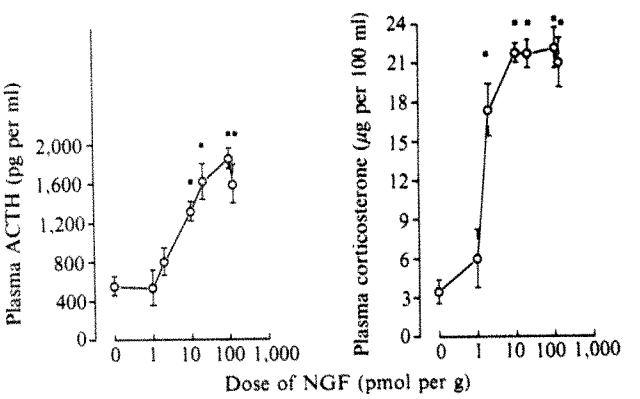

Fig. 2 Effect of concentration of NGF on stimulation of pituitary-adrenocortical axis. Groups of five rats were injected i.v. with NGF at 1.0–300 pmol per g. They were killed 90 min later and plasma was assayed for ACTH and corticosterone[12]. Values are expressed as mean ± s.e.m.

* $P < 0.005$, compared with cytochrome *c* controls.

0028-0836/79/470413-02$01.00

© 1979 Macmillan Journals Ltd

animals showed only hormonal changes of short duration (Fig. 1): plasma ACTH increased ($2,750 \pm 349$ pg ml^{-1}, $n = 10$) at 5 min, returning to resting levels within 35 min, and plasma corticosterone levels peaked at 20 min, returning to normal within 90 min. Thus the systemic application of NGF causes prolonged stimulation of the pituitary-adrenocortical axis that clearly differs from the acute short-lasting response to cytochrome *c*.

Injection of biologically inactive NGF had no significant effect on plasma ACTH or corticosterone levels (Table 1), indicating that only the biologically active molecule can activate the pituitary-adrenocortical axis. The hormonal response to biologically active NGF is dose-dependent (Fig. 2). The minimum dose that resulted in a significant ($P < 0.005$) increase in plasma ACTH and corticosterone 90 min after injection was 10 pmol per g. Maximum effect was achieved with concentrations 10 times greater.

Table 2 Effect of NGF on TH activity in sympathetic ganglia of rats

Treatment	TH activity (nmol dopa per h per mg protein) Superior cervical ganglion	Coeliac ganglion
Saline	1.2 ±0.06	0.95±0.12
NGF	1.71±0.15*	2.51±0.17†
Inactive NGF	1.0 ±0.05	1.01±0.05

Groups of six rats were injected i.v. with saline or equimolar concentrations (10 pmol per g) of biologically active or inactive NGF. TH activity was determined 48 h later[13] by the amount of 3,4-dihydroxyphenylalanine (dopa) formed.

* $P < 0.025$, † $P < 0.01$ } Compared to animals treated with inactive NGF or saline.

The minimum dose of NGF (10 pmol per g) required to induce hormonal changes in plasma is identical to that necessary to elicit a significant ($P < 0.025$) induction of TH in sympathetic ganglia (Table 2). Thus NGF-mediated hormonal changes could have important implications for the initiation of selective induction of TH activity in sympathetic neurones. We do not know whether these hormonal changes are of peripheral or central origin. However, the short latency of the increase in plasma ACTH may indicate direct action on the hypothalamo-pituitary system, as suggested by the observations of Nagaiah *et al.*[14]. Our findings, together with the observation that intracerebral injection of NGF induces an increased drinking response[15,16], indicate that NGF can affect both central and peripheral nervous systems. The significance of the hormonal changes with respect to the physiological role of NGF remains to be elucidated.

We thank Dr K. Stöckel for help with the preparation of inactive NGF, and Miss G. van Hees and Miss S. Graf for technical assistance. The ACTH-antiserum was a gift from Dr X. Depieds, Marseilles. This work was supported in part by the Swiss National Foundation (no. 3.7771.0.76).

Evidence for thyroxine–growth hormone interaction during brain development

L. Jack Roger

Robert E. Fellows*

Department of Physiology and Biophysics, University of Iowa, Iowa City, Iowa 52242

Growth-promoting hormones have complementary and synergistic effects on cell growth. In particular, thyroid hormone–growth hormone (GH) interactions are important in the regulation of somatic development[1]. Although the requirement of thyroid hormone for normal brain development is well established[2], the effects of growth-promoting peptide hormones, including GH, nerve growth factor and insulin, on central nervous system development have not been well characterised. To investigate the possibility of a role for GH in normal CNS development, we have measured its effect on the activity of brain ornithine decarboxylase (ODC), a key enzyme in the synthesis of the polyamines, spermidine and spermine[3,4]. Previously, we reported increased ODC activity in neonatal rat brain after intraperitoneal (i.p.) or intracranial administration of GH and other growth-promoting peptide hormones[5], results which have been supported by other data[6,7]. We now extend our findings to show that GH stimulation of brain ODC activity depends on the presence of thyroid hormone, even though thyroid hormone, by itself, does not stimulate ODC activity in brain. This is in contrast to liver, where GH and thyroid hormones seem to stimulate ODC activity independently. Our results suggest that thyroid hormone selectively alters or modulates the action of GH in mammalian brain and that abnormal brain development observed in hypothyroidism may in part result from decreased expression of GH activity.

One-day-old Sprague–Dawley rats (Zivic–Miller, Allison Park, Pennsylvania) were thyroidectomised (thyrx) by treatment with 100 μCi of $Na^{131}I$ (ref. 8). At 18 d, normal and thyrx rats were injected with saline (control), thyroxine (T_4), bovine GH (bGH), or T_4 and bGH (for details see Table 1 legend). ODC activity was determined *in vitro* as $^{14}CO_2$ produced from [1-^{14}C]ornithine[3,6]. At 18 d, body and brain weights of the thyroid-deficient rats were significantly reduced compared with controls; the body weights of thyrx and control rats averaged 37.5 ± 1.7 g (mean ± s.e.m.) and 42.7 ± 0.5 g ($P < 0.05$), respectively, and respective brain weights averaged 1.43 ± 0.03 g and 1.58 ± 0.03 g ($P < 0.02$).

In normal rats, i.p. bGH stimulated brain ODC activity twofold (217% of control, Table 1, expt 1), a finding similar to that observed in previous studies[5]. Although T_4 alone did not significantly increase brain ODC activity (expt 2), stimulation by T_4 and bGH given together was equivalent to that by bGH alone (expt 1).

The basal ODC activity of thyrx control (saline-treated) rats was elevated (158%) compared with normal controls (expt 2). This may have resulted from post-thyroidectomy delay in the normal decline of ODC activity from high perinatal to low adult levels[10], similar to the hypothyroidism-induced delay of brain maturation observed by others[2]. As in normal animals, brain ODC activity of thyrx rats was not significantly altered by T_4 treatment (129 ± 17% of thyrx controls). Importantly, bGH also failed to increase ODC activity in thyrx rats, and administration

* To whom reprint requests should be addressed.

Table 1 Effects of thyroxine and thyroidectomy on bGH stimulation of brain ODC activity

	Treatment	ODC activity	% of control	P
Expt 1	Control	722 ± 28 (3)	—	—
Normal rats	bGH	1,568 ± 211 (4)	217 ± 29	<0.02
	T_4 + bGH	1,464 ± 159 (5)	203 ± 22	<0.001
Expt 2	Control	817 ± 83 (8)	—	—
Normal rats	T_4	1,036 ± 92 (5)	127 ± 11	NS
Thyrx rats	Control	1,294 ± 122 (7)	158 ± 15*	<0.01*
	T_4	1,663 ± 218 (8)	129 ± 17	NS
	bGH	1,391 ± 146 (9)	108 ± 11	NS
	T_4 ± bGH	2,844 ± 196 (9)	220 ± 15	<0.001

Normal and thyroidectomised (thyrx) rats received saline (control), T_4 (20 μg per 100 g body weight) i.p. at 28, 19 and 4 h before death, bGH (300 μg per 100 g body wt) i.p. 4 h before death, or T_4 plus bGH. bGH (NIH-GH-B16) was chromatographed before use to obtain a monomer fraction[20]. ODC activity (d.p.m. per 30 min per g wet weight) is given as mean ± s.e.m., with the number of animals in parentheses. NS, Not significant.

* Compared with normal control.

of T_4 before bGH completely restored the ODC response, with an activity increased to 220% of control levels. This was comparable to the normal response to bGH (217% of control) seen in euthyroid rats.

This effect of T_4 was not apparent in liver (Table 2). As noted by us and others[5,11], GH treatment of normal rats produced a large (148-fold) increase in liver ODC activity (expt 1). T_4 increased liver ODC activity eightfold in normal and thyrx rats (expt 2), and the increase seen after T_4 and bGH in normal rats did not differ from that of bGH alone (expt 1). In contrast to results with brain, liver ODC activity in thyroid-deficient rats was stimulated by bGH (37-fold increase, expt 2). Furthermore, the response of T_4 plus bGH (48-fold increase) was similar to that for bGH alone. As shown in Table 2, after bGH, or T_4 plus bGH, the stimulation of ODC activity was greater in normal rats than in thyrx rats. This may reflect a decrease in liver responsiveness to GH after thyroidectomy which was not adequately corrected by T_4 administration. It is clear, however, that in contrast to its effect on brain, GH stimulated liver ODC activity in thyrx rats without T_4 pretreatment.

We conclude that an action of T_4 is required for the stimulation of brain ODC by bGH. The mechanism for this 'permissive' (ref. 12) or modulating action of T_4 is unknown. It is possible that the number of receptors for GH or for a GH-dependent agent such as somatomedin[13] is reduced in thyroid deficiency in a manner similar to that reported for prolactin[14] and catecholamine receptors[15]. Alternatively, thyroxine may regulate the availability of GH-dependent (perhaps brain-specific) somatomedin or somatomedin-like factors. The difference between brain and liver response might also result from differential effects of T_4 on ODC isoenzymes, the existence of which is suggested by kinetic data[16].

Because, in severe hypothyroidism, the amount of GH in plasma is greatly reduced[17], attempts have been made to correct the GH deficiency in thyroid-deficient neonatal rats with large amounts of exogenous hormone[18,19]. Interestingly, this treatment partially reversed the abnormal pattern of neonatal brain growth. Thus, in neonatal hypothyroidism, abnormal brain development might result in part not only from decreased GH or GH-dependent growth factors, but also, as suggested by the present study, from a lack of thyroid hormone support for the limited GH present.

As ODC activity and polyamine synthesis seem to be intimately associated with the regulation of nucleic acid and protein synthesis[3,9], the increase in brain ODC activity following GH administration suggests a role for GH in the regulation of brain development. It should be recognised, however, that in this and previous work[5], ODC activity has been used as an indicator of growth stimulation[3]. It remains to be determined whether the regulatory actions of GH on brain development are mediated by changes in polyamine synthesis.

Apamin blocks certain neurotransmitter-induced increases in potassium permeability

Apamin[1] is a neurotoxic polypeptide of known structure[2,3] isolated from bee venom. Shuba and coworkers[4,5] have recently shown that it abolishes the hyperpolarising action of externally-applied ATP on visceral smooth muscle (guinea pig stomach and taenia coli) as well as the hyperpolarisation (inhibitory junction potential) that follows stimulation of the non-adrenergic inhibitory nerve supply to these tissues. As it has been proposed[6] that

ATP is the neurotransmitter involved in the latter response, Vladimirova and Shuba[4] tentatively concluded that apamin is a specific postsynaptic blocking agent of this non-adrenergic, possibly 'purinergic', inhibition. We have confirmed the important observation that nanomolar concentrations of apamin reduce inhibition by ATP and by non-adrenergic nerve stimulation, but further experiments suggest that, rather than acting as a specific blocker of ATP receptors, apamin inhibits the increase in potassium permeability caused by a number of agents, including ATP.

The first new finding (Fig. 1*a*) was that apamin also reduces the inhibition produced by stimulation of the sympathetic (perivascular) nerve supply to the taenia coli. As the transmitter in this case is noradrenaline[7], it seemed possible that apamin interferes with some of the actions of catecholamines as well as of ATP. In keeping with this, inhibition of the taenia by the selective α-adrenoreceptor agonist amidephrine is also blocked by apamin. Figure 1*b* shows the noncompetitive nature of this antagonism, the maximum inhibition by amidephrine being reduced by apamin at concentrations as low as 1–3 nM. In each of four other such experiments, 5 nM apamin was sufficient to abolish amidephrine inhibition. These results contrast with the competitive antagonism seen with α-adrenoreceptor blockers in this tissue[8], and suggest that apamin acts at a stage beyond the recognition site of the receptor. As both α-adrenoreceptor-mediated inhibition[9–11] and the inhibitory response to ATP[12,13], as well as to non-adrenergic nerve stimulation[14] are due mainly to an increase in the potassium permeability of the smooth muscle membrane, it seemed possible that apamin could act by preventing the rise in potassium permeability rather than by blocking the receptors that initiate it.

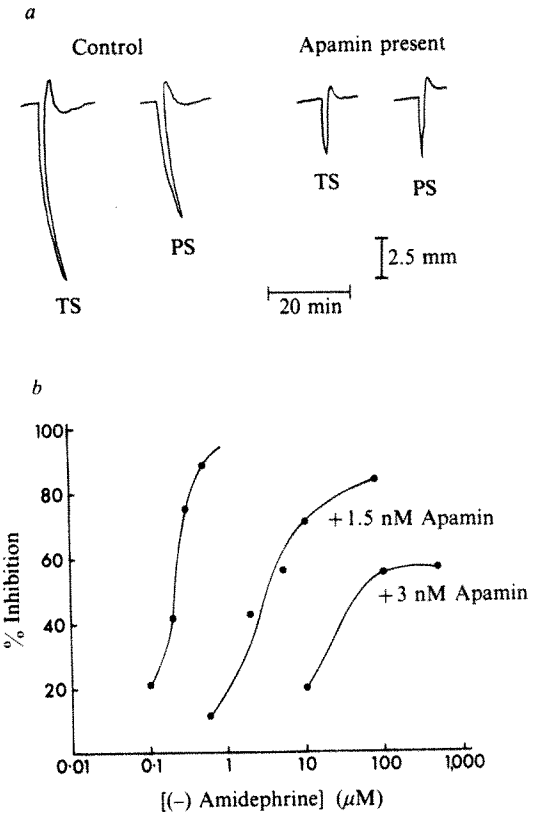

Fig. 1 *a*, Apamin (5 nM) reduces the relaxation caused by both transmural (TS) and perivascular (PS) stimulation of the nerve supply to an isolated strip of guinea pig taenia coli. Atropine (3 μM) present throughout. Stimulation parameters: supramaximal square pulses (200 μs) for 30 s at either 5 (TS) or 20 Hz (PS). Isotonic recording. *b*, Apamin antagonises the inhibition by the α-adrenoreceptor agonist amidephrine of the contractile response of a taenia strip to carbachol (20 nM). For details of the experimental procedures for *a* and *b*, see refs 7 and 8, respectively.

This hypothesis was tested using another tissue, guinea pig liver, in which α-adrenoreceptors also enhance potassium permeability, as indicated by increases in potassium flux, membrane potential and conductance, and in addition a net loss of potassium[15,16]. ATP also hyperpolarises guinea pig liver cells, probably by the same mechanism[17]. The response can be conveniently studied using a suspension of isolated hepatocytes, as the loss of potassium following a substantial increase in potassium permeability is readily detected by means of a potassium-sensitive electrode in the suspension[16,18]. This is shown in Fig. 2, which also shows that apamin greatly reduces the potassium loss, and hence, by inference, the increase in potassium permeability caused by both ATP and noradrenaline. In this respect apamin resembles quinine[18], which is, however, approximately 10^5 times less active.

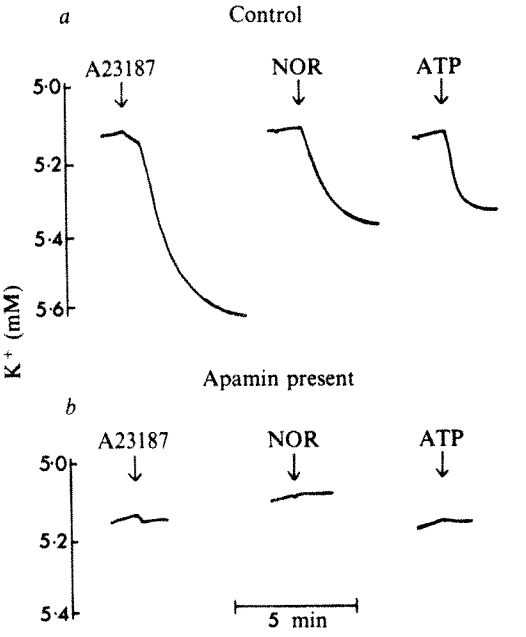

Fig. 2 *a*, A23187 (5 μM), (−)noradrenaline (5 μM, in the presence of propranolol at 5 μM) and ATP (1 μM) cause K loss from isolated guinea pig hepatocytes. The movement of K between the cells and the incubation medium was followed by means of a K-sensitive electrode in the cell suspension (which contained ~50 mg cells in 2 ml and was stirred). A downward deflection indicates an increase in external K concentration, corresponding to loss of K from the cells. For other details, see ref. 18. *b*, Apamin (10 nM, applied 2–3 min beforehand) greatly reduces the response to all three agents applied to other samples from the same batch of hepatocytes.

The rise in potassium permeability is thought[18–20] to be triggered by an increase in the concentration of ionised calcium in the cytosol of the hepatocytes, and this suggested a means of testing whether apamin blocks the receptors or the consequences of receptor activation. If the former is the case, the change in calcium movement should also be abolished. This was studied using noradrenaline as the agonist, and the results are shown in Fig. 3. Apamin at concentrations sufficient to eliminate the potassium movement induced by noradrenaline caused little change in the rapid calcium loss that follows the application of α-agonists to hepatocytes[21,22]. Thus the receptors are still functional. The same dissociation between potassium and calcium movements was seen with the divalent ionophore A23187, which in the presence of apamin no longer caused potassium loss (Fig. 2) although still initiating calcium movement[18]. A further test of the same point was made with rabbit liver slices which respond to α-agonists with increases in ^{45}Ca and ^{42}K efflux and a rise in glucose release[19]. Apamin (10 nM)

abolished the effect on ^{42}K efflux, whereas the changes in ^{45}Ca efflux and glucose release were unaltered.

The conclusion that apamin is not a receptor blocker is strengthened by our finding that it does not inhibit the contractile response of the isolated rat vas deferens preparation to ATP or to α-agonists. Nor are the actions of ATP on histamine release from rat peritoneal mast cells impaired (B. Gomperts, personal communication).

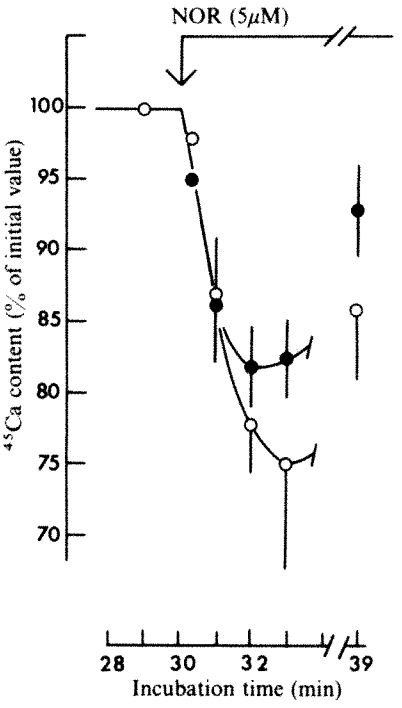

Fig. 3 Noradrenaline (5 μM, in the presence of propranolol at 5 μM) causes isolated guinea pig hepatocytes to lose calcium, and the initial loss is little affected by apamin. Open circles, controls; closed circles, cells treated with apamin at either 10 (4 expts) or 100 nM (1 expt), applied 3 min before noradrenaline. Calcium contents were determined by equilibrating the hepatocytes with ^{45}Ca (total external calcium, 1.8 mmol l^{-1}) for 30 min and then counting the ^{45}Ca content of the pellet after centrifuging the cells through an oil phase, as described in ref. 18. The values (ordinate) have been expressed as percentages of the content before noradrenaline (mean value, 1.91 ± 0.08 (s.e.m., $n = 5$) nmol calcium per mg dry weight). The vertical bars indicate the s.e.m.s of 4–5 observations. Abscissa, incubation time in ^{45}Ca.

It is also clear that apamin is highly selective in that only some potassium permeabilities are blocked. Thus Vladimirova and coworkers have shown[5] that concentrations of apamin much greater than those used for their smooth muscle experiments have little effect on the frog neuromuscular junction, or on synaptic inhibition in an identified molluscan neurone. Other actions that we have found to be unaffected by apamin at up to micromolar concentrations include: (1) the inhibitory effect of acetylcholine on the beat of the isolated perfused rabbit heart; (2) the increase in potassium permeability that follows a rise in intracellular calcium in human red blood cells; and (3) inhibition of the mechanical activity of the guinea pig taenia coli by β-adrenoreceptor agonists and by low concentrations of adenosine and AMP. This last finding is in keeping with other evidence (see refs 23, 24) that inhibition of the taenia coli by β-adrenoreceptors, as well as by the sub-type of purinoceptor which is activated by adenosine and by AMP, does not involve the increase in potassium permeability seen with α-adrenoreceptor agonists and ATP.

In conclusion, apamin abolishes certain responses to ATP and to α-adrenoreceptor agonists by inhibiting the increase in potassium permeability that these agents initiate. The simplest explanation is that apamin blocks the potassium channels involved, although it is also possible that it interferes with the mechanism by which a rise in cytosolic calcium causes these channels to open. The potency and selectivity of apamin should make it useful for the study of neurotransmitter-controlled potassium conductances. In addition, the finding that apamin blocks calcium-mediated increases in the potassium permeability of hepatocytes but not red blood cells suggests that there may be several types of calcium-dependent potassium channel.

Induction and kinetics of natural killer cells in humans following interferon therapy

John R. Huddlestone, Thomas C. Merigan Jr* & Michael B. A. Oldstone

Department of Immunopathology, Scripps Clinic and Research Foundation, La Jolla, California 92037

Natural killer (NK) cells are non-B, non-T lymphocytes that effect spontaneous cytolysis of both virus-infected and neoplastically transformed target cells[1,2]. These NK lymphocytes have been detected in several species including man[3–9]. Interferon is a primary regulator of natural killer activity[6,10,11]. Because NK cells have been implicated in the regulation of tumour cell expression and can be induced by interferon in murine models, we have studied patients receiving large doses of interferon to determine (1) whether interferon could induce NK lymphocytes in the peripheral blood of man, and (2) whether there are characteristic kinetics for the appearance, disappearance and reactivation of NK lymphocytes following interferon therapy.

We report here the activation of human NK cells by the systemic inoculation of human subjects with interferon. Five patients received interferon as therapy for non-Hodgkin's lymphoma. All showed a marked increase in NK cell activity 12–24 h after inoculation. Peak NK activity occurred 18 h after introducing interferon, and thereafter declined rapidly but remained above pre-interferon levels. Induced NK activity occurred with reintroduction of interferon but at lower levels of activity and with different kinetics.

The interferon used in this study was from a human leukocyte interferon preparation containing 1×10^6 units of interferon per mg protein. Patients receiving interferon had non-Hodgkin's lymphoma. (For more details about the interferon preparation, its administration, the diagnostic criteria and clinical course of the non-Hodgkin's lymphoma patients, see ref. 12.) Four (W.M., P.K., B.S., J.B.) of the patients were treated with 10×10^6 units of interferon intramuscularly for 7–30 days, and one patient (GL.) received 5×10^6 units for 2 days, followed by 10×10^6 units daily for the next 27 days. Of these patients only P.K. had received interferon previously. Data for NK activity are expressed in terms of the cytotoxicity index (CI). This allows each patient to act as his own control throughout all observations. The CI was determined by dividing the specific killing of MOLT-4 target cells at a given experimental time by the maximum killing of MOLT-4 target cells observed for that patient's lymphocytes during the entire course of observations. The CI values for each of the patients before interferon therapy were 0.16, 0.08, 0.02, 0.14 and 0.5, respectively (Fig. 1). Lysis was detected in a 6-h ^{51}Cr release assay of triplicate samples, with variance among triplicates of less than 10%. Lymphocytes from the two patients (W.M. and P.K.) with the highest CI values had been tested against various targets including MOLT-4 cells, HeLa cells uninfected or persistently infected with measles virus, HT-29 cells and Daudi cells. The characterisation, handling, passage and ^{51}Cr-labelling of these cells have been reported elsewhere[13,14]. Killing by lymphocytes from several normal controls and from these two patients was effective against the various targets, but more MOLT-4 cells were lysed than other target strains, and so thereafter, only ^{51}Cr-labelled MOLT-4 cells were used. These cells ($1-2\times10^4$ cells ml^{-1}) were mixed with varying amounts of lymphocytes collected from each patient's peripheral blood by Ficoll–Hypaque passage, depleted of adherent cells[14], and used at ratios of 1:10, 1:20 and 1:40. To ensure internal consistency throughout the various time points assayed, mean values of spontaneous ^{51}Cr release (range 10–23%) were calculated and results corrected at each point as described[14].

As shown in Fig. 1, enhanced NK lymphocyte activity was not present at 6 h, but appeared at 12 h and peaked at 18 h after the initial injection of interferon. Thereafter, killing activity fell rapidly but stayed above pre-interferon levels. Lymphocyte killing generated by interferon therapy was caused by lymphocytes which expressed Fc receptors. Patients (W.M. and P.K.) had less than 1% of the total killing activity in Fc-negative lymphocytes. Mean specific ^{51}Cr release ±1 s.d. due to total peripheral blood lymphocytes compared with adherent cell-depleted Fc-positive and Fc-negative populations was: patient W.M., total lymphocytes 44±6%, Fc positive, 32±1%, Fc negative 3±0.3%; patient P.K., total lymphocytes 28±6%, Fc positive 17±0.2%, Fc negative, 0%. Thus, because (1) lymphocytes bearing Fc-positive receptors performed the killing, (2) many different target cell lines were lysed, and (3) cytotoxicity was induced by interferon, these killer cells can be characterised as NK lymphocytes[1,2,15,16].

We were interested in whether NK lymphocyte killing responses could be restimulated in patients who had previously been given interferon therapy. Two patients (J.B., B.S.) received 10×10^6 units interferon daily for 7 days, and were taken off therapy for 46 and 73 days, respectively. They were then given 10×10^6 units interferon daily for 9 or 30 days, respectively. In patient B.S., whose CI was 0.1, the initial course of interferon increased NK activity to a CI of 1.0 by 18 h. However, the

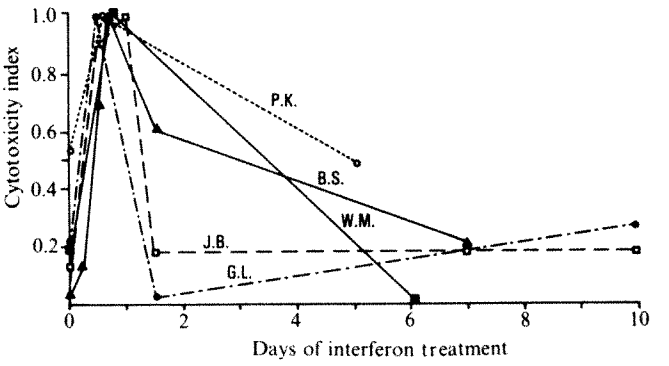

Fig. 1 The cytotoxic indices of peripheral blood lymphocytes (PBLs) from five patients treated with 10×10^6 units interferon daily plotted as a function of time. Peripheral blood lymphocytes, sampled before interfero therapy and at the indicated intervals thereafter, were assayed for spontaneous cytolytic activity against MOLT-4 cells in a standardised 6-h ^{51}Cr-release assay at lymphocyte: target ratios of 5:1, 20:1 and 40:1. The cytotoxic indices were calculated from % specific killing data at a PBL:target ratio of 40:1 by dividing the % specific killing at a given time by the maximum % specific killing observed for that patient during treatment. % Specific killing data represented the mean of at least three replicates and were corrected for variance in the spontaneous releases, which ranged from 6 to 24%. Cytotoxic indices for normal subjects assayed concurrently had a mean of 0.9 and the minimum CI seen in a single normal subject was 0.5.

second interferon course generated no NK activity. Patient J.B. did develop NK lymphocyte activity 73 days after reinoculation with interferon (CI 0.2), but at fivefold lower levels than those generated during the primary inoculation of interferon. When interferon therapy was attempted a third time in patient J.B. (10×10^6 units of interferon given daily for 30 days) 150 days after cessation of the second course, a significant rise in NK activity was seen (CI 0.5). Further, the elevated NK response observed in P.K. (Fig. 1) to interferon occurred 1.5 yr after a prior course of leukocyte interferon. Throughout these studies there was no extension of the patients' lymphoma and no introduction of chemotherapy. Therefore, neither haematological complications of conventional chemotherapy nor a worsening of their disease can explain the transient refractoriness of B.S. and J.B. to repeated interferon induction.

Recently, patients with non-Hodgkin's lymphoma underwent remission in both size and distribution of their lymphadenopathy after intensive therapy with interferon[12]. Prevention of relapse has also been reported in patients with osteosarcoma receiving interferon[17]. We have noted the successful induction of NK lymphocyte activity in patients with non-Hodgkin's lymphomas following interferon treatment. Hence, in humans, like mice, interferon induces NK activity. The role of induced NK activity against the patient's own tumour cells is now under investigation.

After completion of these studies, we became aware that Einhorn, Blomgren and Strander[18] had also demonstrated acute enhancement of NK responses in four of five tumour patients given a single injection of 3×10^6 units of human leukocyte interferon.

The interferon used was obtained from Dr Kari Cantell, Finnish Red Cross Transfusion Service. This research was supported by USPHS research grants NS-12428, AI-07007, AI-09484 and CA-16857-03 and Biomedical Research Support Program grant 1 S07-RR-05514. J.R.H. is a recipient of a postdoctoral fellowship from the Multiple Sclerosis Society.

Desensitisation of cultured glial cells to epidermal growth factor by receptor down-regulation

C.-H. Heldin, B. Westermark* & Å. Wasteson

Institute of Medical and Physiological Chemistry and *The Wallenberg Laboratory, University of Uppsala, Uppsala, Sweden

Epidermal growth factor (EGF), which can be purified from the mouse submaxillary gland[1] or from pregnant human urine[2], is a potent multiplication-stimulating factor for several types of cultured cells, including human fibroblasts[2,3] and glial cells[4]. The molecule binds with high affinity and saturation kinetics to a cell-surface receptor[3], is subsequently internalised[5,7] and finally degraded[5,6]. The binding event is accompanied by a reduction in the number of EGF receptors[5,8]. This phenomenon—'receptor down-regulation'—has been demonstrated with several hormones and may be a general principle for the modulation of binding groups on the outer cell surface[9,10]. Further, it has been proposed that receptor loss acts to regulate the cellular response to the binding ligand[11]. The present study provides direct experimental support for this hypothesis. It demonstrates that down-regulation of EGF receptors on glial cells causes desensitisation of the mitogenic response of these cells to subsequent stimulation with EGF.

Attempts to demonstrate cellular desensitisation, that is, a decreased metabolic response to a factor, may be hampered by the fact that the initial exposure to the factor is likely to produce significant changes in the basal level of the metabolic parameter in question. The present experiments were designed to dissociate the event of down-regulation of EGF receptors on glial cells from the mitogenic response of these cells to EGF. Treatment of glial cells with increasing concentrations of EGF (up to 167 nM) in Ham's F-10 medium for 24 h resulted in progressive down-regulation of the EGF receptors; loss of about 90% of the EGF receptors could be induced, as revealed by Scatchard analysis[12] of binding experiments with ^{125}I-labelled EGF (Fig. 1). This finding was expected by analogy with previous data on EGF receptors of other types of cultured cells[5,8]. In contrast, EGF was incapable of inducing a mitogenic response in the presence of plain F-10 medium; only after supplementation with human serum albumin (HSA) was this medium permissive to multiplication-stimulating activity (Table 1). Pre-exposure of glial cells to plain F-10 medium did not affect the time (about 13 h) required for subsequent recruitment of cells to DNA synthesis on stimulation with EGF in the permissive medium (F-10 medium supplemented with HSA) (Fig. 2). This suggests that the block in the mitogenic response to EGF imposed by the non-permissive conditions was probably at an early step close to the ligand–receptor binding event and preceding the reactions leading to commitment of the cells to enter the cell cycle.

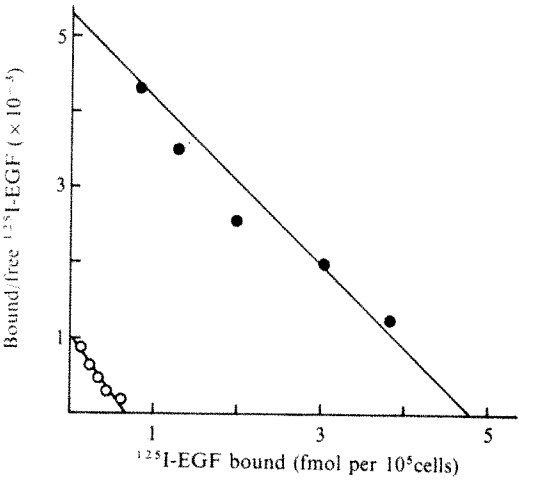

Fig. 1 Effect of EGF pretreatment on ^{125}I-EGF binding to human cultured glial cells. Human normal glia-like cells, line 787 CG (refs 16, 17), were seeded on 2.5-cm dishes in 2 ml of Eagle's medium containing 10% fetal calf serum. After 48 h at 37°C the medium was replaced with 2 ml of Ham's F-10 without serum. The cultures (approximately 1.1×10^5 cells per dish) were then incubated for 22 h in 2 ml of Ham's F-10 medium in the absence (●) or presence of 167 nM EGF (○). Cells were then washed once with 2 ml of plain F-10 medium and five times with F-10 medium containing 1 mg ml^{-1} of HSA. The washed cells were incubated for 2 h at 4°C with various doses of ^{125}I-EGF in 1 ml of F-10 medium containing 1 mg ml^{-1} HSA. The cultures were then washed six times with 2 ml of ice-cold phosphate-buffered saline (137 mM NaCl, 2.7 mM KCl, 8 mM Na_2HPO_4, 1.5 mM KH_2PO_4, 0.9 mM $CaCl_2$, 0.8 mM $MgSO_4$, *p*H 7.3) containing 1% fetal calf serum. Cells were lysed in 1 ml of 0.3 M NaOH and the cell-bound radioactivity determined in a Packard Auto-Gamma scintillation spectrometer. Nonspecific binding, determined in the presence of excess unlabelled EGF (about 1 μM) was subtracted. Binding data were treated by Scatchard analysis[12].

Table 1 Multiplication-stimulating activity of EGF on glial cells in F-10 medium, with or without human serum albumin

Addition	Multiplication-stimulating activity (c.p.m. ^{3}H)
None	814
EGF (1.6 nM)	1,121
HSA (1 mg ml^{-1})	2,716
HSA (1 mg ml^{-1}) + EGF (1.6 nM)	10,926

Multiplication-stimulating activity was estimated using the incorporation of ^{3}H-thymidine into trichloroacetic acid-precipitable material of serum-deprived sparse cultures of a human normal glia-like cell line[16,17] as described elsewhere[18].

Cell cultures in which the EGF receptor number had been reduced by preincubation with EGF (in non-permissive medium) were less responsive to further exposure to EGF (in the permissive medium). The dose–response curve for EGF (based on the increase in labelling index) was more than fivefold shifted to the right in these cells compared with controls with normal EGF receptors (Fig. 3). The maximal response obtained at saturating concentrations of EGF was only slightly lower than in control cultures. Apparently, the post-receptor pathway in EGF-induced mitogenesis did not become limiting by preincubation with EGF; rather, desensitisation occurred by reduction in receptor number. Maximal biological response, demonstrable with only a fraction of the total number of receptors occupied, indicates the presence of spare receptors for EGF on glial cells, in accordance with previous data[13].

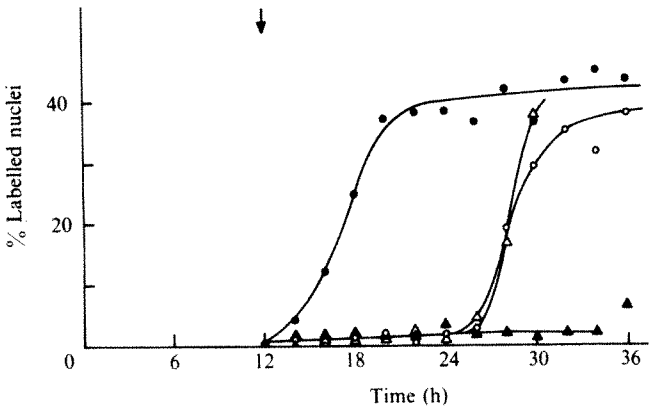

Fig. 2. Effect of EGF pretreatment on the time required for recruitment of glial cells to DNA synthesis on stimulation with EGF. Human normal glia-like cells, line 787 CG (refs 16, 17), were seeded on 2.5-cm dishes in 2 ml of Eagle's medium, containing 10% fetal calf serum ($\sim 10^5$ cells per dish). After 24 h at 37 °C the medium was replaced with 2 ml of Ham's F-10 medium without serum. After another 24 h, medium was changed to fresh F-10 medium containing 0.1 μCi ml^{-1} ^{3}H-thymidine (specific radioactivity 2 Ci mmol^{-1}). The cultures were then given EGF (1.67 nM) and HSA (1 mg ml^{-1}) at the following times: EGF and HSA at 0 h (●); EGF at 0 h and HSA at 12 h (○); EGF and HSA at 12 h (△); EGF only at 0 h (▲). At the indicated times duplicate dishes were collected for autoradiography as described elsewhere[16,18].

Recent experiments by Livingstone *et al.*[14] indicate that insulin-dependent desensitisation of fat cells may be correlated with a decrease in the (low-affinity type of) insulin receptors. Similarly, desensitisation of rat Leydig cells to human chorionic gonadotropin *in vivo* was linked with a concomitant drop in hormone receptors[15]. These results differ from the present ones in some quantitative aspects, but together they suggest that modulation of receptor number may be a general mechanism for the regulation of cellular responsiveness to hormones.

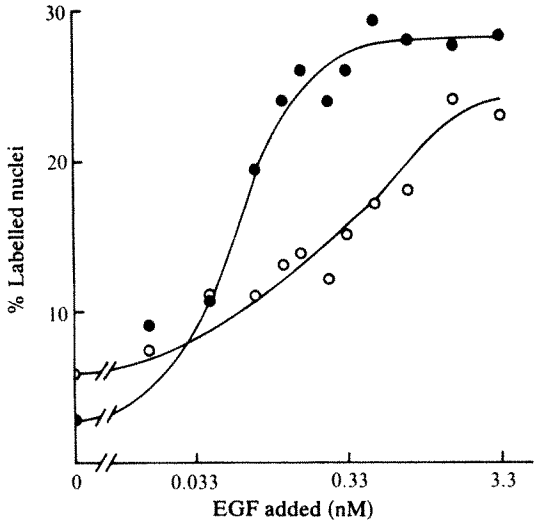

Fig. 3. Effect of EGF receptor down-regulation on the mitogenic response of human cultured glial cells to EGF. Glial cells were seeded as described in Fig. 1. After 24 h at 37 °C the medium was changed to Ham's F-10 without serum and the incubation continued for another 24 h. The cultures were then given 2 ml of fresh F-10 medium (●) or 2 ml of F-10 medium containing 167 nm EGF (○). After 22 h the cells were washed once with 2 ml of plain F-10 medium and five times with F-10 medium supplemented with HSA (1 mg ml^{-1}) and incubated in 2 ml of this medium containing various doses of EGF. After 24 h 0.4 μCi of ^{3}H-thymidine were added and incubation continued for another 60 min. Cultures were then collected for autoradiography[16,18]. Each point represents the average of duplicate dishes.

Adipokinetic hormone inhibits protein synthesis in *Locusta*

James A. Carlisle & Barry G. Loughton

Department of Biology, York University, Downsview, Ontario, Canada

The adipokinetic hormone (AKH) of the locust has been isolated, characterised and synthesised[1,2]. In this insect, its function is to mobilise diglycerides from the fat body to provide energy for sustained flight[3]. In addition, it modifies the metabolic activity of the flight muscles so as to oxidise fatty acids preferentially[4]. We report here another effect of AKH on locust metabolism, the direct inhibition of protein synthesis by the fat-body. This inhibitory activity may function in the locusts' overall adaptation to flight and it may also account for the presence of AKH both in larval locusts[5] and in other species which do not fly for prolonged periods[6].

There have been several studies of the neuroendocrine control of protein synthesis in the locust. Hill[7] has shown that electrocautery of the median neurosecretory cells (MNSC) of the brain brought about a diminution of protein synthesis. Osbourne *et al.*[8] reported that injection of homogenates of corpora cardiaca (CC) stimulated protein synthesis in adult female locusts. In larval locusts alterations in protein synthetic activity may be correlated with changes in ecdysone titre[9,10]. Because the prothoracic gland is under neuroendocrine control in the larval insect the neurosecretory control of protein synthesis may be indirect though the mode of control in the adult insect is not known. To investigate this problem further, we studied the role of the CC in protein synthetic activity. The locust CC presents an unusual opportunity for the study of insect neurohormones because it can be separated into 'storage' and 'glandular' lobes[13]. Activity was tested by injecting CC homogenates into 5-d-old fifth instar larvae together with 1 μCi ^{3}H-leucine (Amersham/Searle specific activity 50.6 Ci mmol^{-1}). Control insects received an equivalent

Affinity chromatography – your keys to success!

- high selectivity and low non-specific adsorption for pure product
- ready-to-use for greater time-saving
- porous matrix for high capacity, concentrated product
- excellent flow properties for fast results
- reusable for economical separations

Group specific adsorbents for the key step in your purification

Protein A-Sepharose CL-4B	IgG, antigens, immune complexes
Con A-Sepharose	glycoproteins, glycolipids, polysaccharides
Lentil Lectin-Sepharose 4B	membrane glycoproteins
Heparin-Sepharose CL-6B	plasma proteins, enzymes etc
Poly(U)-Sepharose 4B	mRNA, plant nucleic acids
Poly(A)-Sepharose 4B	mRNA-binding proteins, hnRNA
Lysine-Sepharose 4B	plasminogen, ribosomal RNA
Blue Sepharose CL-6B	serum albumin, nucleotide-requiring enzymes
5'AMP-Sepharose 4B	NAD^+-dependent dehydrogenases
2'5'ADP-Sepharose 4B	$NADP^+$-dependent dehydrogenases

AT BRL, WE DESIGN OUR GEL ELECTROPHORESIS SYSTEMS TO SATISFY A VERY DEMANDING CUSTOMER. OURSELVES.

BRL® is the only company that manufactures and uses gel electrophoresis systems for research and product production. As a result, our systems have to meet our high standards for workability, quality and — most important — affordability.

For you, this means better nucleic acid and protein separations, as well as improved nucleic acid sequence analysis.

THE HORIZONTALS:

Featuring / • variable gel thickness and sample capacity • removable UV transparent tray • safety interlock lid • optional buffer cycling

MODEL H0/H1:

• 20 cm x 25 cm gel bed • 20 or 40 sample wells for analytical use; 1 or 2 gel-wide sample wells for preparative applications • $450.00 complete* • model H1 with parts and fittings for buffer cycling, $495.00, complete*

NEW MODEL H2/H3 OUR MINI-HORIZONTAL:

• 11 cm x 14 cm gel bed • 14 or 28 analytical sample wells; 1 or 2 gel-wide sample wells for preparative use • $350.00 complete* • for a mini-horizontal with buffer cycling capability, the model H3; $395.00 complete*

THE VERTICALS:

Featuring the greaseless spacer and gasket system, which means / • fast set up • direct buffer-gel contact • no expensive, fragile, notched glass plates.

MODEL V-16:

• 16 cm x 17 cm gel slab • 20 sample capacity • unique safety interlock lid • $150.00, complete*; quantity discounts.

NEW MODEL V-16-2 THE DOUBLE VERTICAL:

• all the convenience of the Model V-16 with up to twice the capacity • versatile — can be used in single or double gel mode $295.00, complete*.

THE SEQUENCERS
MODEL S0:

• for Maxam-Gilbert[2] or Sanger[3] nucleic acid sequencing procedures • 34 cm x 40 cm gel format • $385.00, complete*.

COMING SOON

MODEL S1 • THE ULTIMATE IN FORMAT FLEXIBILITY:

• for any gel length between 20 cm and 90 cm • 17 cm gel width • our unique gasket-spacer system.

injection containing a homogenate of the optic lobe of the brain. After 2 h the animals were bled through the cervical membrane and the incorporation of ^{3}H-leucine into haemolymph protein was determined[12]. When homogenates of whole cardiaca were injected (one gland in 10 μl saline) there was no consistent difference in incorporation of label into haemolymph protein between experimental and control insects.

However, when each lobe was homogenised separately, the injection of glandular lobe homogenates suppressed the incorporation of labelled amino acid into haemolymph protein by 24% compared with controls. A factor was found in extracts of the storage lobe that stimulated protein synthesis. The nature of this enhancement of protein synthesis will be reported elsewhere.

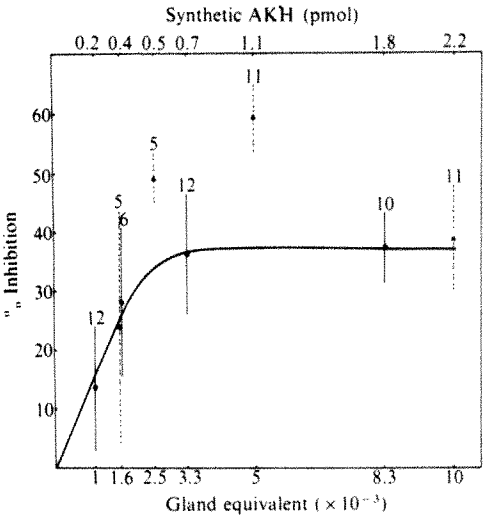

Fig. 1 The inhibition of *in vitro* protein synthesis by adult fatbodies incubated with homogenates of the glandular lobe of the CC (●), concentrations expressed in gland equivalents per 0.5 ml, and synthetic AKH(▲), concentrations expressed in pmol per 0.5 ml. Because the glandular lobes of the adult locust contain about 50 μg of AKH[1] the abscissae for synthetic hormone and for gland homogenates are approximately equivalent. To calculate percentage inhibition, incorporation of ^{3}H-leucine into half fatbodies incubated with gland homogenates or synthetic hormone was compared with that occurring in the contralateral half incubated with optic lobe homogenate. Bars represent twice the standard error. Integers above the bars indicate the number of replicate experiments. Synthetic AKH was a gift from Dr R. Downer.

The insects used in these experiments had a complete neuroendocrine system, and it was possible that the response detected was the result of the activation of one or more elements of their own endocrine system. To test this possibility the fatbody was dissected out from mature adult male locusts, divided longitudinally and each half was incubated *in vitro* in 0.5 ml Schneider's modified *Drosophila* medium (GIBCO) containing 1 μCi ^{3}H-leucine. One half received a homogenate of one pair of glandular lobes in 10 μl of locust saline; the other received 10 μl of a similar homogenate of optic lobe in locust saline. After 45 min at 36 °C, 50 μl of the incubation medium was removed and incubation continued. After 2 h a second 50-μl sample was taken and incubation was terminated. The medium was collected; the fatbody was washed quickly in saline and then homogenised in 100 μl saline. A 20-μl sample of the homogenate was assayed for total radioactivity. A second 20-μl sample was assayed for protein[14] and incorporation of radioactivity into protein[12] along with samples taken from the incubation medium. The incorporation of labelled amino acids into released protein was expressed as a function of protein in the fatbody[15]. For convenience the incorporation of labelled amino acid into proteins will be termed protein synthesis although the size of the amino acid pool was not determined. Because the rate of incorporation was not immediately affected by the gland homogenate, the degree of inhibition was determined by comparing the difference in incorporation of label by the control and treated fatbodies during the last 75 min of incubation. The homogenate of 1/100 glandular lobe suppressed protein synthesis by 38% (Fig. 1). A similar level of inhibition occurred whether fatbodies were taken from fifth instar larvae (5-d-old) or mature adult males. The relationship between concentration of gland extract and the level of inhibition of protein synthesis is shown in Fig. 1. This inhibition of incorporation of label followed a similar pattern in the protein of the fatbody to that of the protein released into the incubation medium. No significant difference in the amount of label in the free amino acid pool of the control and experimental fatbodies could be detected. Gel electrophoresis[16] of the medium after inhibition showed that incorporation of label into all proteins was equally affected by the gland homogenate.

Cheeseman *et al.*[19] have estimated that 0.007 gland pair equivalents are released *in vivo* in response to a short flight resulting in a 135% increase in haemolymph lipid. Because the blood volume of an adult male locust is approximately 360 μl (ref. 20), Fig. 1 shows that significant inhibition of protein synthesis occurs at concentrations of AKH likely to be found in the animal.

The inhibitory activity of the gland extract was stable to boiling for 15 min and to freezing at −12°C, although some activity was lost after both these treatments. The activity was destroyed when gland homogenates were digested with protease (Sigma) (1 mg ml^{-1} at *p*H 6.5 in 0.1 M phosphate buffer for 18 h). Electrophoresis of the homogenates in 5% polyacrylamide gels showed the activity to migrate close to the ion front. These data suggested similarities between the inhibitory factor and locust AKH which is the only hormone demonstrated in the glandular lobe of the CC so far[17]. The relationship between concentration of synthetic AKH and suppression of protein synthesis *in vitro* by adult fatbody is shown in Fig. 1. This relationship leads us to believe that the inhibitory activity of glandular lobe homogenates is due to the presence of AKH.

Mayer and Candy[18] reported that injection of CC extracts into locusts brought about mobilisation of fatbody lipids which was similar to that during flight. It is generally accepted that AKH promotes efficient flight metabolism. It is possible that the suppression of protein synthesis in the flying insect represents another example of such a metabolic switch. The inhibition of protein synthesis by AKH may be significant in circumstances other than flight. AKH is present in larval locusts in which it exerts little effect on lipid mobilisation[5] but a considerable effect on protein metabolism. It is possible that the inhibition of protein synthesis is the predominant action of AKH in larval locusts.

A transposon, Tn732, encoding gentamicin/tobramycin resistance

Marilyn E. Nugent, David H. Bone & Naomi Datta

Bacteriology Department, Royal Postgraduate Medical School, Hammersmith Hospital, London W12, UK

Gentamicin and tobramycin are important antibiotics in the treatment of hospital infections because of their activity against a wide range of bacterial genera. With their increasing use, bacteria resistant to these drugs have appeared, the resistance being frequently plasmid determined[1-4]. The resistance genes determine various enzymes that modify and inactivate the drugs[5] and there is association between particular gentamicin/tobramycin resistance genes and plasmids of particular groups[6,7], implying that acquisition of such a gene by any plasmid is a rare event[4]. We now report the identification of a transposon or 'jumping gene' encoding the gentamicin/tobramycin adenylylating enzyme, ANT(2″), on a plasmid of incompatiblity group FII (IncFII).

This plasmid, pHH1313b, confers resistance to ampicillin, tetracycline, chloramphenicol, gentamicin and tobramycin (Table 1) and was identified during a study of the spread of gentamicin/tobramycin resistant *Klebsiella* in a Toronto hospital[9]. The gentamicin/tobramycin resistance is conferred by the adenylylating enzyme ANT(2″)[7]. It is a non-conjugative plasmid, and to look for transposition of gentamicin/tobramycin resistance, it was mobilised into the *Escherichia coli* K12 *rec*A strain, PB1455 (*thr*$^-$*leu*$^-$*thi*$^-$) using the plasmid R751 (Table 1). Another IncFII plasmid, R1, conferring resistance to ampicillin, kanamycin, sulphonamide, chloramphenicol and streptomycin (Table 1) was transferred into PB1455 (pHH1313b.R751) by conjugation. To look for transposition of gentamicin/tobramycin resistance to R1 we selected for the transfer of gentamicin/tobramycin resistance into the K12 strain J62-2 (*pro*$^-$*his*$^-$*trp*$^-$*rif*^{R}). All of the gentamicin/tobramycin resistant transconjugants obtained were screened for the other resistance markers of pHH1313b, R1 and R751. Ninety per cent of them carried the resistances of pHH1313b and R751 and had resulted from the mobilisation of pHH1313b into J62-2 by R751. However, 10% carried the resistances of R1 plus gentamicin/tobramycin resistance. Some of these colonies were lysed on top of 0.7% agarose vertical slab gels using the method of Eckhardt[10] in order to show their plasmid content. In each case one plasmid of molecular weight (MW) 70×10^6 was seen (Fig. 1). Thus the transposition of gentamicin/tobramycin resistance to R1 resulted in an increase in MW of 7.5×10^6. We have designated this transposed sequence Tn732. The frequency of its transposition to R1 was 1 in 10^6 which is low, compared with other transposons, although within the reported range[11].

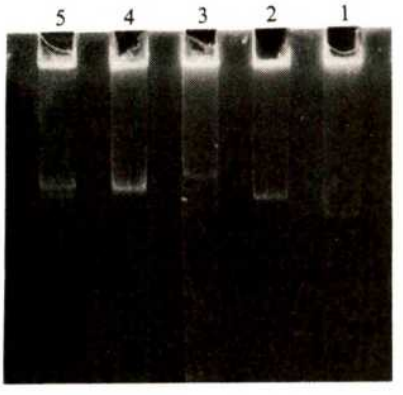

Fig. 1 Single colony lysates of R1 and R1 : Tn732. Colonies were lysed directly on top of a 0.7% agarose vertical slab gel as described by Eckhardt[10]. Standard plasmids of known MW were included. 1, R702, 46×10^6; 2, R1, 62.5×10^6; 3, RA1-1, 85×10^6; 4, R1 : Tn732, 70×10^6; 5, a colony of R1 : Tn732 + R1 lysed together in the same well. Gels were run for 6 h at a constant voltage of 170 V as described in ref. 4. MWs of standard plasmids were obtained from ref. 8.

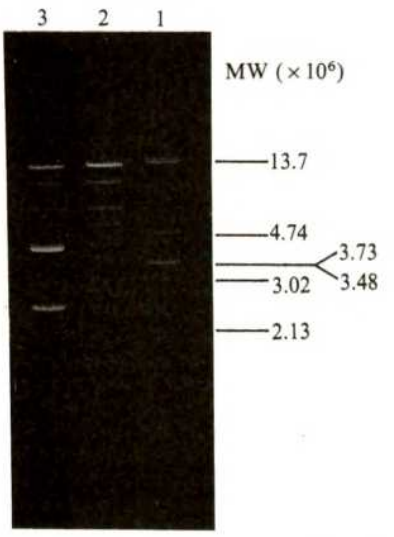

Fig. 2 *Eco*RI restriction enzyme analysis of R1 and R1 : Tn732. Purified plasmid DNA was isolated by a sarkosyl-cleared lysate method (K. Hardy, personal communication). Digestions were performed as described in ref. 4. Digested DNA was run on a 0.7% agarose horizontal submerged gel of dimension $20\times20\times0.4$ cm for 3 h at a constant current of 80 mA. 1, *Eco*RI digested λ DNA; 2, *Eco*RI digested R1 DNA; 3, *Eco*RI digested R1 : Tn732 DNA. Gels were calibrated using the known molecular weights of the λ *Eco*RI fragments[12] and the MWs of the R1 *Eco*RI fragments[13].

Purified DNA was isolated from R1 and from one of the clones of R1 : Tn732. The two plasmids were compared by digestion with the restriction enzyme *Eco*RI (Fig. 2). In this case Tn732 had inserted into R1 in such a way that the difference between R1 and R1 : Tn732 is the presence of two extra fragments with MW of 4.3×10^6 and 2.8×10^6 (Fig. 2). Further analysis of *Eco*RI digests using 2% agarose gels, which showed the smallest *Eco*RI fragments of R1 (ref. 13), confirmed that the only differences between R1 and R1 : Tn732 were the extra fragments in R1 : Tn732. It appears that Tn732 had inserted into an existing *Eco*RI site, duplicating the site and generating the extra fragments.

This is the first report of the identification of transposable gentamicin/tobramycin resistance. Transposons increase the chances of dissemination of resistance genes and it will be interesting to know how widespread Tn732 is among bacteria

Table 1 Plasmids used in this study

Plasmid	Resistances	MW	Inc group
pHH1313b	ApTcCmGmTm	62×10^6*	FII
R1	ApCmSmSuKm	62.5×10^6†	FII
R751	Tp	30×10^6†	P

Ap, ampicillin; Tc, tetracycline; Cm, chloramphenicol; Gm, gentamicin; Tm, tobramycin; Sm, streptomycin; Su, sulphonamide; Tp, trimethoprim; Km, kanamycin.

THE BARR & STROUD INTEGRATING MICRODENSITOMETER- DESIGNED TO REDUCE YOUR LABORATORY WORKLOAD

If you have a regular requirement for full quantitative cell information, it's worth checking out the Barr & Stroud GN5 Integrating Microdensitometer. With a scanning duration of only four seconds yet giving a 0.25 micron resolution, it brings speed and precision to cell preparation analysis.

The use of highest quality Leitz optics ensures reliability of results for even the smallest specimens. For histochemical and cytochemical studies, accuracy is better than ±1% over an optical density range from less than 0.1 to greater than 2.5.

Area measurement, electronic masking and narrowband illumination are just some of the other features which make this instrument a most attractive addition to your laboratory.

The GN5 Integrating Microdensitometer yields results with a speed and at a level of accuracy that far outstrips the standards that can be achieved by manual methods of study.

Designed in accordance with ergonomic principles, it's comfortable to work with too.

Start to reduce your laboratory workload by sending for full literature today. Use the journal reply system or, alternatively, contact us direct.

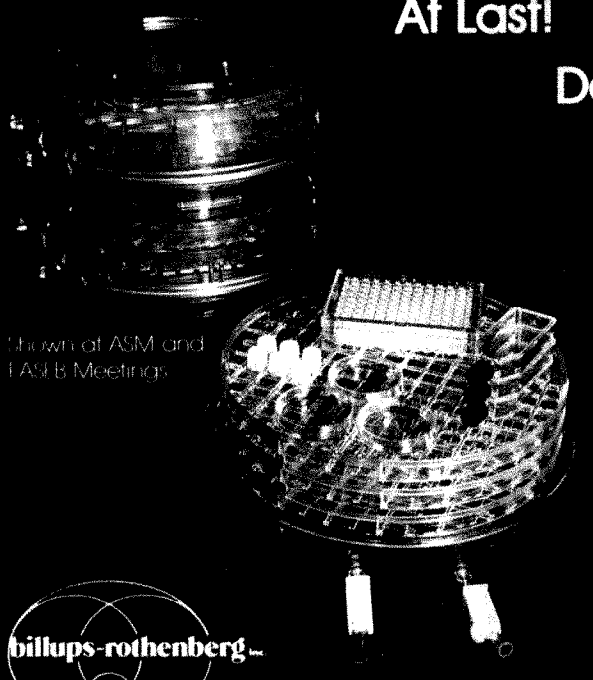
The Viking Mission and the Question of Life on Mars

This special issue of the Journal of Molecular Evolution © by Springer-Verlag 1979 brings together some 20 contributions bearing directly or indirectly on the question of life and organic compounds on Mars.

Excerpt of the *Introduction by J. Oró:*

We believe that these twenty scientific contributions, which are a direct or indirect consequence of the observations made by the Viking Mission, not only provide some of the facts concerning life and organic compounds on Mars, but will also help to clarify our understanding of the limitations and possibilities for the existence and evolution of life in the solar system:

Price of the special issue DM 130,–; US $ 72.20 plus postage and handling; 210 pages
Obtainable from your bookseller or Springer-Verlag Berlin, Heidelberg, New York



Subscription Information: *Journal of Molecular Evolution* 1980; Vol. 15 + 16 (4 issues each): DM 176,– per volume plus postage and handling
North America: US $205.20, including postage and handling.

At Last! A Reliable Incubator Under $100

Designed for Aerobic or Anaerobic Tissue Culture Experiments

Shown at ASM and FASEB Meetings

With this Modular Incubator Chamber* you no longer have to worry about the inherent variability (due to CO_2, temperature and humidity fluctuations) of present day continuous flow and anaerobic incubators.

Simply place your experiment into the sealed chamber, purge the system with the required gas mixture and set in a controlled temperature environment.

Because each chamber is an isolated system you now have the flexibility to design experiments you previously thought were impractical or too expensive.

Chamber and tray components are made from rugged, non-toxic, uv resistant polycarbonate.

Multi purpose trays conveniently hold petri dishes, test tubes, T.C. flasks, microtest plates, etc.

Chambers can be stacked and interlocked for agitation or storage.

And now for the best part. The price of the chamber with 3 trays is only $95.* To order or for further information phone or write Billups-Rothenberg, Inc., Dept. N-1, P.O. Box 977, Del Mar, CA 92014 USA (714) 755-3309.

Carboxy-terminal amino acid sequence of α-tubulin from porcine brain

Herwig Ponstingl, Melvyn Little, Erika Krauhs & Tore Kempf

Institute for Cell Research, German Cancer Research Center, D-6900 Heidelberg, FRG.

Tubulin is the main protein of microtubules, which are found in all eukaryotic cells. These structures participate in cell division, intracellular transport and secretion processes, ciliary and flagellar movement, morphogenesis and cell orientation. Tubulin is generally assumed to consist of two different chains, α and β, each of molecular weight about 55,000, which form a heterodimer in solution[1]. Recently, however, heterogeneity within each type of chain has been claimed on the basis of immunological non-identity[2], peptide mapping[3], isoelectric focusing and gel electrophoresis[4,5]. Another type of heterogeneity has been studied in more detail: a specific ligase binds one tyrosine residue to the carboxy-terminal residue of only a fraction of the tubulin α-chain[5–7]. The enzyme has been found in many tissues of various species[8,9], but the biological significance of the reaction is unknown. Elucidation of the primary structure should clarify whether a family of tubulins exists within one organism, and whether tubulin functions are regulated by post-translational modification. Furthermore, if a general principle underlies the various intracellular movements, one might expect sequence homologies between tubulin and muscle proteins. We have now established the sequence of the carboxy-terminal 78 amino acid residues in α-tubulin from porcine brain by Edman degradation of overlapping cyanogen bromide, tryptic and chymotryptic fragments. A terminal tyrosine was the only evidence for heterogeneity. The region is unusually acidic and not homologous to known proteins. Prediction of the secondary structure suggests a 'jack-in-the-box-like' structural change, dependent on the microenvironment.

We have purified tubulin from porcine brain by a modification of the methods used by Eipper[10] and by Ludueña *et al.*[1]. The 100,000g brain supernatant in 0.05 M sodium pyrophosphate buffer, pH 7.0, was incubated with 0.1 mM colchicine for 15 min at 37 °C before chromatography on DEAE-cellulose with a linear gradient of 0.1–0.3 M sodium chloride. Tubulin was identified by the fluorescence of its complex with colchicine[11]. The preparation was assayed for protein impurities by disc gel electrophoresis in the system of Yang and Criddle[12] using 8% gels. The gels were stained with Coomassie blue and scanned in a Vernon scanner. Only tubulin of more than 95% purity was processed further.

For separation of α- and β-chains the protein was reduced and alkylated with iodoacetic acid[13] and chromatographed on hydroxylapatite in 0.1% SDS with a linear gradient of 0.2–0.4 M sodium phosphate[14]. Fractions were assayed for purity by gel electrophoresis as above. Only α-chain of at least 95% purity was used for sequence determination.

The sequence of 78 residues at the carboxy terminus of tubulin α-chain is shown in Fig. 1. It must represent the terminal region because it contains the only tryptic peptide without a basic residue and the only cyanogen bromide piece devoid of a methionine-derived homoserine lactone. Furthermore, the terminal Glu corresponds to the glutamic acid previously determined to be the last amino acid in the α-chain[17].

The entire segment is devoid of proline and glutamine and has an acidic 'tail'. Residues 78–41 have a net charge of +4, are rich in alanine and in large side chains, whereas the last 40 positions have a net charge of −17, and are extremely rich in glutamic acid (40%) and glycine. It is by far the most acidic region of the α-chain and one of the most acidic sequences known.

Some heterogeneity could be expected from isoelectric focusing data. In this region of the chain, however, we found only one such case: the terminal tryptic peptide was isolated in two forms. About 85% of the material has nine Glu and one Tyr residues (composition Asp 1.88, Ser 1.08, Glu 8.80, Gly 3.99, Val 3.18, Tyr 1.07), whereas 15% shows nine Glu and two Tyr residues (Asp 2.03, Ser 1.17, Glu 8.89, Gly 4.09, Val 3.21, Tyr 1.60). The additional tyrosine is located in the C-terminal position. This corresponds to the observed post-translational binding of a tyrosine residue to the terminal glutamic acid by a tubulin-specific ligase[6]. Only about 45% of α-chain molecules can be tyrosylated[8]. This may be due to the presence of two different α-chains, although the C-terminal part has a homogeneous sequence. A cyanogen bromide fragment, comprising 26 residues almost identical to our C-terminal CNBr peptide, was isolated by Lu and Elzinga[18] from calf brain α-tubulin. These authors found one more glutamic acid at the C-terminus and discuss the possibility of a heterogeneity of Gly-Glu-Glu-Glu or Gly-Glu-Glu-Tyr. In our source, amino acid analyses of the two forms of tryptic peptide clearly show that tyrosine is added to a peptide of otherwise identical composition. Two other peptides,

Fig. 1 Amino acid sequence of the C-terminal region in α-tubulin. Residues are numbered starting at the carboxyl terminus. Batches of about 200 mg of α-chain were cleaved with trypsin, chymotrypsin and cyanogen bromide, respectively. Enzymatic digests were fractionated on Dowex 1X2 in volatile buffers and re-chromatographed on phosphocellulose or cellulose thin layer. Larger enzymatic fragments and the cyanogen bromide cleavage products were separated on columns of Sephadex G-50 Superfine (190 × 1.5 cm) in 8 M urea containing 0.1 M ammonium bicarbonate, and desalted on Sephadex G-10. Amino acid analyses, enzymatic digestions and sequence analyses by automated and manual methods were carried out as described previously[15], except that HPLC was used instead of gas chromatography for the identification of degraded phenylthiohydantoins[16] and assignment of side chain amides.

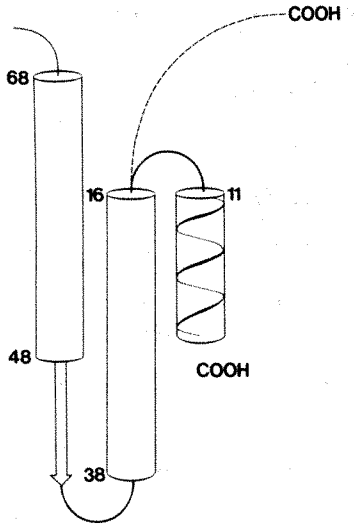

Fig. 2 Predicted secondary structure of the C-terminal region in α-tubulin. Residues 68–48, 38–16 and 11–1 are helical, position 47–42 represents a strand of a β-sheet and residues 41–38 and 15–12 are reverse turns. A jack-in-the-box transition of the labile terminal α-helix to a more extended structure is proposed to take place. The stability of each configuration depends on the microenvironment because of the many glutamic acid side chains, which may repel each other if fully dissociated. A C-terminal tyrosine increases the lability of an α-helix.

characterised but not ordered by Lu and Elzinga[18], match residues 62–53 and 37–26 in our sequence.

We could not detect any significant homologies to other known protein sequences, including bacterial flagellin, nucleotide and calcium binding proteins, actin and other muscle proteins.

The procedure of Chou and Fasman[19] was used to predict the secondary structure of this region (Fig. 2). It yields an α-helix at residues 68–48 (helix potential $P_\alpha = 1.20$ compared with potential for a β-sheet $P_\beta = 0.96$), a strand of a β-sheet at residues 47–42 ($P_\alpha = 1.00$, $P_\beta = 1.42$) which is connected by a reverse turn at positions 41–38 (turn potential $P_t = 1.12$, $P_\alpha = 1.03$, $P_\beta = 0.73$) to a second helix at positions 38–16 ($P_\alpha = 1.26$, $P_\beta = 0.69$) followed by another reverse turn at positions 15–12 ($P_t = 1.24$, $P_\alpha = 0.85$, $P_\beta = 0.93$). This clearcut situation becomes increasingly labile towards the C-terminus. Residues 11–1 have a helix potential ($P_\alpha = 1.21$, $P_\beta = 0.59$), but the many carboxyl groups of the glutamic acid residues, if fully dissociated, may repel each other, as polyglutamic acid loses its helical conformation at about *p*H 5.5 and turns into a random coil at higher *p*H[20]. Furthermore, the interspersed glycines create an underlying potential for turns and the helix potential is decreased by the addition of tyrosine.

We propose a jack-in-the-box-like structural change of the C-terminal residues from a helix to a more extended structure, depending on the microenvironment, for example, a tubulin dimer in solution or incorporated in a microtubule. Experimental support for two different states of the C-terminus of the α-chain comes from the finding by Thompson *et al.*[21] that the post-translationally added tyrosine is exchanged much more rapidly in intact microtubules than in the soluble dimer.

This work was supported by the Deutsche Forschungsgemeinschaft. We thank J. Kretschmer, C. Orlando, C. Sieg and H. Thierberger for technical assistance and G. Osterburg for programming the method of secondary structure prediction.

Stomatal conductance correlates with photosynthetic capacity

S. C. Wong, I. R. Cowan & G. D. Farquhar

Department of Environmental Biology, Research School of Biological Sciences, Australian National University PO Box 475, Canberra City, A.C.T. 2601, Australia

Previous studies on the physiology of stomata in higher plants suggest that stomata influence the rate of CO_2 fixation in leaf mesophyll tissue. We believe that an equally important stomatal function has not been fully recognised; that stomatal aperture is determined by the capacity of the mesophyll tissue to fix carbon. We altered the capacity of leaves to fix carbon by various means, and found invariably that the diffusive conductance of the epidermis to CO_2 transfer, g, (which mainly depends on the number and dimensions of the stomata) changes in nearly the same proportion as the rate of assimilation of CO_2. Thus, the intercellular concentration of CO_2 (c_i), calculated as $c_i = c_a - A/g$ (where c_a is ambient concentration of CO_2, A is assimilation rate of CO_2), tends to remain constant providing c_a is kept constant. We used routine techniques[1] to measure A and estimate g in leaves placed singly in chambers. Conductance takes account of CO_2 transfer through both stomata and leaf boundary layer, the conductance of the latter being 0.5 mol m^{-2} s^{-1}.

Figure 1 shows the effects of applications of 3-(3,4-dichlorophenyl)1,1-dimethylurea (DCMU), an inhibitor of photosynthetic electron transport, and abscisic acid (ABA), a hormone which decreases stomatal aperture, on assimilation rate and leaf conductance in cotton plants. When DCMU was applied, A and g declined in the same proportion, the slope of the line implying that c_i is constant at 220 μl l^{-1}. When ABA was applied, a curvilinear relationship between A and g was obtained. Its shape is consistent with the suppostion that A declined as a result of decrease in intercellular CO_2 concentration brought about by partial closure of the stomata. A similar contrast is shown in Fig. 2. The four points lying almost on a straight line represent A and g in *Eucalyptus pauciflora* at four different irradiances. The line does not extend through the origin and thus c_i was not quite constant in this instance. However, the change was only slight; c_i decreased from 257 to 243 μl l^{-1} with increasing irradiance. The curves in Fig. 2 were computed from measurements of the influence of c_i on A (c_i having been varied by varying c_a) and use of the equation above with c_a taken as 320 μl l^{-1}. They are estimates of the relationships between A and g that would be manifest at each irradiance if g were directly perturbed, as was done in the cotton plants by use of ABA. Figure 3 shows rate of assimilation and leaf conductance in plants of *Zea mays*. Differences between plants were due to differing levels of nitrogen nutrition, phosphorus nutrition and water stress. The points approximate a straight line passing through the origin the slope of which corresponds to $c_i = 100$ μl l^{-1}. The continuous curves show how a direct perturbation of g would have influenced A in four particular plants having differing levels of nitrogen nutrition; they were computed in the same manner as those in Fig. 2.

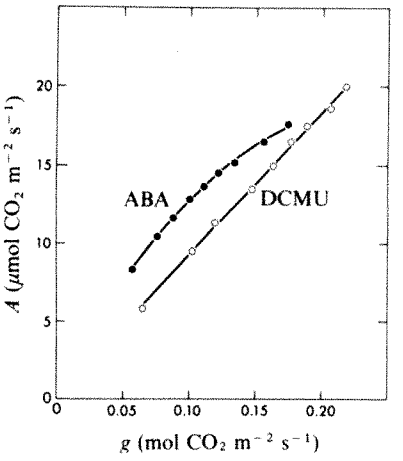

Fig. 1 Relationship between A and g in *Gossypium hirustum* as influenced by ABA, and DCMU. ABA (1×10^{-6} M) and DCMU (5×10^{-6} M) were applied in the water taken up by the detached, transpiring leaves. The different points represent differing periods of accumulation. Ambient CO_2 concentration, 320 μl l^{-1}, leaf temperature, 30 °C; leaf to air vapour pressure difference, 20 mbar.

The treatments which yield the straight line relationships in Figs 1–3 all influence the mechanisms of photosynthesis at the cellular level. The inhibitor DCMU reduces photosynthetic electron transport; increase in irradiance increases the potential rate of electron transport; nitrogen nutrition influences the amounts of chlorophyll and the activities of ribulose 1-5-bisphosphate (RuBP) carboxylase and phosphoenol pyruvate (PEP) carboxylase; and phosphorus availability affects photophosphorylation and the development of chloroplast lamellae[2]. Also, water stress, imposed slowly, caused a decline in both A and g such that intercellular CO_2 concentration remained essentially constant (Fig. 3), the implication being that stress directly affects photosynthetic carbon fixation. Diminution in the amount of soil water resulted in a 40% decrease in A and g but c_i remained constant at 100 μl l^{-1}. There are many other reports of observations of gas exchange which demonstrate the same proportional relationship between g and A; for example in *Phaseolus vulgaris*[3,4] and *Oryza sativa* leaves of various ages[5], in *P. vulgaris* and *Zea mays* plants grown at different irradiances during ontogeny[6], in *O. sativa* plants given different amounts of nitrogen[7], in leaves of *P. vulgaris*, *Z. mays* and *Imperata cylindrica* subjected to different irradiances[4], and in *Z. mays*[8], *Sorghum bicolor*[9] and *Eucalyptus socialis* seedlings[10] subjected to increasing water stress.

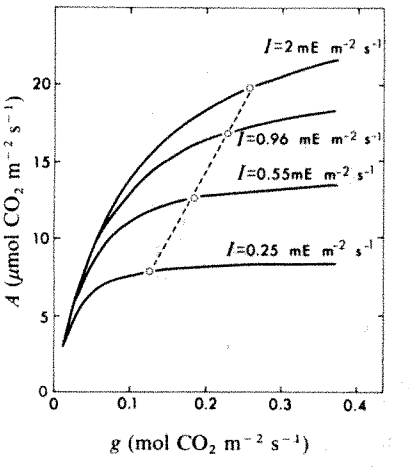

Fig. 2 Relationship between A and g in *Eucalyptus pauciflora*. A and g at four irradiances, I, during measurement with ambient CO_2 concentration = 320 μl l^{-1}, leaf temperature = 25 °C, leaf to air vapour pressure difference = 18 mbar. Curves represent the variation of A that would occur if g were independently perturbed; they are computed from measurements of the responses of A to changes in intercellular CO_2 concentration.

In eight C_3 plant species c_i was maintained at about 220 μl l^{-1} and in four C_4 species it was maintained at about 100 μl l^{-1}. These observations were made at an ambient CO_2 concentration of 320 μl l^{-1}, with a vapour pressure deficit of 20 mbar and with leaf temperatures near the optima for photosynthesis. The influence of leaf temperature on the relationship between g and A differed from that of the other factors so far considered. In general it was such that c_i increased at both low and high temperatures.

Linear relationships between A and g do not necessarily indicate that stomata control the rate of assimilation. When the source of variation was a treatment which directly affected stomata only, as with the application of ABA[11], the resultant variation in rate of assimilation (caused by the influence of conductance on c_i) was different (Fig. 1). Such curves also occur as a result of variation in ambient humidity[12,13] and rapid imposition of water stress[14,15].

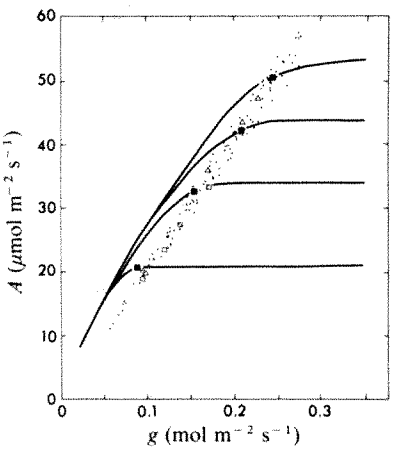

Fig. 3 Relationships between A and g in *Zea mays*, measured at irradiance of 2 mE m^{-2} s^{-1}, ambient CO_2 concentration, 320 μl l^{-1}, leaf temperature, 30 °C and leaf-air vapour pressure difference, 20 mbar: ·, plants having received different amounts of nitrogen and phosphorus nutrients; □, different stages in the recovery of a nitrogen deficient plant after nitrogen nutrient was given; △, different stages in the development of water stress in a plant from which water was withheld. The continuous curves represent the variations in A that would occur in four particular plants having differing photosynthesis capacities due to differing levels of nitrogen nutrient if g were independently perturbed. ■ Indicates actual values of A and g corresponding to c_a of 320 μl l^{-1}.

What, then, are the mechanisms responsible for the linear relationships in Figs 1–3? It is possible that stomata respond directly and independently to factors that influence photosynthetic carbon fixation. It is known that DCMU[16,17], irradiance[16,17] and water potential[16] influence stomatal aperture in isolated epidermal strips. Perhaps nitrogen and phosphorus also do so. Nevertheless, we think that the close correlation between A and g in a variety of conditions, including those associated with development suggests that there is a direct link between the two. The discovery[18] that the abaxial and adaxial patterns of stomatal response to light in a periclinal chimaera—between *Solanum pennellii* epidermis and *Lycopersicon esculentum* mesophyll—were almost identical to those in *L. esculentum*, and quite unlike those in *S. pennellii*, supports this notion.

A likely hypothesis is that stomata respond to changes in c_i so as to maintain it at a constant level by negative feedback. Raschke[16] and Raschke *et al.*[19] have attributed the variation in conductance with variation in irradiance to this mechanism. If the feedback loop maintains c_i constant at a preset value when irradiance is changed, then c_i should also remain constant when ambient CO_2 concentration is changed. Figure 4 illustrates a test of this last proposition. It shows that $\partial c_i/\partial c_a$ is about 0.7 in

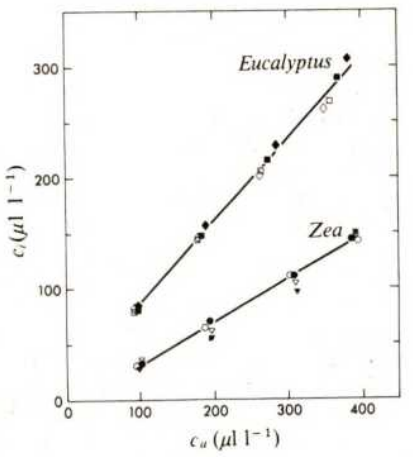

Fig. 4 Relationship of c_i to c_a, in *Eucalyptus pauciflora* at four irradiances during measurement: ◆, 0.25 mE m^{-2} s^{-1}; ■, 0.55 mE m^{-2} s^{-1}; □, 0.96 mE m^{-2} s^{-1}; ◇, 2.0 mE m^{-2} s^{-1}; and in *Zea mays* grown at four nitrogen levels. The *E. pauciflora* plant is that used to obtain the data shown in Fig. 2, and the *Z. mays* plants are those used to obtain the four continuous curves in Fig. 3.

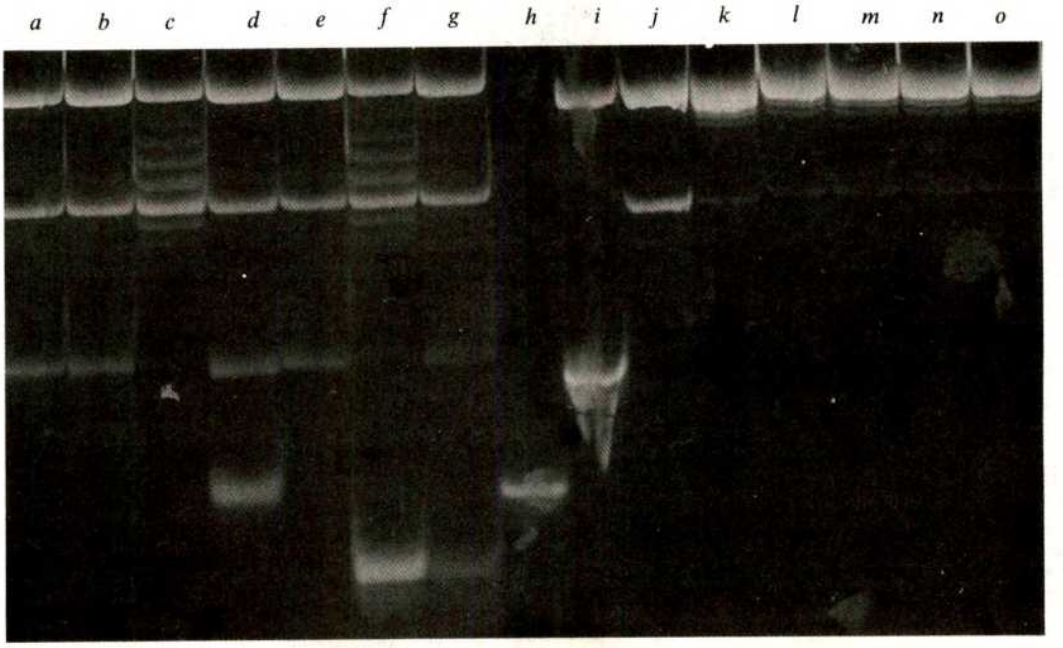
Eucalyptus pauciflora and 0.4 in *Zea mays*. Apart from a report[4] concerning *Zea mays* at high c_a, we know of no instance when the coefficient has been found to be near zero[11]. Therefore negative feedback cannot entirely account for the near constancy of c_i when A is perturbed[1].

We consider that our evidence suggests an additional mechanism: that the stomata respond to another metabolite of photosynthesis in the leaf mesophyll tissue. There are several metabolites (such as ATP, NADPH and ribulose bisphosphate), the concentrations of which partially determine the capacity of the photosynthetic system to fix carbon, but decrease with an increase in the rate of carboxylation associated with an increase in intercellular CO_2 concentration. Their concentrations vary in a complex way with temperature. Our observations would be explained if stomatal aperture were related to the concentration of one of these compounds. This would be consistent with the tendency for stomata to close when the ambient concentration of CO_2 is increased. The suggestion also agrees with evidence of metabolite transport between mesophyll tissue and guard cells[20].



The extent to which stomatal responses modulate the rate of transpiration has been emphasised in the literature. However, it is clear that stomatal aperture is a compromise between the needs to conserve water and to maintain the rate of assimilation at a level dependent on the intrinsic capacity of the leaf mesophyll tissue to fix carbon. Our evidence indicates how closely conductance is influenced by that capacity and is relevant to theories of optimality in the regulation of gas exchange[21–23].

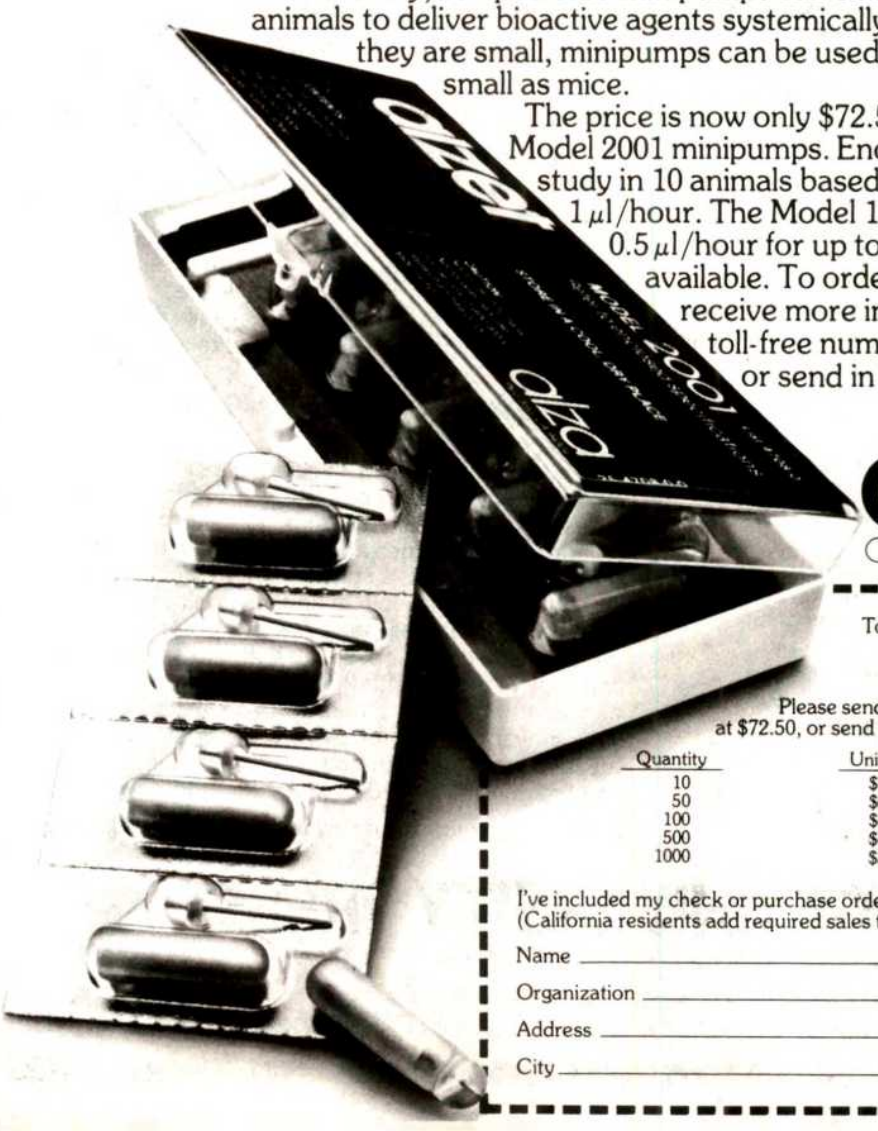
Erratum

In the article 'Single strands induce recA protein to unwind duplex DNA for homologous pairing' by R. P. Cunningham *et al. Nature* **281,** 191–195, Fig 4 was reproduced such that some of the bands were lost. It is shown in a different form below.



HIGH PRECISION. LOW PRICE.

ALZET® minipumps now give you 8 days of precise, round-the-clock drug delivery for only $7.25, or less. And, with a wider range of solvent compatibility, you can deliver some previously difficult-to-solubilize agents.

These tiny, self-powered minipumps can be implanted in laboratory animals to deliver bioactive agents systemically or locally. And since they are small, minipumps can be used easily in animals as small as mice.

The price is now only $72.50 for a 10-pack of Model 2001 minipumps. Enough for a week-long study in 10 animals based on a delivery rate of 1 μl/hour. The Model 1702, which delivers 0.5 μl/hour for up to two weeks, is also available. To order minipumps, or to receive more information, call our toll-free number: 800/227-9953, or send in the coupon below.

A Guide to Identifying and Classifying Yeasts

J. A. BARNETT, R. W. PAYNE and D. YARROW

This reference work is designed for those laboratory workers who are not specialist yeast taxonomists, but need to identify yeasts or require specialised information about them. The book includes a comprehensive table of yeast characteristics, lists of tests and an up-to-date classification of yeasts that will enable the reader to identify any yeast with the minimum of difficulty.

Phase contrast micrographs of sulphate-reducing bacteria – *The Sulphate-Reducing Bacteria*

The Sulphate-Reducing Bacteria

JOHN R. POSTGATE

This monograph brings together all the currently available information on the unusual and little studied group of the sulphate-reducing bacteria. These microbes are difficult to work with and may be considered harmful, though not pathogenic, because they are agents of pollution, corrosion and spoilage of food. However, in some respects they are beneficial because they contribute to the world's resources. In view of the increasing importance of these bacteria this monograph will interest students, research workers and professionals in microbiology, biochemical engineering and corrosion technology.

Simple Quantum Physics

P. V. LANDSHOFF and A. J. F. METHERELL

Based on lecture courses given to students of mathematics and physics in Cambridge, this book provides a straightforward introduction to quantum theory and its applications. The discussion is kept on as simple a level as possible, and there is a set of problems at the end of each chapter with hints and solutions provided. An ideal textbook for students of mathematics, physics and engineering.

Mechanisms of Hormone Action

Edited by C. R. AUSTIN and R. V. SHORT

This is the seventh in a series of eight books concerned with different aspects of reproduction in mammals. This volume deals with the isolation and characteristics of hypothalamic releasing hormones and describes how these hormones act on the pituitary gland and cause it to release hormones that stimulate the gonads to produce steroids. This simple and readable book is ideal for undergraduates in the biological and medical sciences.

Hard covers £12.00 net

Reproduction in Mammals 7

The Physiology of Thirst and Sodium Appetite

J. T. FITZSIMONS

Dr Fitzsimons has written a comprehensive and critical account of the physiology of thirst and sodium appetite that will be of interest to teachers and research workers in physiology, neurobiology, endocrinology, experimental psychology and clinical medicine. This monograph covers all aspects of the field and pays particular attention to the mechanisms and significance of angiotensin-induced drinking. Disorders of thirst and sodium appetite and their possible connection with hypertension are also considered.

Sources of Gravitational Radiation

Edited by LARRY L. SMARR

In this volume the most active and distinguished researchers in the field present a timely survey of dynamical general relativity with accounts both of the theoretical foundations of dynamical relativity and of current research which is now at a crossroads. An essential source book for all those involved in gravitational physics and related fields.

£12.50 net

Biology of Cartilage Cells

R. A. STOCKWELL

This book provides a critical analysis of the mechanical properties of cartilage, a field that has aroused a lot of interest in recent years, and emphasises the importance of the cell in the biology of cartilage. There is a comprehensive account of the fine structure, metabolism and environment of the cartilage cells and of their interaction with matrix molecules and hormones. The author also discusses cartilage cell differentiation and the growth, degeneration and calcification of cartilage. A valuable monograph for advanced students and research workers in anatomy, biomechanics, embryology, orthopaedics and rheumatology.

Adapt or be damned

Eric Ashby

Uncertain Futures: Challenges for Decision-Makers. By R.U. Ayres. Pp.429. (Wiley-Interscience: New York and Chichester, UK, 1979.) £13.

To call futures 'uncertain' is an understatement. All that can be said with certainty about the future is that publishers still welcome books about it. Good luck to the publishers, for these books keep the debate going, and that is important. Dr Ayres makes useful contributions to this debate, though in style and content the book is in places exasperating. His contributions to the debate are that he gives priority to social and political issues and that he writes from practical experience as an industrial consultant whose living depends on the common sense of the judgements he makes; so his essay is comparatively free from the irresponsibilities of academic utopians and doomsters.

The preface is excellent. To forecast the future, Dr Ayres says, one has to examine not only technological issues, "but the trends in the culture — in society's political and social life, in . . . its people's attitudes, beliefs, and customs". Time after time, "it turns out to be social, political, ideological, legal, economic, and religious issues that stand in the way of technological solutions to human problems". He makes the distinction between projections — contingent statements which are valid provided all the 'if' clauses are clear — and predictions of what *will* happen in the future, most of which, he says, "are either disreputable or ambiguous". And, as Dr Ayres' examples show, most projections, though valid, are so weakened by the 'ifs' that they are precious little use to decision-makers. He backs up his argument with nice examples: thus IBM and Kodak lacked the foresight to invest in the infant technology of xerography, and a distinguished astronomer royal is reported to have said, one year before Sputnik I went up, that "space travel is utter bilge".

Dr Ayres' approach to the practice of forecasting is sober and systematic. First, the forecaster himself must be scrutinised. Is he a conservative who sees change as incremental projections from the present? Or a radical who sees change as cataclysmic discontinuities with the present? Does he create scenarios using as a tool a computer or his imagination? Is his approach clinical and objective or does he speak as a committed advocate? What is his implicit theory of history? Does he believe that leaders really lead? Or do they simply articulate what 'society' believes? He makes the important point to which mathematicians are now trying to apply catastrophe theory: namely that human institutions do not adjust to small pressures. The pressures build up — as the earth-stresses do before an earthquake — until a critical point is reached and there is an explosion; it happened in Lebanon, in Ulster, in the Southern States of America, in Rhodesia; and it is likely to happen over the energy shortage in the United States and the food shortage in India. (There is a wry similarity between the gas-guzzling Cadillac in America and the 100 million or so sacred cows in India: the one wasting oil resources, the other wasting food resources; the one a symbol of the religion of materialism, the other a symbol of an ancient oriental religion.)

After this admirable introduction, the book becomes disappointing. Dr Ayres makes a systematic appraisal of the present state of Mankind (he calls it 'measures of man'); man's values, his international relations, his prospects judged from the present levels of population and economics, his technology and the way it seems to be going, and the resources left in the world (and from the Sun) to carry Mankind into the next millennium. He uses familiar examples and draws on secondary sources (and some of them not very expert sources at that). To judge him by his own criteria for scrutiny, he is an incrementalist with misgivings about the prospects for incrementalism; a forecaster who prefers to use imagination rather than to rely on quantitative data; an analyst who tries hard to follow his own recipe (forecasters must be "indifferent to outcomes") but whose personal convictions keep breaking in. The bulk of the book records Dr Ayres' views on these 'measures of man' supported by telling anecdotes and some rather sketchy data. This is no bad thing; there are plenty of data to be found elsewhere, but the book has to be judged on the originality of its reflections rather than the comprehensiveness of its information.

I think it would be a fair summary of Dr Ayres' views to say that they are an articulation of what in Britain might be called sound CBI (Confederation of British Industry) doctrine. He has the courage to say some unpalatable things. He is apprehensive about the future of liberal democracies and he holds out little hope that Britain's brand of 'soft socialism' which stresses equity and freedom at the cost of efficiency, will even be able to preseve equity and freedom in the long run. He makes a list of wealth-creating values (motivation, positive attitude to work, integrity and personal honour, concern about the future) and describes how these are being eroded. (He might have added loyalty to the firm, to the institution, to the employer, for the erosion of these loyalties is the most obvious national danger.) He has some robust down-to-earth things to say about some of the current panaceas we talk about. Plans for rural development, for example, he thinks are impracticable, for the infrastructure necessary must be created by an urbanised society; and, with the prospect that transport will become more difficult as the oil shortage bites, there may be a revival of urban living. Among the attitudes which contribute to the growing malaise in western civilisation Dr Ayres selects two for special treatment: one is the resistance to innovation exemplified by a wide variety of practices, from the 'catastrophic' regulations which inhibit the production of new pharmaceutical drugs, to the attitude of some trade unions which (as he bluntly puts it) is to "increase the number of man-hours required to produce a unit of output, *at no decrease in wages*, as a device to create even more unnecessary jobs". The other attitude which Ayres criticises is the proliferation of what he calls "parasitic professions". Lawyers, in particular, get his goat: "the most parasitic single group in the United States . . . a unique ability to create demand for their own unproductive services". Health services, battening on Blue Cross, come in for similar, though milder, criticism. He challenges the medical 'ethics' which prevents doctors from competing by offering definite services for fixed prices, and he thinks fewer resources ought to be spent on the unproductive practice of keeping old people alive who suffer from degenerative diseases. Education is another social activity which, in Dr Ayres' opinion, is failing to equip the next generation to cope with its uncertain future. There is, he believes, a decline in quality of education due in part to unionisation among teachers ("the organization of effective teachers' unions has tended to reduce the average level of performance by the teachers . . ."), in part to time wasted looking at TV, and in part due to the use by children

of minicalculators.

When Dr Ayres talks about technology he is on firm ground, but his knowledge of economics and political science unfortunately does not match his admirable determination to give these subjects a higher priority than technology as determinants of the future. However, towards the end of the book, in the last 75 pages, he no longer comments on familiar facts; instead he gives free rein to his imagination. He describes, in the form of fictitious brief press extracts, the way in which a world energy crisis might develop in the west, or a food crisis in the Third World. As a scenario for the possible political response to an oil shortage between 1981 and 1985, I found the 18 pages of 'press cuttings' far more convincing than any sophisticated computer print-out. Ayres cites precedents from past history for some of his speculations about future history, and he presents the reader with a spine-chilling but quite credible series of social reactions which might follow another embargo of oil from the Middle East.

Forecasters, writes Dr Ayres in his preface, "must be independent-minded and indifferent to outcomes". He may have started to write this book as a true-blue forecaster. He ends the book as an advocate. Perhaps that is the moral to be got from the book: that the intervening chapters dispel indifference. It is as well they should, for what emerges from this book, despite its superficialities and its flimsy supporting evidence, is not superficial at all. It is that democratic institutions, "never deeply rooted in most countries, have already proved to be pretty much incapable of grappling with problems for which all the solutions are painful". This, in my view, is a more imminent and serious danger than the danger of nuclear war. And an insidious danger, too, for there is no external enemy to be defeated: the enemy is within and invisible. President Carter asked the American people to regard the energy crisis as the "moral equivalent of war". But this is to ask a nation to adapt itself *in anticipation* of an environmental change, not — as happens with organisms other than man — as a *response* to the change after it has occurred. The American people have not responded. The sixty four dollar question is: will communities of people respond in anticipation in a way that communities of animals would not? We may not have to wait long now for an answer. □

Lord Ashby is Chancellor of the Queen's University, Belfast, and Fellow of Clare College, Cambridge, UK.

Perceptual phenomena

Handbook of Sensory Physiology. Vol. VIII: *Perception*. Edited by R. Held, H.W. Leibowitz and H. L. Teuber. (Springer: Berlin, Heidelberg and New York, 1978.) DM240; $120.

OUR knowledge of perception has advanced in bursts. The mid-nineteenth century saw the inauguration of psychophysics, the doctrine of specific nerve energies, the foundation of colour vision, the discovery of the horopter, and the remarkable insights of Helmholtz. Between 1912 and the early 1930s, the discoveries of the Gestalt psychologists posed a whole new set of problems.

After a period of comparative quiescence, the modern era began in the mid-1950s. Since then, thanks to the development of many new techniques and the ingenious refinement of old ones, a wealth of new phenomena has been uncovered. The use of microelectrodes to record from single cells has revealed much about the amazingly systematic wiring that underlies the early stages of visual processing, and has made it possible to explain at least some psychophysical results in terms of known neurophysiological mechanisms. Thus, the dispute between Helmholtz and Hering about whether colour vision was achieved by a three colour system or by two pairs of opponent colours has been resolved: in the retina there are three different cone pigments, but more centrally hue is recoded into two mechanisms each based on opponent colours. Many other psychophysical phenomena, for example, those connected with visual acuity, stereoscopic vision and the perception of motion, also fit in with recent physiological findings, though their detailed interpretation is often still in dispute. We are, for example, still uncertain of the exact physiological correlates of the after-effects of prolonged inspection of motion or of a tilted line: some argue for a passive process of neuronal adaptation, others for a more active inhibitory mechanism.

Moreover, much recent work has served only to emphasise the extreme complexity and subtlety of perceptual mechanisms without necessarily clarifying them. In speech perception we have little idea of how phonemes are extracted, though we do know that there are no separate segments of the speech sound wave that correspond in a one-to-one fashion with individual phonemes. Despite the mass of work undertaken using new physiological and psychological techniques to investigate perception in infants and young animals, we do not understand the subtle interplay between maturation and experience. Nor is there any secure explanation of visual masking — the obliteration of one stimulus by a second presented several milliseconds later.

Perhaps even more dispiriting is the fact that many perceptual phenomena discovered long ago still await explanation: our understanding of the traditional visual illusions is no more secure today than at the end of the last century; nor do we know any more about the mechanisms that enable us to see an object as of the size it really is, despite the variations in the retinal size caused by changes in distance.

Only a man with the bravery and erudition of Hans-Lukas Teuber could have undertaken the task of editing a volume reviewing all the disparate results and theories that have emerged in recent years. He died before he had finished the job and it was left to the two co-editors whom he had co-opted to complete it. The finished product is worthy of his erudition. I can vividly recall him as he stood confronting one of his graduate students and saying in consternation, with that characteristic raise of his bushy eyebrows, "You mean you've never *heard* of Imaizikie?". The publication of Volume VIII of the *Handbook of Sensory Physiology* removes the wretched graduate student's last excuse for such ignorance. It provides a comprehensive source of references on the topics covered, but I feel it would not have met Luke Teuber's exacting standards in other ways. With the exception of his own contribution, the writing is for the most part pedestrian and fails to convey any sense of enthusiasm or excitement. Too many of the authors concentrate on listing facts or on attempting to resolve the many disagreements between recent results: they fail to place the findings they record in the context of what perception is all about. There are, of course, exceptions such as A. M. Liberman and M. Studdert-Kennedy who write on phonetic perception.

The vast number of phenomena recorded in this *Handbook* would have been easier to assimilate had more of the authors asked themselves what light the findings throw on the way in which perceptual tasks are carried out. Indeed, the one approach to the subject that is almost wholly missing from this volume is the theoretical study of precisely this question, that is, work on computational models of perception. Such research has revealed the role of the mechanisms discovered by microelectrode work: they provide a description of the retinal image that can in turn be manipulated to yield a representation of the external world.

In short, this *Handbook*, despite the solemnity of its approach, fails to make much sense of perception, and the boring parade of findings it presents is not worth the outrageous price asked by the publishers.

The Chemistry of Heterocyclic Compounds

Series Editors: **A. Weissberger** and **E.C. Taylor**

Volume 34: Thiazole and Its Derivatives Part 1

edited by **J.V. Metzger**, *University of Aix-Marseilles, France*

Contents: Properties and Reactions of Thiazole; General Synthetic Methods for Thiazole and Thiazolium Salts; Alkyl, Aryl, Aralkyl, and Related Derivatives; Thiazole Carboxylic Acids, Thiazole Carboxaldehydes, and Thiazolyl Ketones; Halo and Nitrothiazoles; Subject Index.

April 1979 — 628 pages
0471 03993 4 — (Part 1) $105.00/£50.00

Volume 34: Thiazole and Its Derivatives Part 2

edited by **J.V. Metzger**, *University of Aix-Marseilles, France*

Contents: Aminothiazoles and Their Derivatives; Mercaptothiazoles, Hydroxythiazoles and Their Derivatives; Subject Index.

August 1979 — 604 pages
0471 04126 2 — (Part 2) $106.00/£49.00

Volume 34: Thiazole and Its Derivatives Part 3

edited by **J.V. Metzger**, *University of Aix-Marseilles, France*

Contents: Mesoinic Thiazoles; Cyanine Dyes Derived from Thiazolium Salts; Selenazole and Derivatives; Indexes.

October 1979 — 422 pages
0471 04127 0 — (Part 3) $93.50/£43.00

Volume 35: Condensed Pyrazines

by **G.W.H. Cheeseman**, *University of London*
and **R.F. Cookson**, *Janssen Pharmaceutical Ltd.*

Presents an account of the preparation, properties, and uses of the more important bi- and tri- cyclic ring systems incorporating the pyrazine ring. The first eighteen chapters survey the developments in the chemistry of quinoxalines since the appearance in 1953 of a previous monograph in this series. The subsequent chapters provide the first authoritative reviews of the chemistry of such important related ring systems as the pyrrolopyrazines.

August 1979 — 848 pages
0471 38204 3 — $153.00/£70.00

Geology and Mineral Resources of South-East Asia

edited by **P. Nutalaya**, *Division of Geotechnical and Transportation Engineering, Asian Institute of Technology, Bangkok, Thailand*

A volume of original, contributed papers arising from the Third Regional Conference held in Bangkok in November 1978, and offering up-to-date information on the geology and mineral resources of the South-East Asian countries. Besides discussing regional geological problems, the volume explores methods and techniques which are used to study these problems in the context of both fundamental research and economic development.

November 1979 — 888 pages
0471 27696 0 — $75.00/£27.00

The Australian Climatic Environment

by **E. Linacre**, *Fellow, Institute of Physics, and Associate Professor of Climatology, School of Earth Sciences, Macquarie University, Sydney,*
and **J. Hobbs**, *Senior Lecturer, Department of Geography, University of New England, Armidale*

Primary focus is on Australian climates but the rest of the hemisphere is not ignored. The basic physics, chemistry and biology of the atmosphere are universal, and they are so treated in the book. The book goes from the basic universal science to the impact of climate on the human economy and health. The text is reinforced by quantitative problems and a comprehensive bibliography.

September 1979 — 364 pages
0471 02203 9 — $28.15/£11.35

World Facts and Figures

by **V. Showers**

This completely updated and expanded edition of *The World in Figures* (Wiley, 1973) uses current comparative data to make thousands of facts more meaningful and useful. It provides comparisons of physical geography (largest islands, longest rivers, deepest lakes, highest mountains etc by country) outstanding works of man (highest dams, longest bridges and railways, largest universities etc) and includes gazetteers of every nation and of 2045 important cities and tourist resorts (date of settlement, population evolution; latitude and longtitude; height above sea-level; mean and extreme temperatures and rainfall; hydrography; libraries etc).

August 1979 — 772 pages
0471 04941 7 — $25.00/£11.75

Citation Indexing: Its Theory and Application in Science, Technology, and Humanities

by **E. Garfield**, *Institute for Scientific Information*

A clear, concise treatment by the author of the Science Index. He discusses conceptual and historical views of citation indexing; design and production of a citation index; its use as a search and science-management tool; and the future of citation indexing. *(Information Science Series)*

August 1979 — 296 pages

New Titles in Environmental Toxicology

TOPICS IN ENVIRONMENTAL HEALTH

Devoted to questions of considerable contemporary significance, this series provides interdisciplinary and comprehensive coverage of the effects of chemicals and pollutants on the individual organism and environment.

Volume 3

The Biogeochemistry of Mercury in the Environment

edited by J.O. NRIAGU

1979 xiv + 706 pages US$136.50/Dfl.280.00
ISBN 0-444-80110-3

An outstanding group of international researchers present a detailed analysis of the sources, mechanisms of transport, transformations and sinks of mercury in the environment.

Volume 2

The Chemistry, Biochemistry and Biology of Cadmium

edited by M. WEBB

1979 476 pages US$ 80.50/Dfl. 120.00
ISBN 0-444-80109-X

Volume 2 in this series represents the first attempt at integrating the toxicological aspects of cadmium with the chemistry and biochemistry of the cadmium ion. As such it will be essential reading for anyone concerned with environmental, health and toxicological problems.

Toxicology and Occupational Medicine

Proceedings of the Xth Inter-American Conference on Toxicology and Occupational Medicine held in Key Biscayne, Miami, Florida, U.S.A. 22-25 October, 1978

organised by WILLIAM B. DEICHMAN

DEVELOPMENTS IN TOXICOLOGY AND ENVIRONMENTAL SCIENCE, Volume 4

1979 494 pages US$55.00/Dfl.113.00
ISBN 0-444-00288-x

An up-to-date and comprehensive survey that will be invaluable to anyone wishing to keep abreast of the latest developments in the area.

Handbook on the Toxicology of Metals

edited by LARS FRIBERG, GUNNAR F. NORDBERG *and* VELIMIR VOUK

1979 xx + 700 pages US$117.00/Dfl.240.00
ISBN 0-444-80075-1

A comprehensive handbook allowing easy access to toxicological data along with pertinent analyses of major topics in the field - promises to become a major reference source for many years to come.

Chemical Porphyria in Man

edited by J.J.T.W.A. STRIK *and* J.H. KOEMAN
1979 xiv + 236 pages US$41.50/Dfl.85.00
ISBN 0-444-80159-6

A timely analysis of the diagnosis and occurrence of hepatic porphyria in man that will be of great value to toxicologists, clinical chemists and researchers concerned with environmental health

Behavioural neurobiology handbook

Handbook of Behavioral Neurobiology. Vol.2: *Neurophsychology.* Pp.566. Edited by M.S. Gazzaniga. (Plenum: New York, 1979.) £35.

THE general public expect from academic psychologists useful, and preferably unexpected and striking, insights into the human condition. They are interested in the psychology of conscious experience rather than in the minutiae of behaviour and performance usually discussed in academic lecture theatres. It is arguable that while they remain concerned only with human performance academic psychologists can seldom be interesting and never surprising. At best they can clarify the precise nature of limitations of which we have all been aware all our lives, and they make their greatest contribution only by suggesting models for central nervous system function which explain why we have these particular limitations and not others.

In contrast neuropsychologists, who study changes in function after brain damage or central nervous system disease, have far more surprising and vivid stories to tell. Their recent discoveries concern the very texture of daily experience and sometimes offer scary glimpses into the darkness within. Their work raises questions about ourselves and our experience which could hardly have occurred to us in any other way. Until Weiskrantz's recent demonstrations it would have appeared merely a far-fetched philosophical exercise, based on an elementary semantic misconception, to enquire whether any alert and articulate human being could, deliberately on request, make accurate discriminations between patterns which he cannot *consciously* report seeing. It is also hardly likely that we should have asked, as Le Doux, Wilson and Gazzaniga do in this book, not only whether the two hemispheres of the brain have different and independent functions but also whether, when separated surgically, they may have some degree of independent conscious experience while they share, *but independently interpret in different ways,* a commonly experienced shift in emotional tone controlled by lower brain centres communicating with both independently.

This second volume of the *'Handbook of Behavioral Neurobiology'*, edited by Gazzaniga, provokes many such startling questions. It also illustrates many of the conceptual and practical difficulties which beset this fascinating field of new knowledge about ourselves.

The title *Handbook* raises expectations of a detailed comprehensive reference work. Few of the contributors seem willing to attempt this useful task. Exceptions are the chapter on aphasias by Hecaen, on the frontal lobes by Jonander and Gazzaniga, on thalamic mechanisms in language by Brown, and a useful chapter on long term consequences of central lesions by Newcombe and Ratcliff.

Only a concise chapter on assessment of cognitive deficits in brain-injured patients by Goodglass and Kaplan literally meets the promise of the book's title by providing a handy guide to a complex applied literature for novice practitioners. This chapter, inadvertently, highlights a crucial difficulty currently obstructing progress in neurophysiology. Most tests of function currently used by neurophysiologists and neurosurgeons are crude, pragmatic survivals from wards and consulting rooms fifty or a hundred years ago. They have survived because they are rapidly administered indices which have been found, by experience, to very roughly categorise particular kinds of deficit when and if they are supplemented by the (often brilliant) intuitions of clinicians who, ritualistically, still administer them. A human experimental psychologist, accustomed to constructing models for normal performance at similar tasks, is at once struck by the fact that these particular tests involve such a complex muddle of interacting performance indices that it is quite impossible to say what are the precise functional deficits in performance any of them can demonstrate. However well they may serve as *ad hoc* diagnostic tools (not too well, reading between the lines of Goodglass and Kaplan's lucid chapter) they as yet give us little insight into the fascinating changes in function which actually accompany particular brain lesions.

The obvious solution is for human, experimental psychologist, knowledgeable about specific indices of performance, to interest themselves in the problem of defining precisely how performance changes when brain lesions occur. Morris Moscovitch's chapter 17 (''Information Processing and the Cerebral Hemispheres'') is the nearest attempt to this desirable end. As we see from the bulk of this useful book even crude and conceptually muddled tests of residual function do work in practical diagnosis. The crucial question is why they work, when they work (that is precisely what are the deficits which each of them actually exposes), and whether better, more clearly understood and more efficient diagnostic procedures cannot be developed from the considerable expertise built up by human experimental psychologists. From this point of view Moscovitch's chapter is disappointing. He describes only his own work. He is not concerned with questions of diagnosis but with the relationship of abstract models of human information processing to differences in hemisphere function. This would be interesting if the experimental techniques he uses gave the results which he supposes that they do. In particular the results illustrated in Fig. 1b and Fig. 2 on pages 386-388 and Fig. 5a and b on page 389 may have a number of different interpretations other then those which he places upon them.

For me this is a very exciting book indeed. If the excitement is flawed by impatience I am sorry. But the limitations to further progress are very distressing to anyone who avidly reads chapters 1-4, 7, 9-12, 14, 15 and most particularly 17 for the *ideas.* This is a book which is a key to our current conceptualisations of what we are, and to how the thin bright film of our experience covers the complex darkness within us, out of range of our introspection but perhaps within the grasp of clever and accurate experiments. The lack of experiments is galling, but I would wish the pleasure I have had reading this book to be as widely shared as possible by other scientists of many different educations and fields.

Patrick Rabbitt

Patrick Rabbitt is Lecturer in Experimental Psychology at the University of Oxford, UK.

Permutation symmetry in chemical and physical problems

Molecular Symmetry and Spectroscopy. By P.R. Bunker. Pp. 424. (Academic: New York, 1979.) $33.

THIS volume is the first comprehensive treatment of the use of permutation symmetry in molecules, that is, in chemical and physical problems. As such, it will be widely welcomed, and fills a void which has long plagued those who had a need for this material. Fortunately, the writing in this volume is extremely lucid.

The volume begins with a clear definition of permutation operations and groups, then adds the (space) inversion operation to lead to the complete nuclear permutation inversion group (CNPI). The author next leads the reader through the more conventional application of group theory to molecules, with, however, a quite unconventional set of emphases. This reviewer feels that persons previously unfamiliar with chemical applications of group theory would have considerable difficulty with the treatment given. Fortunately, however, one may assume today (and it seems that the author has done so, although he claims the contrary) that anyone interested in the subject matter of this book has previously attained a working knowledge of molecular point groups and their use in spectroscopic problems. The emphasis in the appropriate chapters of this volume lies with the symmetry properties of the Hamiltonian and of its eigenfunctions, a much more fundamental approach than that commonly pursued. After these preliminaries are dealt with in 8 chapters the real meat of the volume follows: the definition of the molecular symmetry group on the basis of permutation and space inversion and its applications, primarily to problems of molecular spectroscopy and to non-rigid molecules.

It is to be welcomed that the author has been very careful and explicit in his definitions. Thus, the emphasis on the distinction between space and molecule fixed coordinate systems has led to a clean and unambiguous distinction of the two inversion operations, E^* and i, which have been far from clear in much of the previous literature. Similarly the very careful phrasing of the conditions of feasibility, although they may at times seem redundant, make a significant contribution to the understanding of the subject matter.

The book is extensively illustrated with well-drawn figures, essential when discussing symmetry operations and their effect. The author has attempted, and it seems successfully, to illustrate each theoretical concept he introduces immediately with appropriate examples. For further emphasis, throughout the volume he has provided problems to illustrate the principles, and then given detailed solutions.

Although this book addresses itself to a relatively restricted audience — spectroscopists, and quantum mechanicians interested in classificaion of excited states — it may be expected to rapidly become an essential tool to this audience. It is further to be hoped that the volume will help to make more scientists aware of permutation symmetry and thereby provide new insights into other phenomena.

H.H. Jaffe

H.H. Jaffe is Professor of Chemistry at the University of Cincinnati, Ohio.

Electron microscopy in chemical investigations

The Chemical Applications of Transmission Electron Microscopy. By J. R. Fryer. Pp.286. (Academic: London and New York, 1979.) £18; $38.

THE electron microscope finds application in almost all branches of science and technology. Over the years there have appeared many books describing its uses in biology, medicine, metallurgy and materials science, but we have had to wait until now for a treatment of its role in chemical research. The reasons for such a lack are not far to seek. Chemistry is rarely as interested in morphology (except in polymers) as are biology and metallurgy for differing purposes. Its problems so often involve knowledge at the atomic and molecular level, whether of structure or function. In recent years, however, the instrument has found increasing application in surface chemistry (catalysts and thin films), crystal chemistry (defects, non-stoichiometry and phase changes), solution chemistry (clay minerals, polymers) and in chemical kinetics (solid-state reactions, intercalation).

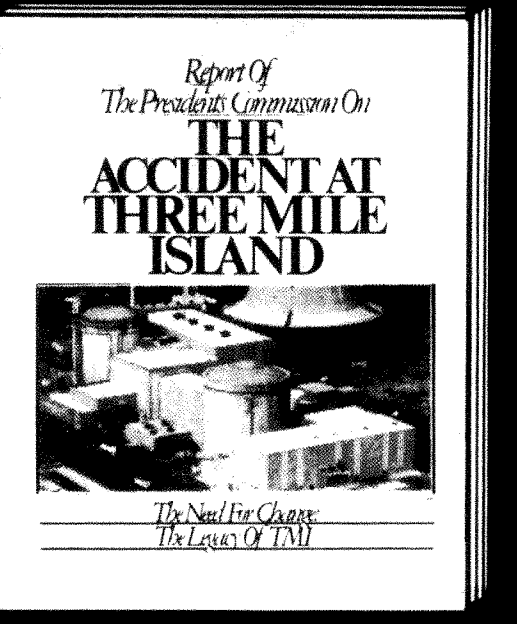
Progress in these new fields has now been brought together and critically presented by an active worker. Description of the various applications is preceded by four chapters which set out the physical principles and operational techniques. The microscope itself is dealt with briefly, fuller accounts being readily available. Greater attention is paid to the interaction of electrons with the specimen, including radiation damage, and to the mechanism of image formation and contrast. A separate chapter is devoted to the special conditions of high resolution microscopy, where phase contrast and lattice imaging are principally involved. The design of ancillary apparatus, with particular reference to special stages, and the various methods of specimen preparation, are also surveyed.

The meat of the book, however, is comprised in the later four chapters describing the use of electron microscopy in a variety of chemical investigations. Not unnaturally, greatest space is accorded to catalysts and their reactions, to the structure of crystals (especially graphite) and to molecular crystals and radiation damage to them, all subjects in which the author has made important contributions. These chapters are very fully illustrated with micrographs, not always well reproduced in my copy of the book, and line diagrams. Polymers and proteins receive less attention here; they are adequately covered elsewhere in the literature. In spite of the blurb on the cover, there is very little on the use of the electron microscope in biochemistry and materials science, but after all Dr Fryer did not set out to write an encyclopaedia of its applications.

He has done very well within this restricted plan, and the book can be highly recommended to research chemists who wish to know what this comparatively new technique could do for them. Two reservations must be stated, however. First, the references are not so completely up-to-date as could be desired. Apart from publications from his own laboratory, there are only three or four post-1975 references. The consequent omission of a great deal of recent research, especially at high resolution, is much to be regretted and is probably ascribable to delays in printing and binding, which seem to be on the increase. My second reservation concerns the price. Little more than a decade ago we could expect a well produced scientific book to cost about £1 per 100 pages. The price of this volume works out at well over six times as much, with some sacrifice in quality. Though this may be of the same order as the increase in price of a motor-car, it outstrips the rise in chemists' salaries. Sadly, few of them will be able to afford Dr Fryer's excellent monograph, but I urge librarians in spite of equally restricted resources to get it for their shelves.

V. E. Cosslett

V. E. Cosslett is Emeritus Reader in Electron Physics in the Cavendish Laboratory, University of Cambridge, UK.



IMMEDIATE DELIVERY!

The Report of the President's Commission on

THE ACCIDENT AT THREE MILE ISLAND

The Need for Change:
The Legacy of TMI

Chairman of the Commission,
John G. Kemeny

On March 28, 1979 the United States experienced the worst accident in the history of commercial nuclear power generation. The facts of this momentous event and its controversial aftermath are available NOW in The Report of the President's Commission on **THE ACCIDENT AT THREE MILE ISLAND.**

Order your copy today, and Pergamon will assure immediate, postage-paid delivery of the flexicover edition which includes full text and illustrations as well as the supplemental views by six members of the Commission.
The energy question is urgent, and the details of this report are crucial to the understanding of the decisions to be made on the current status of nuclear energy. The 200-page text contains:
• Preface • Overview • Commission Findings • Commission Recommendations • Account of the Accident

Flexicover **$15.00 £ 7.50**
Hardcover **$30.00 £15.00**

TECHNICAL STAFF ANALYSIS REPORTS
Public Health & Safety; Public's Right to Information; Technical Assessment of Events; Office of the Chief Counsel Reports — approximately 3000 pages in ten volumes, will be supplied complete or individually. Complete price **$600 £300.** Detailed brochure sent on request.

TRANSCRIPTS OF PUBLIC HEARINGS
Are also available in Microfiche or Microfilm **$200 £100**

new products: lab instrumentation

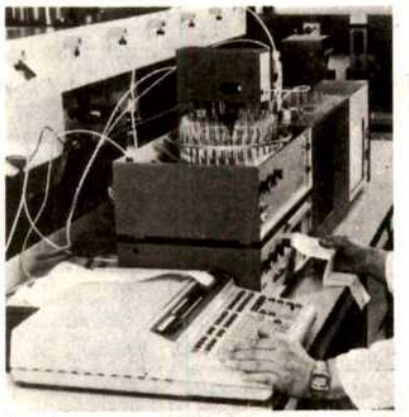
These notes, prepared from material provided by the manufacturers, are intended to give an outline of the range of products on the market. Information on further equipment can be found in the insert in the centre of the journal. For more details use the Reader Enquiry Card bound inside the journal.

A feature on water purification and analysis will appear in the 13 December issue.

HITACHI

The Hitachi Model 100-80 is a completely computerised low-cost UV-visible double-beam spectrophotometer system which achieves a high level of automation, data acquisition, data processing, data presentation, and operating functions. The Model 80 provides the analyst with the utmost flexibility in wavelength scanning while greatly expanding the capability to collect, process and report quantitative data. Standard equipment includes a built-in X/Y recorder and high-speed digital printer which provides a wide variety of operating and data functions. Standard functions are wavelength scanning, repetitive scanning, derivatives, wavelength programming, time scan, automatic baseline correction, curve correction, and automatic print.

Circle No. 118 on Reader Enquiry Card.



L-W INTERNATIONAL

For those who spend many tedious hours analysing film or other images, then computing the results, the L-W 110C digitiser is a simple, easy-to-operate system that can save many man hours. A system may include a projector, console viewer with display, X-Y coordinates, area and length, angle calculation and electronic frame count. It may also include peripheral equipment, such as printer and tape drive, or plotter or graphic display. Bit parallel or RS232C interface is standard and custom output programs may be developed to suit special requirements. Images are easily analysed, measured and data computed by use of a light-weight cursor, which moves over the screen area, and entry keyboard to microprocessor, conveniently placed at the screen's edge. Although originally designed for use with L-W International's analytical projectors, the 110C systems may be used with virtually any type projector, or hard copy may be digitised by placement on surface of the screen. Photos, maps, charts and drawings, may therefore be independently digitised or intermixed with other images for more complete information on a project.

SCHOTT-GERÄTE

Schott-Geräte GmbH of Hofheim, West Germany, introduce a table computer to its AVS automated viscosity measuring system. The new computer is intended to eliminate subjective measuring errors from automatic viscosity measurements. System design will allow the operator to make such complex calculations as determination of viscosity numbers, viscosity index and absolute viscosities, and computation of Hagenbach corrections. The new system

A table computer in use with the Schott-Geräte viscosity measuring system

utilises an HP 9825 A computer, interfaced to the BCD-coded computer output of the AVS basic unit. Programs are cassette stored, and the computer calculations are printed out. If printout on DIN-A format is required a printing unit can be added to the system. Additionally, the computer has the capability to control the AVS unit's automated sampler.

Schott-Geräte GmbH manufacture a wide range of measuring devices for laboratory and chemical purposes. In the USA Schott-Geräte are represented by Schott America Inc. of New York.

Circle No. 120 on Reader Enquiry Card.

EDT RESEARCH

The increasingly widespread application of the OAS 400 Optoacoustic Spectrometer has led to a demand for an interface through which the OAS 400 can be connected with users' computers. EDT have now announced an option on new instruments, an RS232 serial output interface for the OAS 400. This will mean that data on absorption intensity and wavelength will be available digitally through this interface for feeding into a mini- micro- or even main-frame computer for storage and/or subsequent processing. Operations such as subtraction of spectra for more precise depth profiling, differentiation and normalisation of spectra, can now be performed in a computer thus extending the usefulness of the basic instrument.

Circle No. 121 on Reader Enquiry Card.

INTERSTATE ELECTRONICS

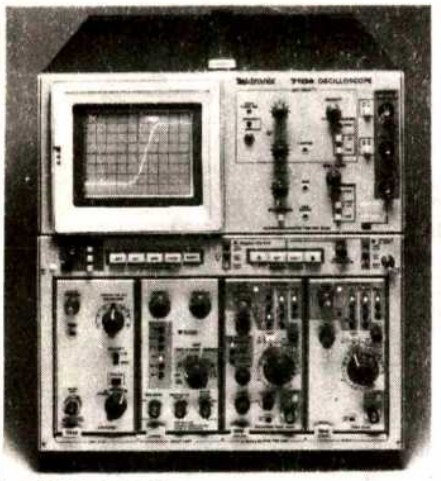
Instructions and data can be entered into most types of computer systems using the human voice via a new terminal from Interstate Electronics Corporation of Anaheim, California. The voice data entry system has a vocabulary of over 900 words, a flexible syntax structure, can be operated by several operators simulataneously and can be used with a telephone interface.

Circle No. 122 on Reader Enquiry Card.

PERKIN-ELMER

New from Perkin-Elmer are the Models 320 and 330 double-monochromator microcomputer-controlled UV-visible and UV-visible near IR spectrophotometers. Both instruments incorporate a grating-grating double monochromator. Their instrument resolution is 0.07 nm (UV-vis) and stray light is less than 0.0001% at 220 nm, giving a photometric range of 4.0 A.

Circle No. 123 on Reader Enquiry Card.



ARTEK

The new image analysis system from Artek Systems Corporation will count, measure the area and perimeter of objects, and produce a size histogram of the objects in the field in a matter of seconds. The operator can isolate objects of interest and obtain information on the object's integrated density, size, perimeter and area on any of three user-determined density levels. The system features two monitors, one for the data table and one for the display of the field of interst. Many types of cells, surfaces, histological sections, photographs and particles can be scanned via the control panel (see photograph).

Circle No. 124 on Reader Enquiry Card.

The Artek model l800 quantifier

TEKTRONIX

The Tektronix 7104 is a general purpose plug-in oscilloscope compatible with all standard 7000 series plug-ins. The bandwidth covered is a full 1 GHz, with a horizontal bandwidth of 350 MHz and a risetime of 350 ps or less.

Circle No. 125 on Reader Enquiry Card.

LTT

The ICAP 510 printer-plotter from Lignes Télégraphiques et Téléphoniques can print integration contours of chromatogram peaks. It also divides the time axis in units of peak width at half height.

Circle No. 126 on Reader Enquiry Card.

DIGITAL EQUIPMENT

MiniMINC, a new low-cost entry-level member of Digital Equipment's MINC laboratory computer systems family, retains the full computational capabilities of the larger MINC systems but houses them in a compact desk-top design. It can be used as an analysis tool in scientific, engineering and management problem solving, as well as for data reduction of laboratory information. Over 60 application programs have been written in BASIC for MiniMINC, for use in numerical, statistical, regression and financial analysis. Like MINC, MiniMINC requires no previous programming experience — a full set of 'teach-yourself' BASIC manuals has been written to guide the first time user through the various aspects of the system.

Circle No. 127 on Reader Enquiry Card.

NORTH STAR COMPUTERS

The Horizon microcomputer forms the basis of the product range from North Star Computers of Berkeley, California. The Horizon is a complete high-performance microcomputer system with integrated floppy disk memory. The North Star Z80A processor board operates at 4 MHz, and the 16K RAM memory board allows the Z80A to operate at full speed. Using minifloppy disks, the Horizon can load a 10K program in less than 2 seconds.

Circle No. 128 on Reader Enquiry Card.

CHEMLAB INSTRUMENTS

The ChemLab data processor for continuous flow applications can analyse simultaneously up to eight different channels. The processor can be fitted to any make of flow analysis equipment and is also suitable for use with flame photometers and atomic absorption spectrophotometers with an analog output. The data collection rate is one item every ¼ second from each channel, and total memory capacity is 16K. A feature of the system is peak shape analysis, and very accurate mesurement of peak height is possible.

Circle No. 129 on Reader Enquiry Card.

PHYSICAL DATA INC.

A new high-performance transient waveform recorder from Physical Data digitally captures an analog signal up to 120 MHz in a 4K 10-bit word memory, then plays it back later at variable rates over and over again in high-resolution digital and/or analog form to a computer, calculator, oscilloscope, teletype, stripchart recorder — or any combination of these for analysis. Other features of the new 523A transient waveform recorder include: adjustable pre- and post-event trigger delay and dual timebase controls. Applications include laser spectroscopy, chemical kinetics and photochemistry.

Mettler CL Data Communication System:

Data Communication is easier now,

because data is exchanged at a single data interface.

And more productive,

because data is transferred in both directions at once.

And more independent,

because subsystems are autonomous and do not depend on a central EDP system.

And more reliable,

because every instrument rechecks itself and, in case of trouble, indicates where the malfunction is.

And more.

LIQUID CHROMATOGRAPHY
for
BIOMEDICAL RESEARCH

Bioanalytical Systems offers complete liquid chromatographs specifically designed for the biomedical research community. Modular liquid chromatographs are ideal for trace determinations of biochemically significant compounds such as catecholamines, indoles, sulfhydryls, amino acids, and PTH amino acid derivatives. Systems based on reverse phase chromatography and electrochemical or uv absorption detection are available in several flexible configurations.

Using Iodine-125?

New Microvial*

- **reduced exposure**
- **reduced contamination risk**

Reduced exposure

The new packaging consists of 2 parts

- An outer plastic container incorporating a steel shield
- An inner plastic vial with a conical glass insert containing the iodide solution

Reduced contamination risk

The cap of the plastic outer container is keyed so that it can be used to unscrew the cap of the inner vial — no need to handle this vial from start to finish.

SCHOEFFEL INSTRUMENTS

A new completely automated HPLC system was recently introduced by the Schoeffel Instrument Division of Kratos. The system utilises the new KLIC 1 interactive controller to control all the system elements which include the Schoeffel Series 250 chromatograph and detector. The extent of automation in the system makes it ideal for unattended operation, even overnight. With a 1,000-step programmable memory, the KLIC 1 is capable of control over gradient, flow, wavelength, and injection programming. Additionally, with up to 32 input ports, the KLIC 1 can observe and maintain the proper action of external system elements such as fraction collectors, auto-injectors, and pumps. This two-way, interactive feedback control permits automatic inprocess 'servicing' of malfunctioning components. The interactive feedback control can, for instance, sense a bubble in the pump head and automatically step-up the flow rate to flush it out, or, observing that a fraction collector has failed to advance, repeat the advance instruction until the proper action is executed.

TRACOR NORTHERN, INC.

The Tracor Northern TN-4500 computer system is capable of true Foreground/Background operation utilising the popular RT-11 operating system. This permits routine PHA operation in the Foreground simultaneous with FORTRAN IV programming in the Background. Up to eight independent, multiport data memories support separates ADCs and MCS interfaces. Performance is further optimised through the use of a PDP-11/34 (with up to 118K memory) which provides the fast CPU necessary for efficient quantitative analysis. Dual density floppy disks provide program storage but for greater mass storage capacity.

MATEC INC

A gating modulator for use with a separate cw r.f. source in studies of nuclear resonance, ultrasonics, or any research area requiring high power, coherent r.f pulses is available from Matec, Inc. of Warwick, Rhode Island. The Matec Model 5100 is a mainframe gating modulator that produces single or double pulse sequences of high power, coherent r.f., when used with any Matec 500 Series r.f. amplifier plug-in. The circuitry keeps r.f. pulses coherent and eliminates time jitter of pulse widths and pulse separation.

BRYANS

Series BS8000 microprocessor-based data-acquisition/manipulation recorders from Bryans are designed as alternatives to conventional X-Y recorders, strip-chart recorders, oscilloscopes, microcomputers or minicomputer systems. Featuring microprocessor-based data acquisition and manipulation, the Bryans Series BS8000 can have up to eight analogue input channels, each with a differential input. Matching software packages are available for: liquid chromatography, spectroscopy, battery research, thermal gravimetric analysis, thermal mass analysis, and mechanical engineering applications. Each model in the Series BS8000 range provides the following mathematical functions, to 16-bit precision: add, subtract, multiply, divide, average any two curves (500 points each) point by point, differentiate, integrate, logarithm, reciprocal, normalise, and smooth any curve (500 points) point by point. Plotting functions are also incorporated: offset, scale, expand, compress and shift. Real-time plotting is standard, unless the input signal is too fast, in which case the signal is stored and recorded automatically by the plotter at a suitable speed. Each recorder has its own floppy disk, allowing up to 300 graphs, each of 500 points, to be stored. The data can be recalled and recorded graphically by the BS8000's own X-Y plotter. A line-printer output is also provided, along with a standard RS232C interface. A wide range of software options is available to further extend the capabilities of the BS8000.

Gallenkamp electronic calculator/clock

GALLENKAMP

A pocket-size calculator/clock has recently been added to the Gallenkamp catalogue. In addition to all the basic mathematical functions, the calculator incorporates a clock, stopwatch, alarm, time memory, countdown alarm and a calendar. Results from the calculator are shown on an eight digit LCD display. The clock, using a crystal oscillator frequency is accurate to ±15s per month and has a 12-h digital display system. Readout is given in hours, minutes, seconds and a.m./p.m. The stopwatch of the calculator has a measuring capacity of 23 h, 59 min, 59.9 s and an accuracy of 0.1s. The calendar has been programmed up to 31 December 2099. Digital readout gives the year, month, day and date. The calculator/clock is supplied with a protective case, instructions and batteries.

Savant Speed Vac Evaporator/Concentrator

NOW WITH MAGNETIC DRIVE –

Isolates the upper vacuum chamber from the lower motor drive section – for more efficient solvent evaporation.

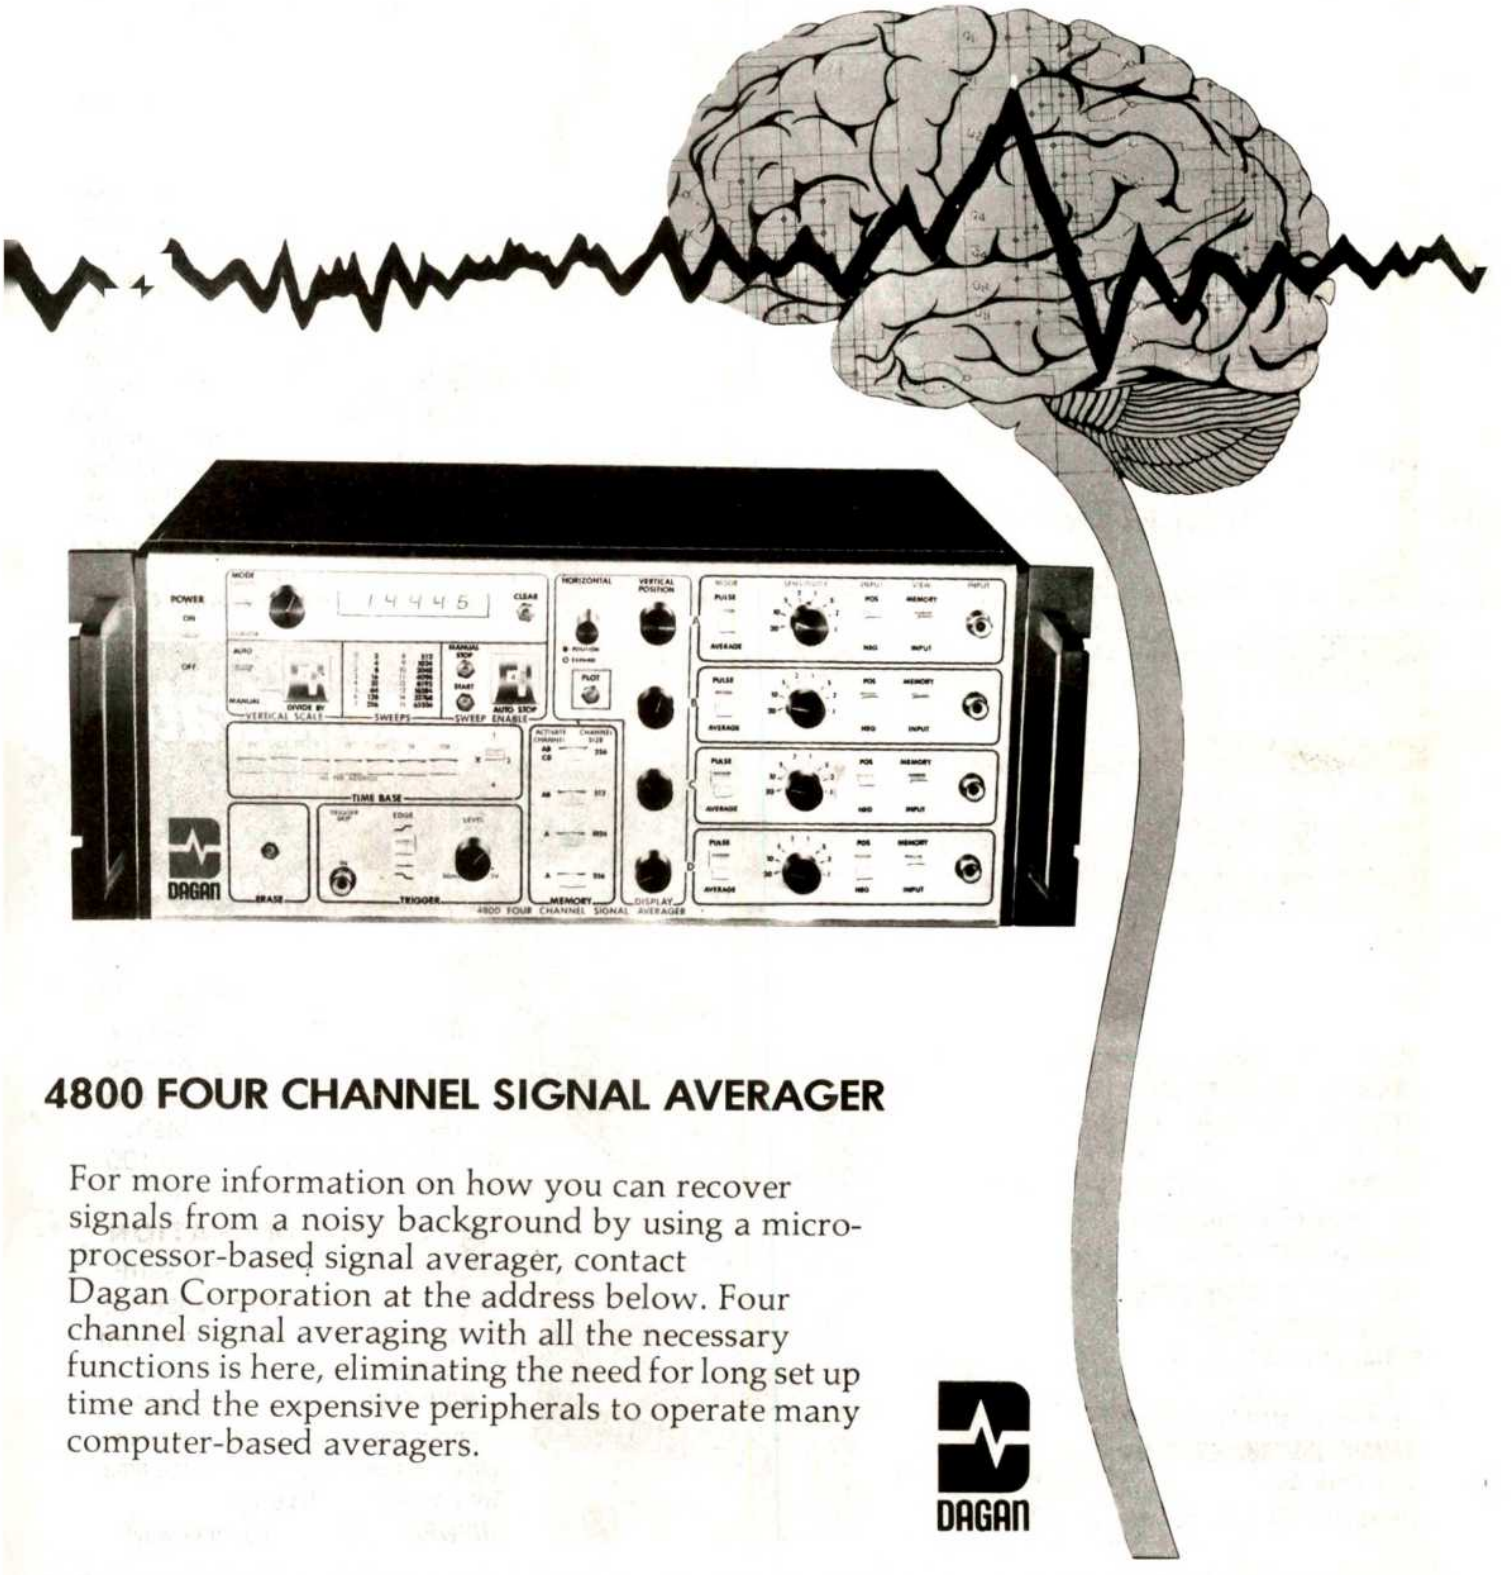
WHY — are so many research laboratories around the world using the Savant Speed Vac?

Acid Hydrolysates, Eluates, Extracts, Dialysed Solutions, Preparing Samples for GLC or HPLC in Biomedical Research, Clinical Chemistry, Radioimmunoassays, Mass Spectromotry.

Use with standard culture tubes, tapered tubes, mini vials, silylation vials.

BECAUSE —100% sample recovery . . . Evaporates and concentrates at the same time...No splash... No smearing ... 20 to 100 samples at one time.

SIMPLE OPERATION — Load 20 to 100 samples in the rotor, close lid, turn to "on" and turn vacuum pump "on".



HOW ELSE can you evaporate and concentrate small volumes of biological samples in quantity at one time with maximum efficiency?

ANSWER — There is no other way!

5 years ago we made Britain's first recording thermobalance.

It still works.

Now, here's the world's first simultaneous thermal analyser based on an electronic microbalance.

Reliability is something Stanton Redcroft build into every instrument they make. Like the 25 year old thermobalance, or the new STA 780. It's the world's first simultaneous TG/DTG/DTA with a microprocessor-based balance control, with LED display for ease of use and visual observation, and a range of interfaces for easy linkage to computers, calculators or timers.

The new STA 780 has a water-cooled furnace for quicker turn-around time and decreased drift, with a unique micro-environment within the furnace which ensures exact location of the DTA head.

The STA 780 also features a solid state low noise D.C. amplifier – giving very reproducible DTA results – and impressive versatility afforded by a 5g total capacity.

So if you're looking for a TG/DTG/DTA system that can record all three parameters at the same time and overcome some of the problems of analysing non-homogeneous samples, look at the Stanton Redcroft STA 780.

It'll still be working in the year 2003.

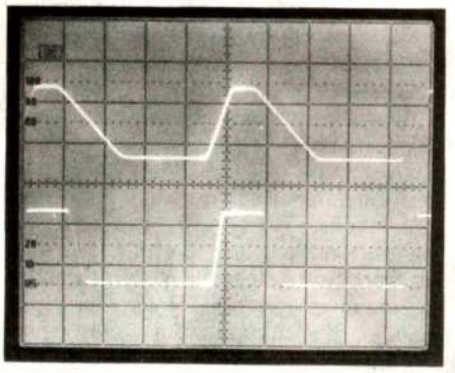
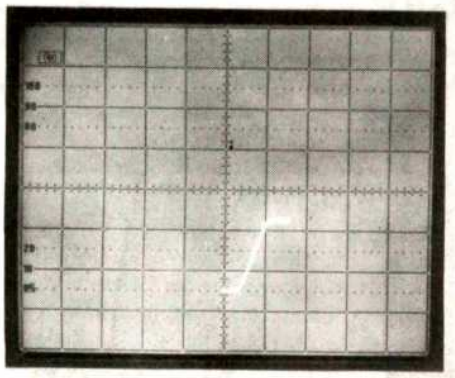
FLOATING POINT SYSTEMS

The AP-120B array processor from Floating Point Systems Inc. gives economical minicomputer systems the computational power of large scientific computers. For example, an AP-120B has been used in a PDR-11/34 system to reconstruct and analyse complex digital images. Without the AP-120B, the task would take more than 2 hours. With the AP-120B, it takes less than 30 seconds — a 240 × improvement. FPS now offer a new library of scientific subroutines for use with the array processor in image processing applications. The image processing library is composed of 11 two-dimensional filtering, convolution and fast Fourier transform (FFT) routines. The routines provide array processor users with the computational tools to filter and enhance monochrome colour, and multi-spectral scanner images. As with all FPS libraries, these routines are written in highly efficient AP assembly language, but callable from host FORTRAN. Possible





applications of the image processing library are data processing for X-ray tomography, LANDSAT and EROS satellites, high-resolution video micrography systems, and other multi-dimensional sources.

This new library is in addition to FPS's extensive application support: scientific math library, signal processing library, and advanced math library for simulation.

Vibration protection for sensitive instruments! MICRO-g™ Tables and Bench Top Units.

Low cost MICRO-g air-isolation systems can reduce building vibration at least 95 to 98%. Even low frequency (7-25 Hz) vibrations that conventional static systems can't handle. The self-leveling top surface is supported on ultra-sensitive air-pistons that adjust automatically to changing loads. Performance is guaranteed.

Standard MICRO-g Tables and Bench Top units cost approximately $1000 and will support equipment loads of over 900-lbs. All that is needed for operation is a compressed air supply or bottled air or gas.

If you're using microscopes, microtomes, interferometers, mask alignment tools or other ultra-sensitive equipment you need to know about MICRO-g systems. There are six standard configurations in a wide range of sizes. Special configurations are readily available. Write for a catalog and price list today.

CHROMATIX

A new application note is available from Chromatix entitled 'A new data system for the polymer characterisation laboratory: application to GPC data treatment'. This 12-page note (reference LS-6) describes the use of Chromatix GPC software for branched and linear polymer characterisation. A total of 11 application notes is available from Chromatix with details on methods of molecular weight measurement and data treatment.

Circle No. 147 on Reader Enquiry Card.

BECKMAN

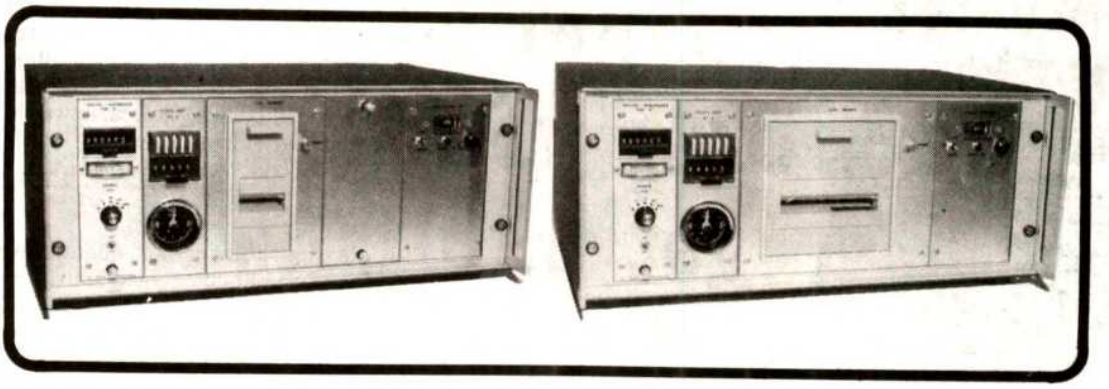
Providing qualitative and quantitative analysis of multi-component mixtures, Beckman's new Microlab 620 MX computing infrared spectrophotometer can provide the analytical power of a microcomputer, floppy-disk data storage centre, and totally preprogrammed and interfaced software systems at a fraction of the cost, space and training requirement of conventional instruments and data-processing systems.

Circle No. 148 on Reader Enquiry Card.

JOBIN-YVON

Two new instruments for measuring dichroism have been introduced by Jobin-Yvon of Longjumeau, France — the Dichrographes IV and V. Both are based on a microprocessor to control the performance of the instrument measuring process. Spectra can be recorded for both circular and linear dichroism with facilities including baseline correction, signal averaging. A measurements and very precise calibrations. Both instruments use the holographic gratings system developed for the Dichrographe III, covering the range 180 to 1,000 nm.

As well as the basic microprocessor the Dichrographe V contains a sophisticated minicomputer which makes it possible to perform advance curve manipulations and calculations. The BASIC programming makes it simple for the user to develop software to supplement that provided by the manufacturer. The facility for rapid scan, curve accumulation and signal averaging allow much higher sensitivity and faster response times than previously possible in circular dichroism measurements. This may make study of reactions kinetics and use of stopped flow real possibilities. Jobin-Yvon instruments are available from EDT Research.



Circle No. 149 on Reader Enquiry Card.

BASCOM-TURNER

Bascom-Turner Instruments have introduced their Series 8000 recorders, which are microprocessor-based systems for data management applications. With the Series 8000 it is possible to digitise, record, and process up to eight channels of analog data. Raw or processed data are graphed in real time on strip or X-Y chart paper and stored on flexible disk.

Circle No. 150 on Reader Enquiry Card.

BATTERY POWERED INTEGRATORS TYPE CJ10/CJ20.

● LOW COST/GENERAL PURPOSE. ● BATTERY/MAINS OPERATION.

● TIMED PRINT-OUT.

The CJ10 has been designed as a low cost instrument suitable for general use where signals require integration before print-out. It is particularly suitable for remote field work since battery power enables continuous unattended operation for several months without battery charge. The internal battery will power the CJ10 for up to 10 days, while the use of an external 12 volt battery (e.g. a standard car battery) of 60Ah capacity will give continuous operation for 3 months or more at low print rates (less than 1 per 4 hours).

Applications of the CJ10 are many, however the CJ10 has been found to be particularly useful for SOLAR RADIATION measurements. With the addition of a solar radiation sensor the CJ10 will "average" the radiation strength over a timed period, a simple calculation on the printed result gives 'grams cals per sq cm per minute'.

EXAMPLE OF PRINT OUT:

6 5 4 3 2 1
6 5 4 3 2 1

CJ10 PRINT-OUT

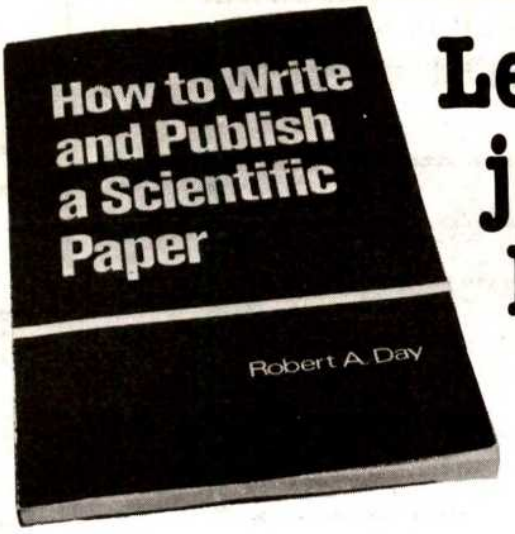
6 5 4 3 2 1 4 5 1 23 5 9
6 5 4 3 2 1 4 5 1 23 5 9
DATA **DAY NO. TIME**

CJ20 PRINT-OUT

The CJ20 differs only in print format from the CJ10. The print out from the CJ20 has day number and time printed along side the data (see examples above) this feature is very useful if records are to be kept over a long period of time, it also makes manual prints easily identifiable on the print-out.

PROTECTIVE CASE

Provides extra protection when the instrument is being used in other than laboratory conditions. Particularly suitable for dusty or humid climates. The case is lockable to prevent unauthorised adjustments etc.



AUTOMATIC CONTROL UNIT TE9570

This unit allows external equipment such as irrigation controllers etc to be driven. The unit plugs into the CJ10 frame and provides a contact closure for 300 mS when a preset count is reached, after which the unit resets to the set value and continues cycling. Maximum preset value 99999. (The TE9570 is external with CJ20).

Let an experienced journal editor help you get published.

Consider this: many of the better scientific journals reject 50% or more of the papers submitted. And all too often the cause for rejection isn't bad science, but bad presentation.

In *How to Write and Publish a Scientific Paper,* Robert A. Day has written a handbook which should substantially improve the would-be author's probability of publication. Day is certainly well qualified to address the subject: for the past 18 years he's been Managing Editor of nine journals published by the American Society for Microbiology.

The book itself is a demonstration of clear and concise presentation. Step by step, it covers every aspect of the writer's task—from preparing a title (more important than most people think) to dealing with editors and printers. The chapters on the use and abuse of tables and illustrations and on interpreting letters of rejection are particularly instructive.

Throughout, the point of view is that of a working editor. The style is lively, the treatment often amusing; but the content is thoroughly serious. Much of the information offered here is not readily available elsewhere.

For certain, this is a book you will use—whether you read it from cover to cover or reach for it in times of desperate need. In the words of one reviewer,* "[it] should be in the hands of young, middle-aged, and old scientists. It should be on the desk of everyone who aspires to write a scientific paper."

Available direct from the publisher: $15.00, clothbound; $8.95, paperback. 160 pages, illustrated, with six appendixes and an index.

*Albert Balows, Editor-in-Chief, *Journal of Clinical Microbiology.*

APPOINTMENTS VACANT

POST-DOCTORAL RESEARCH ASSOCIATE NUCLEAR PHYSICS

A post-doctoral research associate position is open in the application of nuclear physics techniques to mass spectrometry employing a 3 MV tandetron as a molecular dissociator. Applicants should have experience in nuclear physics with electrostatic accelerators and the instrumentation of nuclear physics.

The position is for a maximum of three years and involves the supervision of the construction and the installation of the apparatus and further development of the systems for radio carbon dating, geological ion microprobe work and nuclear physics.

Send resume and two letters of reference to: Prof. D.W. Strangway, Department of Geology, University of Toronto, Toronto, Ontario, M5S 1A1. W541(A)

MATHEMATICIANS

with active research interests in either numerical analysis (emphasis on partial differential equations or finite element methods or applied modeling (emphasis on inter-disciplinary interest in natural/biological sciences) are invited to apply for

TENURE-TRACK POSITIONS ASSISTANT PROFESSOR LEVEL

to start September, 1980. PhD with undergraduate/graduate teaching/thesis direction competence required.

Send curriculum vitae and names of 3 references by February 1, 1980, to: Professor Sherman C. Lowell, Department of Pure and Applied Mathematics, Washington State University, Pullman, Washington 99164.

An Equal Opportunity/Affirmative Action Employer. W546(A)

UNIVERSITY OF CAMBRIDGE

DEPARTMENT OF PATHOLOGY

The Department of Pathology, University of Cambridge wish to appoint a post-doctoral scientist to join an MRC team led by Dr H Waldmann. The programme is concerned with the Immunology of Bone Marrow Transplantation in man and mouse. Emphasis will be on the exploitation of monoclonal antibodies and fluorescence activated cell sorting in conjunction with conventional techniques of experimental haematology.

This will involve extensive collaboration with the Laboratory of Molecular Biology. Candidates aged under 30 should be appropriately qualified. Salary up to £6,066 p.a. The appointment is for 3 years in the first instance.

Please send Curriculum Vitae together with names of two referees to The Superintendent, Department of Pathology, Tennis Court Road, Cambridge CB2 1QP. 3795(A)

UNIVERSITY OF HAWAII — MANOA

POPULATION GENETICS LABORATORY

RESEARCHER GENETIC EPIDEMIOLOGY

Full-time investigator in one of several areas relevant to inherited causes of disease in populations. Doctoral degree necessary. Salary and rank commensurate with experience.

Send curriculum vitae to: Dr Newton E Morton, Director, Population Genetics Laboratory, 1980 East West Road, Honolulu, HI 96822. W543(A)

UNIVERSITY OF CALIFORNIA, Berkeley

COLLEGE OF NATURAL RESOURCES

Faculty and Agricultural Experiment Station Position in the Divsion of Biological Control and Department of Entomological Sciences.

A position as

ASSISTANT PROFESSOR OF ENTOMOLOGY and ASSISTANT ENTOMOLOGIST

in the Experimental Station will be available 18 January, 1980. A PhD in a biological sciences with specialization in invertebrate ecology is required.

Qualifications must include training in insect population ecology applicable to biological control, insect ecology, and population ecology; skills in statistical and quantitative evaluation and computer methodology would be an asset. Research responsibilities (80%) in the Division of Biological Control will include field and experimental ecology, working with live insects, with emphasis on biological control, assessment of efficiency of entomophagous arthropods in relation to both physical and biotic environmental factors.

The assignment includes conceptualization, organization and conduct of classical biological control, assessment of pest potential for economic damage and of naturally-occurring biological control, and experimentation on predator-prey/host-parasite relationships. Teaching (20%) is in the Department of Entomological Sciences in insect ecology, especially population ecology, and biological control.

Applicants should send full curriculum vitae, relevant publications and manuscripts, official academic transcripts, the names of three persons as reference, and a statement on research interests by 18 January 1980 to:

L E Caltagirone, Chairman, Division of Biological Control, University of California, 1050 San Pablo Avenue, Albany, California

The University of California is an affirmative action employer. W545(A)

INTERNATIONAL DEVELOPMENT RESEARCH CENTRE

ASSOCIATE DIRECTOR Science and Technology Policy Programme

Applications are invited for the post of Associate Director for the Science and Technology Policy Programme of the International Development Research Centre (Canada). The Associate Director who will be based in Ottawa will report to the Director of the Social Sciences Division and will be responsible for IDRC's programme of support for science and technology policy research in the developing world.

The successful applicant will undertake the following duties: 1) Develop and monitor research projects in the Science and Technology Policy Programme in Asia, Africa and Latin America. 2) Evaluate research proposals from developing countries in science and technology policy. 3) Supervise the preparation of project proposals and documentation undertaken by Programme Officers. 4) Prepare annual Programme budget estimated at $1,500,000. 5) Advise the Director on future Programme directions and priorities.

Qualifications required: 1) PhD with appropriate specialization. 2) Familiarity with a broad range of science and technology policy research issues in developing countries. 3) Previous experience with international agencies desirable. 4) Relevant overseas experience. 5) Working capacity in either Spanish or French desirable. Salary commensurate with qualifications and experience.

Applications with the names of 3 referees should be submitted to the Director, Social Sciences Division, IDRC, PO Box 8500, Ottawa by December 31, 1979. 3793(A)

IMMUNOLOGIST

Boehringer Mannheim is a leading research-orientated pharmaceutical company in Western Germany. A research position is immediately available in the Cell Culture Division of our Biochemical Research Centre, Tutzing near Munich. The candidate will be expected to build up a research group in the field of hybridoma technology.

Previous experience in cellular immunology, cell culture techniques, hybridoma production, cell cloning and anti-body analysis is essential.

Applicants without a PhD but with appropriate experience will also be considered.

Boehringer Mannheim offers an excellent salary and an attractive benefits package.

Interested applicants should send curriculum vitae, list of publications and salary requirements to

RESEARCH OPPORTUNITIES

Birds in an agricultural and airfield environment

These posts are in the Land Pests and Bird Research Department near Guildford which undertakes ecological, biological and pathological studies with a view to controlling harmful birds and mammals. There are excellent library and experimental facilities.

ETHOLOGIST

. . . to lead a small team studying the foraging strategies and food preferences of birds, particularly bullfinches, under natural conditions with a view to developing repellants for use in crop protection. This will involve planning and carrying out aviary and field experiments and publishing results.

Candidates, normally aged under 30, should have a good honours degree or equivalent in an appropriate discipline. At least 2 years' postgraduate experience in the study of animal behaviour and a sound knowledge of statistical methods is essential. An interest in optimal foraging theories and experience of working with birds is highly desirable. Appointment as Higher Scientific Officer. *Ref: SB/41/AF.*

ORNITHOLOGIST/ ECOLOGIST

. . . to initiate a study of the relationship between the roosting and feeding habits of starlings in agricultural habitats. The work will also involve analysing the factors that may influence the selection of feeding grounds, assessing the profitability of producing cheap alternative food for starlings in an attempt to reduce damage to economically important crops, investigating breeding control methods and preparing results for publication.

Candidates, normally aged under 27, should have a good honours degree or equivalent in an appropriate discipline. Appointment as Scientific Officer. *Ref: SB/42/AF.*

ORNITHOLOGIST

. . . to join a small team studying the behaviour of birds in airfield environments and advising on the potential danger to aircraft. The work will involve collecting and analysing data on populations and movements of lapwings whose affinity for airfields by both day and night is well established but little understood. In addition, the successful candidate will improve methods to alleviate bird hazards, advise civil and military aviation authorities on ornithological problems and instruct airfield personnel on bird control techniques.

Candidates, normally aged under 27, should have an honours degree or equivalent in an appropriate discipline. Appointment as Scientific Officer. *Ref: SB/43/AF.*

Salary (from 1.1.80) for Higher Scientific Officer ranges between £5,095 and £6,735 and for Scientific Officer between £3,590 and £5,485. Promotion prospects. Non-contributory pension scheme.

Candidates who applied for similar posts earlier this year are invited to apply again if they still wish to be considered. Men and women may apply.

For further details and an application form (to be returned by 14 December 1978) write to Civil Service Commission, Alencon Link, Basingstoke, Hants, RG21 1JB, or telephone Basingstoke (0256) 68551 (answering service operates outside office hours). *Please quote appropriate reference.*

Agricultural Science Service, Worplesdon Laboratory, Surrey.

Science Group CIVIL SERVICE

RESEARCH TECHNICIAN Specializing n endocrine research with specialized xperience in catecholamines. Duties nclude conduction radioenzymatic assays for catecholamines. Experience in RIA work and Preparative Biochem. BS in Biology or Chemistry required. Salary $1250.00/month. Send resume to: Raul Artal, MD, 1240 N Mission Rd, 5K-22, Los Angeles, CA 90033. W552(A)

UNIVERSITY OF BATH
SCHOOL OF PHARMACY & PHARMACOLOGY
POST-DOCTORAL RESEARCH OFFICER IN MEDICINAL CHEMISTRY

Applications are invited for the above post rom graduates in Pharmacy, Chemistry or Biochemistry, with postgraduate ualifications and experience. The uccessful candidate will work with rofessor R T Parfitt on Novel Centrally acting Tropanes. A good knowledge of rganic synthesis and modern spectro-copic techniques is essential and some ackground in either medicinal chemistry r pharmacology is desirable.

The post is tenable for two years with a arting salary of up to £5,199 per annum nder review).

Application forms and further articulars from the Personnel Officer, niversity of Bath, Bath, BA2 7AY, uoting reference number 79/217R. losing date will be 7th December, 1979.

3779(A)

SENIOR TOXICOLOGIST

Owing to extending needs and facilities in toxicology (new laboratories will open soon), we are looking for a Senior Toxicologist.

Applicants (normally aged under 40) must have a doctoral degree (MD, or VMD, or PhD). Qualification as pathologist and knowledge and/or experience in carcinogenicity and mutagenicity fields are desirable. Experience of contacts with official regulatory organizations would be an important consideration.

Reporting directly to the Toxicology Department Head, the successful applicant will take over the supervision of the toxicological evaluations conducted in outside facilities. He is also expected to take an active role in official contacts and representation in scientific or professional organizations. Fields to be covered: pharmaceuticals, veterinary products, animal feed.

Fluent English is mandatory. French is not required at the time of application but the engaged candidate will have to learn it.

Position to be filled near Paris. Salary depending upon qualification and experience.

Please send application including curriculum vitae and credentials to *Nature*, quoting box number W539A, c/o Nature, 3, Dyers Buildings, London EC1N 2NR.

W539(A)

LINCOLN COLLEGE
(University College of Agriculture)
New Zealand

LECTURER IN CROP PHYSIOLOGY

Applications are invited for the position of Lecturer in the Department of Plant Science. Applicants should have a postgraduate qualification and research experience in crop physiology, preferably combining a sound knowledge of physiological principles with personal experience of crop pasture production. Teaching at undergraduate and post-graduate levels will necessitate competence in such topics as photosynthesis, water relations, competition, etc.

Commencing salary according to qualifications and experience. Present salary scale for lecturing staff is: NZ$13,722 to NZ$16,861.

Travel and removal expenses are reimbursed up to specified limits. New Zealand Government Superannuation available.

Conditions of Appointment are obtainable from the Association of Commonwealth Universities (Appts), 36 Gordon Square, London WC1H 0PF, or from the Registrar of the University. Applications close on 15 January 1980. Please quote Vacancy No. 78/50.

3774(A)

POSITIONS OPEN
Medical University of South Carolina
DEPARTMENT OF BIOCHEMISTRY

Three positions are available from 1 January, 1980.

1. ASSISTANT PROFESSOR

with strong research background in biochemistry of lymphocyte recognition and function. The individual should be an effective lecturer in this area and be capable of generating research support. Several years of postdoctoral experience are required.

2. ASSISTANT PROFESSOR

with proven research and teaching ability in the area of demonstration and characterization of cell surface receptors. Several years of postdoctoral experience are required and the individual should be capable of developing a fundable research program in this area.

3. ASSOCIATE PROFESSOR

with established research program in molecular immunology. Research interests should center around the evolution of antibodies and cell receptors. The individual should be an effective teacher in these areas.

Closing date for applications is 30 November, 1979. Send curriculum vitae to Dr J J Marchalonis, C/O Office of the Dean, College of Medicine, Medical University of South Carolina, 171 Ashley Avenue, Charleston, South Carolina 29403. W553(A)

Water Quality Department

CHIEF ASSISTANT CHEMIST

Location: **Initially at Lichfield, permanent location at new Central Laboratory, Walsall, West Midlands**

Salary: **NJC Water Services Staff Grade 10 Range: £9,096 — £9,771 Plus Regular Car User Allowance**

Applications are invited for the above post from professionally qualified chemists, aged 30 to 40, holding a good honours degree in an appropriate scientific subject. Technical experience may relate directly to the water industry or to a broadly similar area and applicants should have a good command of management skills.

The person appointed will assist the Chief Chemist and Deputy Chief Chemist in the full range of departmental responsibilities which include the control of water treatment and the provision of laboratory analytical facilities. The laboratory's analytical duties include comprehensive chemical, biological and bacteriological analyses necessary for the provision of a wholesome water supply. Advanced instrumentation is available for a wide range of these analyses and is to be extended when the laboratory is transferred to new accommodation. The development of the laboratory's facilities is at a particularly challenging stage at the present time, in relation to data handling systems.

The Company offers approved relocation expenses where appropriate and first class superannuation provision. Opportunities for further advancement exist for a candidate who can demonstrate exceptional technical and managerial ability and a progressive and enthusiastic approach to his work.

Applications, including comprehensive details of qualifications, experience, and present responsibilities and salary, together with the names of two referees, should be marked "Confidential" and sent by 11th December to the General Manager, The South Staffordshire Waterworks Company, 50 Sheepcote Street, Birmingham B16 8AR.

3775(A)

UNIVERSITY OF LEIDEN
The Netherlands Faculty of Science

The Subfaculty of Chemistry of the University of Leiden, The Netherlands, invites applications for the tenured position of

ASSOCIATE PROFESSOR OF BIOPHYSICAL CHEMISTRY (M/F)
vacancy number 9-480/2407

The appointee is expected to focus his/her research on the structure and dynamics of biological macromolecules and molecular assemblies with the aid of physical methods. It is also expected that the appointee will stimulate and coordinate cooperative research efforts in this field between the department of biochemistry and other disciplines.

Responsibilities will include teaching.

Applications with curriculum vitae and including full details of qualifications and experience should be addressed to the University of Leiden, Personnel department, Stationsweg 46, Leiden, The Netherlands.

RU leiden

Information:
Dr A van der Gen,
Gorleaus Laboratoria,
University of Leiden,
Netherlands.

W538(A)

SCOTTISH SOCIETY FOR RESEARCH IN PLANT BREEDING
SCIENTIFIC OFFICER/ HIGHER SCIENTIFIC OFFICER

A Scientific Officer is required to join the Cereals Department at the Scottish Plant Breeding Station.

The appointee will be required to join a group working with spring barley and spring oats with the object of producing crop varieties adapted to local conditions. Training in genetics and/or pathology along with an interest in the practical aspects of plant breeding would be an advantage.

Qualifications: A pass degree or HNC with relevant experience or an honours degree in a biological science. At least five years relevant post-graduate experience is normally required for appointment as HSO.

Salary: Depending on qualifications and experience:
Scientific Officer: In the range £3,289 to £5,085 per annum.
Higher Scientific Officer: In the range £4,726 to £6,211 per annum.
The post is superannuable.

Application forms and further information may be obtained from the Secretary, Scottish Plant Breeding Station, Pentlandfield, Roslin, Midlothian, EH25 9RF, to whom completed application forms should be returned not later than 3rd January 1980.

IMPERIAL COLLEGE
Silwood Park, Ascot, Berks. SL5 7PY

INSECT BEHAVIOUR

A POST-DOCTORAL RESEARCH ASSISTANT

is required at the Department of Zoology and Applied Entomology to work on tsetse fly behaviour. Candidates should have a PhD or equivalent, preferably with research experience, in insect behaviour or sensory physiology. The project is part of a long-term study of the visual responses and circadian rhythms of tsetse flies.

Salary within the range £4,333 to £5,488 per annum (salary under review) plus USS benefits and 5 weeks holiday. The appointment is for one year in the first instance, renewable for a further year. Extension beyond that will depend on the success of the project and the outcome of future grant applications. Starting date 1 February 1980.

Apply in writing to Dr J Brady (above address), with curriculum vitae and the names and addresses (plus phone numbers) of two referees, before December 21st.

UNIVERSITE DE MONTREAL
FACULTÉ DES ARTS ET DES SCIENCES
Département de sciences biologiques

PROFESSEUR A PLEIN TEMPS

Fonctions: Enseignement de la biométr de la dynamique des populations et modélisation. Encadrement des étudian de 2e et 3e cycles. Participation aux trava de recherche et aux activités d département.

Exigences: PhD et expérience recherche en dynamique des populations en modélisation. Très bonne connaissan de la langue française.

Traitement: Selon les normes de convention collective en vigueur. Da d'entrée en fonction: 1er juin 1980 ou plus tôt possible après cette date. Date clôture des candidatures: 1er mars 1980.

Les candidats sont priés de faire parve leur curriculum vitae à: M. Jean-G Pilon, Directeur, Département de scienc biologiques, Faculté des arts et d sciences, Université de Montréal, Ca postale 6128, Succurssale A, Montr (Québec), H3C 3J7. Tel.: (514) 343-687

W556(A)

We have the following vacancies in our Biochemistry Section:

Experimental Officer — Biochemist

A graduate biochemist to play a part in the discovery of new insecticides. An understanding of neurobiology would be desirable, but practical experience in insect biochemistry is not essential. However, candidates must have considerable experience of modern biochemical techniques.

The successful applicant will join a small team composed of one PhD and one graduate, responsible for initiating research in areas of insect biochemistry that could lead to a programme of chemical synthesis or produce *in vitro* methods for detecting active chemicals. Complementary work will be concerned with evaluating the mode of action of promising new insecticides and gaining an early understanding of the factors that may contribute to the development of resistance.

Experimental Officer — Physical Chemist/ Electrochemist

A Physical Chemist to work on the electrochemistry and reaction kinetics of exploratory organic compounds being synthesised as potential pesticides. A knowledge of chemistry at least up to HNC level is required, and experience of polarography or related techniques is desirable but not essential. The successful candidate will work closely with organic and bio-chemists, and will be in a small team headed by a PhD physical chemist. There will be scope for initative in developing techniques and helping to design structures with the desired electrochemical properties.

Jealott's Hill is the chemical and biological research centre for the crop protection interests of ICI. It is situated in open country 30 miles west of London, between Bracknell and Maidenhead. We offer competitive salaries and fringe benefits including membership of the ICI Profit Sharing and Pension Fund. Coaches run between Jealott's Hill, Bracknell and Maidenhead.

If you are interested in this vacancy please write or telephone for an application to:

Mr S R Stephenson, ICI Plant Protection Division, Jealott's Hill Research Station, Bracknell, Berks. Ref no 79/Biochem

ICI Plant Protection Division

3794(A)

FACULTY POSITION

Organic Chemistry

Applications are invited for a tenured senior appointment which the Department of Chemistry at Stanford University expects to be able to make in the near future. Applicants must have outstanding research credentials in organic chemistry and a strong commitment to teaching undergraduates as well as graduates.

In applying, send curriculum vitae and bibliography to: Professor K.O. Hodgson, Department of Chemistry, Stanford University, Stanford, California 94305. Stanford is committed to Equal Opportunity through Affirmative Action in employment and we are especially eager to identify women and minority persons with appropriate qualifications.

Applications should be received by 15 December, 1979. W516(A)

UNIVERSITY OF OXFORD

DEPARTMENT OF BIOCHEMISTRY

POST-DOCTORAL RESEARCH ASSISTANT 1A

Ref: B/R/10

Applications are invited for the position of Post-Doctoral Assistant (Grade 1A) funded by a 3 year project grant from the MRC awarded to Dr A J Kingsman. The research concerns the characterisation of dispersed repetitive DNA sequences in the genome of *Saccharomyces Cerevisiae* by both genetic and recombinant DNA techniques. The appointment should start as soon as possible after 1st January, 1980.

Salary on the scale £4333 — £6066.

Applications, including the names of 2 referees should be sent to: The Administrator, Department of Biochemistry, South Parks Road, Oxford OX1 3QU. 3808(A)

ROCHE

Senior Pharmacologist

Roche Research Institute of Marine Pharmacology (R.R.I.M.P.)

invites applications for the position of

Section Leader Pharmacology

Roche has established a Research Institute of Marine Pharmacology in Sydney to carry out basic research into the biology, chemistry, microbiology, chemotherapy and pharmacology of a wide range of natural products obtained from marine organisms. There is a close interaction between the scientific sections. The Institute collaborates with Australasian universities and its operation is integrated with that of other Roche research centres in Switzerland, the U.K., Japan and the U.S.A.

The Section Leader will direct the Pharmacology programme which evaluates activities of material isolated from marine organisms.

Responsibilities will include development and coordination of research projects in the Pharmacology section, appropriate to the function of the Research Institute, interaction with clinical pharmacologists in specific projects, and interaction with such authorities as are necessary for the development of a drug.

The appointee will advise the Director on development of the Pharmacology section and will be a member of the RRIMP Research Management Committee.

Applicants should have demonstrated the ability to organise and supervise a scientific team involved in both routine and research application.

Salary will be negotiated on the basis that the level of appointment is regarded as comparable in expected expertise and responsibility to that of a Reader or Associate Professor in a University or Senior Principal Research Scientist in a Commonwealth Research organisation.

Generous superannuation benefits are available.

Applications marked confidential, and including curriculum vitae and the names of three referees, should be forwarded to:

The Director,
Roche Research Institute of Marine Pharmacology,
P.O. Box 255,
DEE WHY. N.S.W. Australia 2099.

Closing date is: 14th January, 1980.

3786(A)

Cytogeneticist

Chief Medical Officers Department

Up to £7,500-Windscale

British Nuclear Fuels Limited rely on specialists—professionals who can fill specific roles vital to our continuing success, consolidating our position as a conscientious world leader in a challenging industry.

Right now we require a graduate with at least 2 years experience in human genetics preferably including tissue culture and banding techniques to join our expanding laboratory.

The work is primarily concerned with the evaluation of chromosome aberrations in relation to radiation dosimetry together with a programme of research in this field. In addition a close liaison is maintained with the hospital services in the area for whom some diagnostic work is undertaken.

We have a superb location—right on the West Cumbrian Coast and on the fringe of the lake District National Park. This picturesque area provides a eutopian combination of lakeland, hills, forestry and coastline—offering a relaxed and charming way of life with excellent opportunities for outdoor pursuits.

We offer an excellent salary, up to £7,500, plus a productivity bonus, and benefits include generous resettlement allowances in appropriate cases. Housing, both rural and urban, is readily available at realistic prices and company accommodation may be obtainable.

To apply, write now with details to Dr. G.B. Schofield, Chief Medical Officer, British Nuclear Fuels Limited, FREEPOST, Windscale and Calder Works, Sellafield, Seascale, Cumbria.

BNFL

For an infinitely brighter future

3787(A)

UNIVERSITY OF MANCHESTER

LECTURESHIP IN PHYSICS

Applications are invited for the above post. The Lecturer will be expected to take part in teaching in the Physics Department and to carry out research on Experimental Elementary Particle Physics, in either the JADE Collaboration on the PETRA e^+e^- storage ring at Hamburg or the Photon Collaboration on the OMEGA detector at the SPS at CERN, Geneva. Further information can be obtained from Professor P G Murphy. Salary within the range £4,333 to £8,992. Superannuation. Initial salary will depend on age and experience but is unlikely to be above £5,199.

Applicants with appropriate experience in experimental particle physics should apply to the Registrar, The University, Manchester M13 9PL, from whom further particulars and application forms are obtainable. Completed forms should be returned by December 15th. Quote ref: 234/79/N. 3730(A)

MEDICAL RESEARCH COUNCIL

National Institute for Medical Research

DIVISION OF VIROLOGY

A vacancy exists for a researcher to join a small group investigating the basic mechanisms of virus infection using the adenovirus model system. Ideally, he/she should have had some years' postdoctoral experience in a similar or related field. The appointment would be a temporary one for three years but, given sufficient experience and evidence of research abilities, a five year limited-term appointment (which could progress to a permanent post) would be considered. The salary would depend on age and experience in the range £5,199 to £6,932 pa plus £740 pa London Allowance. Superannuation provision.

Applications, enclosing curriculum vitae and the names of two referees, should be sent to the Director, National Institute for Medical Research, The Ridgeway, Mill Hill, London NW7 1AA, before 14th December, 1979. 3776(A)

UNIVERSITY OF WESTERN AUSTRALIA

Perth

SENIOR TUTOR IN PHYSICS

Applications are invited for two positions in the Department of Physics. These will be temporary appointments, one for an initial period of two years with the possibility of extension, and the other to 31st December, 1980. Applicants should hold a higher degree in physics and have had appropriate teaching experience at tertiary level. They should be prepared to take a full part in the Department's teaching programme, but the appointees will also be expected to participate in one of the current research projects, which include Elementary Particles, General Relativity, Detection of Gravitational Radiation, Solid State Physics, Atmospheric Physics, Mass Spectrometry, Molecular Collisions and Photonuclear Reactions.

Current salary range: $A14,041 to $A16,085 per annum. An appointee for two years will be entitled to fares to Perth for self and fully dependent family and removal allowance, and to similar return benefits to place of engagement on completion of two or more years' service. An appointee for one year will be entitled to an allowance of up to $A2,066 towards appointment expenses.

Applications in duplicate stating full personal particulars, qualifications and experience should reach the Acting Staffing Officer, University of Western Australia, Nedlands, 6009, Western Australia, by 8th December, 1979. Candidates should request three referees to write immediately to the Acting Staffing Officer. 3773(A)

KINGSTON POLYTECHNIC

SCHOOL OF GEOLOGY

SLIDE MAKER

To be responsible for all thin section preparation for the School, together with such ancillary techniques as preparation of polished ore specimens, specimen slabbing, and preparation and polishing of grain slides. Experience essential; Advanced technician certficiate an advantage.

T3/4 grade £4470-£5457 inclusive. Application forms from Assistant Registrar (Personnel), Kingston Polytechnic Penrhyn Road, Kingston-upon-Thames KT1 2EE. 01-549 1366. 3788(A)

FACULTY POSITION IN BIOLOGICAL SCIENCES

at the Hopkins Marine Station of Stanford University

Applications are invited for an appointment in the Department of Biological Sciences of Stanford University, to be resident at the Hopkins Marine Station in Pacific Grove, California. The position is without restriction as to rank although some preference will be given to younger candidates.

The position involves both teaching and research. The areas in which the Station wishes to expand its faculty include Cellular, Neuro- and Developmental Biology. All applications must include a curriculum vitae, a statement of research interests and a list of three people from whom letters of reference will be sought.

Applications should reach C S Pittendrigh, Hopkins Marine Station, Pacific Grove, CA 93950 by January 15, 1980. Stanford University is an equal opportunity employer. W505(A)

UNIVERSITÄT FREIBURG

DEPARTMENT OF BIOLOGY

TWO POST-DOCTORAL POSITIONS

(BAT IIa: approx. 42,000 DM/year) will be available for at least two years at the beginning of 1980 for research on light-dependent development of barley and on cloning of cereal DNA.

Applications with curriculum vitae and names of two referees should be sent to Dr K Apel or Dr G Feix, Institut für Biologie, Schänzlestraße 1, 7800 Freiburg, W. Germany. W560(A)

THE UNIVERSITY OF BRITISH COLUMBIA

CLINICAL ENGINEERING PROGRAM

Applications are invited for the position of

DIRECTOR OF THE CLINICAL ENGINEERING PROGRAM

The Director's responsibility will be the operation and development of a Master-level program approved to start in September, 1980. The Director must hold an advanced engineering degree (PhD preferred), have several years clinical experience and be eligible for registration as a Professional Engineer in British Columbia. The appointment will be at the Associate Professor level and applications should be sent, by January 15, 1980, to: Professor Axel Meisen, Chairman, Clinical Engineering Search Committee, Faculty of Applied Science, University of British Columbia, Vancouver, BC V6T 1W5, Canada. (Late applications may be considered. W549(A)

UNIVERSITY OF GLASGOW

DEPARTMENT OF ELECTRONICS AND ELECTRICAL ENGINEERING

RESEARCH ASSISTANT

(Readvertisement)

Applications are invited from well qualified persons to take part in a Ministry of Defence sponsored investigation into the growth of indium phosphide by molecular beam epitaxy.

Applicants should have at least three years postgraduate research experience in one or more of the following topics: thin film deposition; assessment of III-V semiconductor materials; surface physics and related techniques. It may be possible for a suitably qualified person to register for a higher degree.

Starting salary up to £5,488 on the grade 1A scale for research staff.

The appointment is tenable for two years.

Applications (two copies) should be sent to Professor John Lamb, Department of Electronics and Electrical Engineering, The University, Glasgow G12 8QQ, giving the names and addresses of at least TWO persons to whom reference can be made.

Closing date: 31st December 1979.

In reply please quote Ref.No.4551M. 3806(A)

Director, Institute of Biological Sciences

SYNTEX, a unique Multinational Pharmaceutical Corporation, is located in the hills of Palo Alto, California, adjacent to Stanford University.

Applications are now being accepted for the position of Director of our Institute of Biological Science from individuals with broad research experience in biological science and drug development. This position reports to the Sr. Vice President of Syntex Research.

The individual selected will help ensure the highest quality of research in the Institute and will contribute directly to the long range success of the Company.

Responsibilities include directing the efforts of a number of groups of Biological and Biochemical Scientists working in the areas of inflammation, immunology, thrombosis and atherosclerosis, dermatology and reproductive physiology. Projects involve drug testing, study of mechanism of action of therapeutic agents and basic biology of diseases.

Your broad overview of Biology and Medicine and your interdisciplinary approach to problem solving are key qualifications for this position. You will function in close collaboration with other Syntex Institutes (e.g., Clinical Medicine and Pharmacology) and will exercise your strong managerial and motivational skills. Experience in the Pharmaceutical Industry highly desirable.

This Senior-level position offers a most attractive salary and compensation package along with continued professional recognition and challenge.

Please address your resume, in confidence, to John Hudson, Director of Personnel, SYNTEX, 3401 Hillview Avenue, Palo Alto, CA 94304. We are an equal opportunity employer. W554(A)

SYNTEX

UNIVERSITY OF LIVERPOOL

CYTOGENETICS UNIT

SCIENTIFIC OFFICER

Applications are invited from Science graduates for a basic grade post on the Whitley A Scales in this Unit, which provides the Cytogenetics service for the Mersey Regional Health Authority. This post primarily involves work in pre-natal diagnosis and experience in human cytogenetic techniques/tissue culture is desirable.

Salary within range £4,035 to £4,935 pa depending on qualifications and experience.

Application forms may be obtained from The Registrar, The University, PO Box 147, Liverpool, L69 3BX. Closing date for return of forms 3rd December, 1979. Quote Ref: RV/845/N. 3777(A)

THE SIDNEY FARBER CANCER INSTITUTE and the HARVARD MEDICAL SCHOOL seek an ASSOCIATE OR FULL PROFESSOR OF PHARMACOLOGY to head a division of PHARMACOLOGY

at the Institute. The incumbent should have research interests and accomplishments related to pharmacology or biochemistry.

Candidates should send a curriculum vitae and a statement of their research interests to Dr Peter Goldman, Chairman of Search Committee, Department of Pharmacology, Harvard Medical School, 250 Longwood Avenue, Boston, Massachusetts 02115. An Affirmative Action/Equal Opportunity Employer. W550(A)

CIRMF — GABOON

VETERINARIAN

International Center of Biomedical Research in Franceville — Gaboon is looking for a veterinarian in charge of Higher Primates as well as of other monkeys and usual laboratory animals.

Ten years' experience wished. French language not necessarily needed. Two-year contract renewable will be offered. For details write to our office in Paris CIRMF, 28 boulevard de Grenelle 75015 — Paris. W540(A)

PLANT GENETICIST UNIVERSITY OF FLORIDA

THE DEPARTMENT OF BOTANY

invites applications for a tenure track

ASSISTANT/ASSOCIATE PROFESSOR

position in plant genetics. Applicants with experience in biochemical/molecular/somatic cell genetics are especially encouraged to apply.

The appointee will be expected to establish an active research program, develop and teach a plant genetics course at the advanced undergraduate/graduate level, and participate in the general education biology courses.

Rank and salary will be determined by the experience and qualifications of the appointee.

Send application, a statement of research interests, and three letters of recommendation, before January 31, 1980, to Dr Indra K Vasil, Department of Botany, University of Florida, Gainesville, FL32611, USA. An equal opportunity/affirmative action employer. W555(A)

MEDICAL RESEARCH COUNCIL

UNIT ON THE EXPERIMENTAL PATHOLOGY OF SKIN

(University of Birmingham)

TECHNICIAN

(Temporary Appointment)

A Technician is required to assist in cell separation procedures and biochemical studies of mammalian cell membranes. A degree or similar qualification in biochemistry is essential.

The post is a temporary one for 1 year to a maximum of 18 months. Salary £3,768.

UNIVERSITY OF LIVERPOOL

DEPARTMENT OF PHARMACOLOGY AND THERAPEUTICS

Applications are invited for the post of Lecturer in Pharmacology. The principal duties of the person appointed will be to teach science students. Preference will be given to applicants with post-graduate experience in physiological pharmacology. Salary scale £4,333 to £8,992 per annum.

Applications, together with the names of three referees, should be received not later than December 17th, 1979, by the Registrar, The University, PO Box 147, Liverpool, L69 3BX, from whom further particulars may be obtained. Quote Ref RV/842/N. 3778(A)

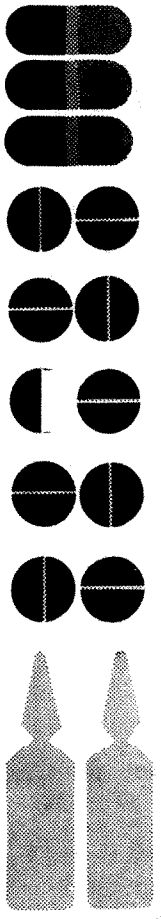
Applications are invited for a position at the

EUROPEAN MOLECULAR BIOLOGY LABORATORY

in Heidelberg, Federal Republic of Germany, as

BIOCHEMISTRY TECHNICIAN

The successful applicant will work on the *isolation* and *purification of enzymes* and will be expected to operate a fermenter for bacterial cultures of up to 100 litres.



Applicants should have had appropriate technical training and some experience in *enzyme purification* or *nucleic acid biochemistry* is highly desirable. A working knowledge of English is essential.

The salary offered to the successful candidate will be between DM 2200 and DM 2700 monthly, in addition to which certain allowances are payable, depending on personal circumstances.

Please write briefly for an application form, quoting reference 79/18, to:

EMBL, Personnel Section, Postfach 10.2209, D — 6900 Heidelberg, Germany.

W558(A)

Head of Pharmacology Ware

An opportunity has arisen for an experienced pharmacologist to head up a department primarily engaged in research aimed at identifying and developing improved drugs for the treatment of cardiovascular and respiratory disease and disorders of the gastrointestinal tract. You should have a proven scientific understanding of at least one of these areas, a good working knowledge of other scientific disciplines and the ability to lead multi-disciplinary project groups.

You will be expected to make a scientific contribution to existing programmes and initiate new research projects. The Head of Department will also be responsible for the management and administration of the Department and its staff of 70, one third of whom are graduates.

You should be in your mid-thirties, preferably with experience of pharmacological research in an industrial environment.

The post carries a competitive salary and a company car. Other benefits include pension, profit sharing and productivity schemes, and relocation assistance if appropriate to this pleasant river-valley location.

Further details will be sent upon request. Applicants should send a full curriculum vitae in confidence to:

Ian Collins, PhD, Personnel Manager, Glaxo Group Research Ltd., Ware, Herts. SG12 0DJ. Tel: Ware 3232. 3812(A)

Glaxo Group Research Ltd.

THE UNIVERSITY OF LEEDS

ASTBURY DEPARTMENT OF BIOPHYSICS

Applications are invited for a post of

POSTDOCTORAL RESEARCH FELLOW

to work on a project, supported by the SRC, concerned with the study of molecular conformations and inter-molecular interactions by use of an interactive computer display system. Topics being investigated include the conformation of insulin and drug-receptor interactions. Applicants should have experience in crystallographic studies of biological molecules and in computing. The appointment will be made for a fixed period of up to eleven months.

Salary at an appropriate point on the IA scale for Research and Analogous Staff (£4,333 to £7,521) (under review from 1 October 1979) according to age, qualifications and experience.

Preliminary enquiries about the post will be welcomed by Professor A C T North, Astbury Department of Biophysics.

Application forms and further particulars may be obtained from the Registrar, The University, Leeds LS2 9JT, quoting reference number 42/2. Applications should be submitted as soon as possible. 3803(A)

SYDNEY HOSPITAL

Director of Medical Research

Kanematsu Memorial Institute

Applications are invited from medical graduates with senior degrees and substantial research experience for the position of Director of Medical Research.

Sydney Hospital, the oldest Hospital in Australia, was founded 191 years ago. It is situated in the centre of the City of Sydney and is a Teaching Hospital of the University of Sydney. During the year 1978/79, 18,828 inpatients were admitted to its 476 beds and 250,000 persons attended as outpatients.

The Kanematsu Memorial Institute, an integral part of Sydney Hospital, was established in 1933 and provides a clinical service as well as both clinical and applied research.

The Director will be in charge of the Medical Research Department which has well equipped laboratories, a workshop, an animal house and its own associated wards. The Director may develop fundamental and/or clinical research along any line appropriate to the work of the Hospital.

The salary will be that of a Senior Medical Specialist (at present up to A$39,061). There is also an administrative allowance and a right of limited private practice.

A supporting statement giving information about the Department, the Institute, and the Hospital, as well as details of the conditions of employment and instructions to applicants is available from the undersigned.

Applications close on 1st January, 1980, and should be forwarded to the undersigned in an envelope marked "Director of Medical Research". Further enquiries should be addressed to Chief Executive Officer, Sydney Hospital, Macquarie Street, Sydney, NSW 2000, Australia. 3723(A)

WORCESTER COLLEGE OF HIGHER EDUCATION

County Council of Hereford and Worcester

LECTURER IN HUMAN PHYSIOLOGY

Applications are invited for the above post from candidates with appropriate first and higher research degrees to lecture in the College Honours degree programmes validated by CNAA. The appointment will be from as early in 1980 as possible.

Candidates should have particular interest and expertise in the field of exercise physiology and will be expected to play a leading role in the development of courses in Human and Social Biology.

The salary will be at an appropriate point in the Lecturer Grade II/Senior Lecturer Scale, £4,542 to £8,325.

Application forms and further particulars may be obtained from The Principal, Worcester College of Higher Education, Henwick Grove, Worcester WR2 6AJ, to whom completed application form should be returned as soon as possible. 3780(A)

STANFORD UNIVERSITY

GEOCHEMIST —PETROLOGIST

The Department of Geology in the School of Earth Sciences invites applications for a faculty position beginning September, 1980. Areas of interest include (but are not limited to) geochemical processes in the crust and mantle of the earth including isotope geochemistry, thermodynamics, kinetics, element distribution and phase equilibria studies. Teaching responsibilities might include graduate and undergraduate courses in geochemistry and igneous petrology. Level of appointment is open, but we are particularly interested in a creative young person, with a well-established record in research.

Applications should include (1) a resume of education, professional experience, and published research; (2) a brief statement of plans for future research, and (3) the names of 4 referees. Send to: Prof. J.G. Liou, Department of Geology, Stanford University, Stanford, CA 94305, by December 1st, 1979. Stanford University is an equal-opportunity/affirmative-action employer. W329(A)

UNIVERSITY OF SURREY

DEPARTMENT OF HUMAN BIOLOGY AND HEALTH

RESEARCH TECHNICIAN GRADE 5

Required for interesting work in the field of neurobiology. Candidates must be of a good academic and practical standard and be competent to work with the minimum of supervision under the direction of the Reader in Physiology. A small amount of class preparation may also be involved.

If you have a degree or an HNC in Applied Biology, Advanced City & Guilds Laboratory Technicians Certificate or similar, and have several years' laboratory experience we would like to hear from you.

The Department is in a new building in attractive surroundings, adjacent to an historic town with excellent recreational facilities on the campus and in the surrounding area.

Further particulars and application forms for the post may be obtained from the Staff Officer, University of Surrey, Guildford, Surrey, GU2 5XH, or telephone Guildford 71281, ext. 452. 3807(A)

university college of swansea

SENIOR RESEARCH ASSISTANT

Applications are invited for the vacancy of post-doctoral **Senior Research Assistant** in the **Department of Genetics**. Applicants should have graduate experience in microbial genetics and/or biochemistry, and the successful candidate will join an MRC funded project, studying the mechanism of action of tumour promoting chemicals.

The appointment will date from 1 January, 1980, and will be for one year in the first instance, with the possibility of renewal for up to a further two years. The commencing salary will be on a scale up to £4,910 per annum, together with USS/USDPS benefits.

Further particulars and application forms (2 copies) may be obtained from the Personnel Officer, University College of Swansea, Singleton Park, Swansea, SA2 8PP, to whom they should be returned by *Friday, 14 December, 1979.* 3798(A)

UNIVERSITY OF NOTTINGHAM

DEPARTMENT OF ZOOLOGY

POSTGRADUATE RESEARCH ASSISTANT

Applications are invited from graduates with interests in behavioural ecology to work on a project investigating species ratios in mixed flocks of birds. Research will centre on the influences of species-specific costs and benefits of flocking and feeding strategies on the time budgets of individual birds and the role of time budgeting in producing equilibrium species mixtures.

Applicants must possess a full driving licence and some field work experience would be an advantage. The project is funded by the NERC and the appointment will be made as soon as possible at a starting salary of £3,775.

Applications, together with the names and addresses of two referees, to Dr C J Barnard, Department of Zoology, University of Nottingham, University Park, Nottingham NG7 2RD 3781(A)

GEOLOGY AND GEOPHYSICS

University of California

Berkeley

THE DEPARTMENT OF GEOLOGY AND GEOPHYSICS

anticipates a vacancy for a tenured faculty member at the

ASSOCIATE OR FULL PROFESSOR

level, beginning in 1980. Areas of research interest should be in the fields of geological and geochemical processes responsible for the formation of mineral and energy resources.

For example, organic geochemistry as applied to the origin and thermal evolution of sediments, or isotope geochemistry applied to hydrothermal mineral resources, or the study of stratiform mineral deposits would all be appropriate fields.

Applicants with at least six years post-PhD research experience should send resumes, including the names of three references, to The Chairman, Department of Geology and Geophysics, University of California, Berkeley, Ca 94720, by March 31, 1980.

The University of California is an Affirmative Action employer. W547(A)

SRC

Energy Projects Co-ordinator-

A Senior Appointment

The primary function of the Science Research Council is to sustain high standards of research and post-graduate education in Universities and Polytechnics. Over the past several years, the SRC has been increasingly concerned that its support for energy-related research should be as effective as possible in terms of both the quality of the research and its relevance to national needs. The Council has decided to appoint an Energy Project Co-ordinator to:

i) **act as the agent of the SRC's Energy Committee in simulating a programme of energy research.**
ii) **act as the co-ordinator for the Council's specially promoted programme in Materials and Energy Conservation in the Materials Processing Industries.**
iii) **be responsible to the Director of the Rutherford Laboratory for the Energy Research Support Unit (ERSU) at the Laboratory, and the Energy research carried out there.**
iv) **act as the interface with Government and Industry in the identification of appropriate areas for SRC support.**

Energy research supported by the SRC covers a wide range of disciplines. The person appointed must be able to appreciate the relevance of each type of research and be able to demonstrate the ability to work with colleagues in Universities, Industry and Government. It is expected that the successful applicant will have had several years experience in research relevant to energy and to have held a senior post concerned with Energy in a University, Polytechnic or Industry.

The Co-ordinator will be based at the Rutherford Laboratory. He will have directly available to him the staff of ERSU, and will be able to call upon a wide range of expertise from other staff in the Laboratory.

The appointment will be for a three year term.

The salary will be in the range £14,200 to £17,200 with Superannuation arrangements to be negotiated.

Applicants should send curriculum vitae quoting Ref: VN 860 to Jane Griffiths, Recruitment Office, Building R20, Rutherford & Appleton Laboratories, Chilton, Didcot, Oxfordshire OX11 0QX to whom enquiries should be made.

Closing date for applications is:-

7th December, 1979.

ESSOCHEM EUROPE INC., located at Machelen, near Brussels, the coordinating headquarters for Esso Chemicals activities in Europe, Africa and the Middle East, has a vacancy for a

TOXICOLOGIST
(M/F)

We offer:

- ☐ a challenging position involving participation in ongoing toxicology program, including contract testing consultation and advisory work product groups;
- ☐ attractive salary and benefits.

Requirements:

- ☐ university degree in toxicology;
- ☐ 1-3 years of relevant industrial experience;
- ☐ fluency in English;
- ☐ willingness to travel and/or relocate.

Please forward applications with full curriculum vitae in English to ESSOCHEM EUROPE INC., Employee Relations Department, Nieuwe Nijverheidslaan 2, 1920 MACHELEN, BELGIUM.

Universiteit van Amsterdam

Applications are invited for the post of

Reader (m/f) in embryology

in the Medical Faculty of the University of Amsterdam. He/she should have a wide knowledge of the field and will be working in the Laboratory for Anatomy and Embryology of the University. Together with members of the staff of this Laboratory he/she will be responsible for the teaching of embryology to medical and dental students. His/her research interests should be in molecular biological aspects of embryological development. Apart from pursuing his/her own work he/she will be expected to participate in current research in this field in the Laboratory.

Salary scales from Dfl. 6,023.- to Dfl 8,604.- max. per month.

The candidate must be prepared to learn the Dutch language.

Applications (with curriculum vitae and list of publications) should be submitted within 2 weeks to the Secretary of the search committee:

Prof Dr. P. Borst.
Jan Swammerdam Instituut,
afdeling Medische Enzymologie.
1e Const. Huygensstraat 20,
1054 BW Amsterdam, The Netherlands.

Telephone: 020 - 181313, ext. 66.

SCOTTISH SOCIETY FOR RESEARCH IN PLANT BREEDING
PRINCIPAL SCIENTIFIC OFFICER

A vacancy exists in the staff of the Potato Breeding Department at the Scottish Plant Breeding Station for a Potato Breeder in the grade of Principal Scientific Officer.

The person appointed to fill this post will be responsible to the Head of Department for a wide range of potato breeding and associated work carried out by the Department, and will be expected to collaborate with other senior staff members in the up-dating and development of the department's breeding programme. The appointee will be required to lead teams engaged in field work, which will involve travel to trial sites in various parts of the United Kingdom, and to liaise with collaborators in the potato processing industry and in other breeding organisations.

Applicants should be experienced plant breeders with a flair for planning, analysis and interpretation of field trials data, and a facility for collaboration.

Qualifications: 1st or upper 2nd class Honours degree in a biological subject, with considerable relevant post-graduate research experience.

Salary: In the range £7,534 to £9,646 per annum.
The post is superannuable.

Application forms may be obtained from The Secretary, Scottish Plant Breeding Station, Pentlandfield, Roslin, Midlothian, EH25 9RF, to whom completed forms should be returned not later than 7th December 1979. 3727(A)

Public Health Laboratory Service
Central Public Health Laboratory

Microbiologist

A vacancy exists in the **Bacterial Metabolism Research Laboratory** for a recent graduate to undertake a 3 year project supported by the M.R.C. on the use of gas-liquid chromatography for diagnosis of Legionnaires' Disease. The successful candidate will be expected to register for a higher degree.

NHS Whitley Council conditions apply. Starting salary (from 1.1.80) £4,464 plus London Weighting.

Application forms may be obtained from The Personnel Officer, Central Public Health Laboratory, Colindale Avenue, London NW9 5HT, Closing date 7 December 1979.

DIRECTOR GENERAL

International Service for National Agricultural Research (ISNAR)

The Consultative Group on International Agricultural Research (CGIAR) is an association of official and private aid donors, co-sponsored by FAO, the UNDP and the World Bank. It currently supports 12 major international agricultural research and technical assistance organisations, requiring an annual budget of some US$120 million.

The CGIAR is establishing a new organization, the International Service for National Agricultural Research (ISNAR) with its headquarters in the Netherlands. Its working language will be English. ISNAR will provide assistance to developing countries in strengthening their national agricultural research capacities. It will be concerned with research policy, research planning, research organisation and research management.

Those interested in being considered for the post of Director General, ISNAR, should apply to the German Agency for Technical Cooperation (GTZ) enclosing a current curriculum vitae, by not later than *December 16, 1979.* The successful candidate is likely to have:

relevant experience in organisation and management, preferably in the field of agricultural research;
understanding of conditions in developing countries;
knowledge of and contacts with development assistance organisations and development assistance programs.

GTZ will be able to provide additional information.
ISNAR — Secretariat
c/o German Agency for Technical Cooperation (GTZ)
Postfach 5180, 6236 Eschborn 1
Federal Republic of Germany.

W561(A)

CANCER RESEARCH UNIT, University of Western Ontario, London, Ontario. Positions are available for staff at the Assistant or Associate Professor level (non-tenure track) and for postdoctoral fellows and graduate students. Research is focussed on the areas of cellular and viral DNA replication, nucleic acid metabolism in eukaryotic cells, mRNA cloning, and mechanisms of cell transformation.

The unit is well funded by the National Cancer Institute of Canada and is affiliated with the Department of Biochemistry and the Department of Microbiology and Immunology in the Medical School of the University.

Candidates for a staff position should submit a curriculum vitae, statement of research interests, and the names of three referees to Dr. David T. Denhardt, c/o The Administrative Secretary, Cancer Research Unit, University of Western Ontario, London, Ontario N6A 5B7, Canada. Students should apply for admission through the above mentioned Departments. W544(A)

COLAISTE NA hOLLSCOILE CORCAIGH
UNIVERSITY COLLEGE CORK

BIOCHEMISTRY

Applications are invited for a research position supported by a grant from the National Board for Science and Technology.

The Research project is concerned with the relationship between purine metabolism and various stages of meat production.

Applicants should have either an honours degree in Biochemistry, or an honours degree, with Biochemistry as subsidiary subject. Research experience is desirable but not essential.

The appointment is for one year in the first instance with the possibility of extension for one or more years. Salary will be in accordance with qualifications and experience.

Applications, including a Curriculum Vitae and the names of two referees should be sent to Dr Eric R. Tully, Department of Biochemistry, University College, Lee Maltings, Prospect Row, Cork (Ireland). 3791(A)

Please mention **Nature** when replying to these advertisements

ASSISTANTSHIPS

UNIVERSITY OF OXFORD
DEPARTMENT OF THEORETICAL PHYSICS
POSTDOCTORAL RESEARCH ASSISTANTSHIP IN SOLAR PHYSICS

Applications are invited for a Postdoctoral Research Assistantship supported by the SRC for studies of solar flare and active region physics.

The project will make use of observations to be obtained from the Solar Maximum Mission satellite, and experience in theoretical work associated with the physics of high temperature plasmas, including spectroscopic techniques, would be an advantage.

The appointment would be from October 1, 1980, for a maximum of three years. Salary would be on the appropriate point of the SRC IA scale.

Applications with curriculum vitae and names and addresses of two referees should be sent by December 31st to Dr C Jordan, Department of Theoretical Physics, 1 Keble Road, Oxford OX1 3NP. 3796(P)

THE UNIVERSITY OF SHEFFIELD
DEPARTMENT OF MICROBIOLOGY

Applications are invited for a
POSTDOCTORAL RESEARCH ASSISTANTSHIP
financed by the S.R.C. for work on biochemical and genetic aspects of anaerobic energy metabolism in *E.coli* involving several λ-cloned functions. Tenable for three years.

Starting salary up to £5,199 a year. Applicants should possess or expect soon to possess a PhD in molecular biology, genetics, microbiology or biochemistry.

Applications, including curriculum vitae and names of two referees to Dr J R Guest, Department of Microbiology, the University, Sheffield S10 2TN as soon as possible.

ANNOUNCEMENTS

ANNOUNCEMENT

Cold Spring Harbor Laboratory

COLD SPRING HARBOR, LONG ISLAND, NEW YORK 11724

MEETING ON

THE BIOLOGY OF THE VASCULAR ENDOTHELIAL CELL

MAY 6 to 11, 1980

The main purpose of the meeting is to bring together investigators in the field of endothelial cell biology to discuss new findings in the following areas:

GROWTH AND REGENERATION
- Control of contact inhibition
- Tumor angiogenesis factor
- Defined growth factors & hormones
- Extracellular matrix: effects on proliferation & cell morphogenesis

CELL-CELL INTERACTION
- Tumor cells & vascular endothelium
- Platelets, granulocytes, erythrocytes
- Endothelial cell-smooth muscle cell interaction

METABOLISM
- Prostacyclins, angiotensin, serotonin
- Fibrinolysis, plasminogen activators
- Factor VIII, von Willebrant
- Lipid metabolism, LDL, HDL, chylomicrons
- Lipoprotein lipase

STRUCTURE
- Cytoskeleton
- Cell surface
- Basement membrane, Fibronectin
- Surface specializations
  - junctional complexes, coated vesicles, vesicular transport

Persons interested in attending please contact:

Mrs. Gladys Kist, Meetings Secretary
Cold Spring Harbor Laboratory
P. O. Box 100
Cold Spring Harbor, New York 11724

GRANTS and SCHOLARSHIPS

UNIVERSITY OF WAIKATO
New Zealand

HILARY JOLLY PHD SCHOLARSHIP IN LIMNOLOGY

(Vacancy A79/21)

Under the terms of a bequest from the late Dr V H Jolly, the University of Waikato offers an annual scholarship for doctoral work in limnology, for a period of up to three years. Limnological work in the University is centred in the Biological Sciences Department, where the main emphasis at present is on small dystrophic lakes. Work is in progress on their plankton, benthos and palaeolimnology. Opportunities are available for work in these and other freshwater habitats in the Waikato Valley.

The scholarship will carry remuneration of NZ$4,020 per annum for up to three years. An allowance for expenses incurred during the fellowship of up to NZ$750 in any one year may be available. No financial assistance however will be payable to an appointee in taking up the scholarship.

Further information on conditions of appointment and method of application is available from the Registrar, University of Waikato, Private Bag, Hamilton, New Zealand, or from the Association of Commonwealth Universities (Appts), 36 Gordon Square, London WC1H OPF. Enquiries of an academic nature may be addressed to Dr M A Chapman, Reader in Biological Sciences, in the University.

Applications should be in the hands of the Registrar by: *12 January 1980.*

3810(H)

Please mention
Nature

STUDENTSHIPS and FELLOWSHIPS

THE UNIVERSITY OF BIRMINGHAM
FACULTY OF MEDICINE AND DENTISTRY
DEPARTMENT OF PHYSIOLOGY
RESEARCH FELLOW

Applications are invited for a three year MRC financed research fellowship. Salary will be on the scale Research Fellow 1A (£4,333 to £7,521) plus superannuation. Maximum starting salary will be £4,910.

The project involves an electrophysiological analysis of chemo — and baroreceptor afferents to the hypothalmic supraoptic and paraventricular nuclei.

The successful candidate, who will work with Dr M C Harris, should have a PhD, experience with neurophysiological techniques is essential and a knowledge of histochemical technique would be an advantage.

Further information may be obtained from Dr M C Harris.

Applications (three copies) should be sent to the Assistant Registrar, the Medical School, Birmingham B15 2TJ, with a full curriculum vitae and naming three referees by 14th December 1979. 3802(E)

THE UNIVERSITY OF SUSSEX
SCHOOL OF BIOLIGICAL SCIENCES
POSTDOCTORAL RESEARCH FELLOW GRADE 1A

Applications are invited for an SRC financed Postdoctoral Research Fellowship to work in the Schools of Biological and Molecular Sciences on the ecomones which influence the behaviour and physiology of the snail hosts of bilharzia with Dr J D Thomas, Dr F McCapra and other members of an interdisciplinary group working on various aspects of the chemical ecology and biological control of pulmonate snails. The post is tenable until 31st March 1980, with prospects of renewal, to commence as soon as possible.

Research experience in either Biochemistry, Phytochemistry or Physiology, and a broad interest in the field of chemical ecology, would be considered and advantage. Salary on the Grade 1A scale £4333 — £7521 p.a.

Curriculum Vitae and the names of two referees should be sent as soon as possible to Dr J D Thomas, School of Biological Sciences, University of Sussex, Falmer, Brighton from whom further particulars may also be obtained.

3785(E)

THE ROYAL SOCIETY
BRUNO MENDEL FELLOWSHIP

Applications are invited for a Bruno Mendel Fellowship for one year from 1 October, 1980, renewable for one and exceptionally two additional years, from postgraduate candidates normally resident in the United Kingdom, The Netherlands, or Israel, to carry out research in medicine or the biomedical sciences at a university, medical research centre or medical school.

The stipend will normally be at the level of a junior research fellowship appointment in the United Kingdom; additional allowances for travel and superannuation may be provided as appropriate.

Application forms, receivable by 15 January, 1980, and regulations (revised in May 1976) are available from the Executive Secretary, The Royal Society, 6 Carlton House Terrace, London SW1Y 5AG.

3797(E)

UNIVERSITY OF NEWCASTLE UPON TYNE

Applications are invited for the following Fellowships (tenable for two years from October 1980) from persons who have shown themselves able to carry out original research. The value of each Fellowship is £4,333 in the first year and £4,622 in the second year (under review).

SIR JAMES KNOTT FELLOWSHIPS

TWO Fellowships available in any faculty.

LORD ADAMS FELLOWSHIP

ONE Fellowship available for research in any faculty. Preference will be given to candidates who, through family, residence or education, are connected with the former County of Cumberland or whose proposed research has connections with, or will be of benefit to that County.

Further particulars and application forms (which must be returned by 31 December 1979) may be obtained from the Registrar, University of Newcastle upon Tyne, 6 Kensington Terrace, Newcastle upon Tyne NE1 7RU. 3784(E)

UNIVERSITY OF STRATHCLYDE

Applications are invited for a

POSTDOCTORAL RESEARCH FELLOWSHIP

in Laser Physics in the Department of Natural Philosophy to work on a C02 TEA laser contract. Previous experience in laser physics and vacuum technology would be an advantage.

The appointment which is on Range 1A of the national salary structure for research and analogous staff, will have a salary within the range £4,333 to £5,777 (under review) with placing according to age, qualifications and experience. USS benefit. The appointment is until 30th September 1984 in the first instance.

Written applications including a curriculum vitae (quoting R44/79) and the names of two referees should be sent as soon as possible to Professor A.L.S. Smith, University of Strathcylde, Department of Natural Philosophy, John Anderson Building, 107 Rottenrow, Glasgow, G4 0NG from whom further details can be obtained. 3792(E)

QUEEN MARY COLLEGE
UNIVERSITY OF LONDON
LASER MEASUREMENT OF BOVINE SPERMATOZOA MOTILITY

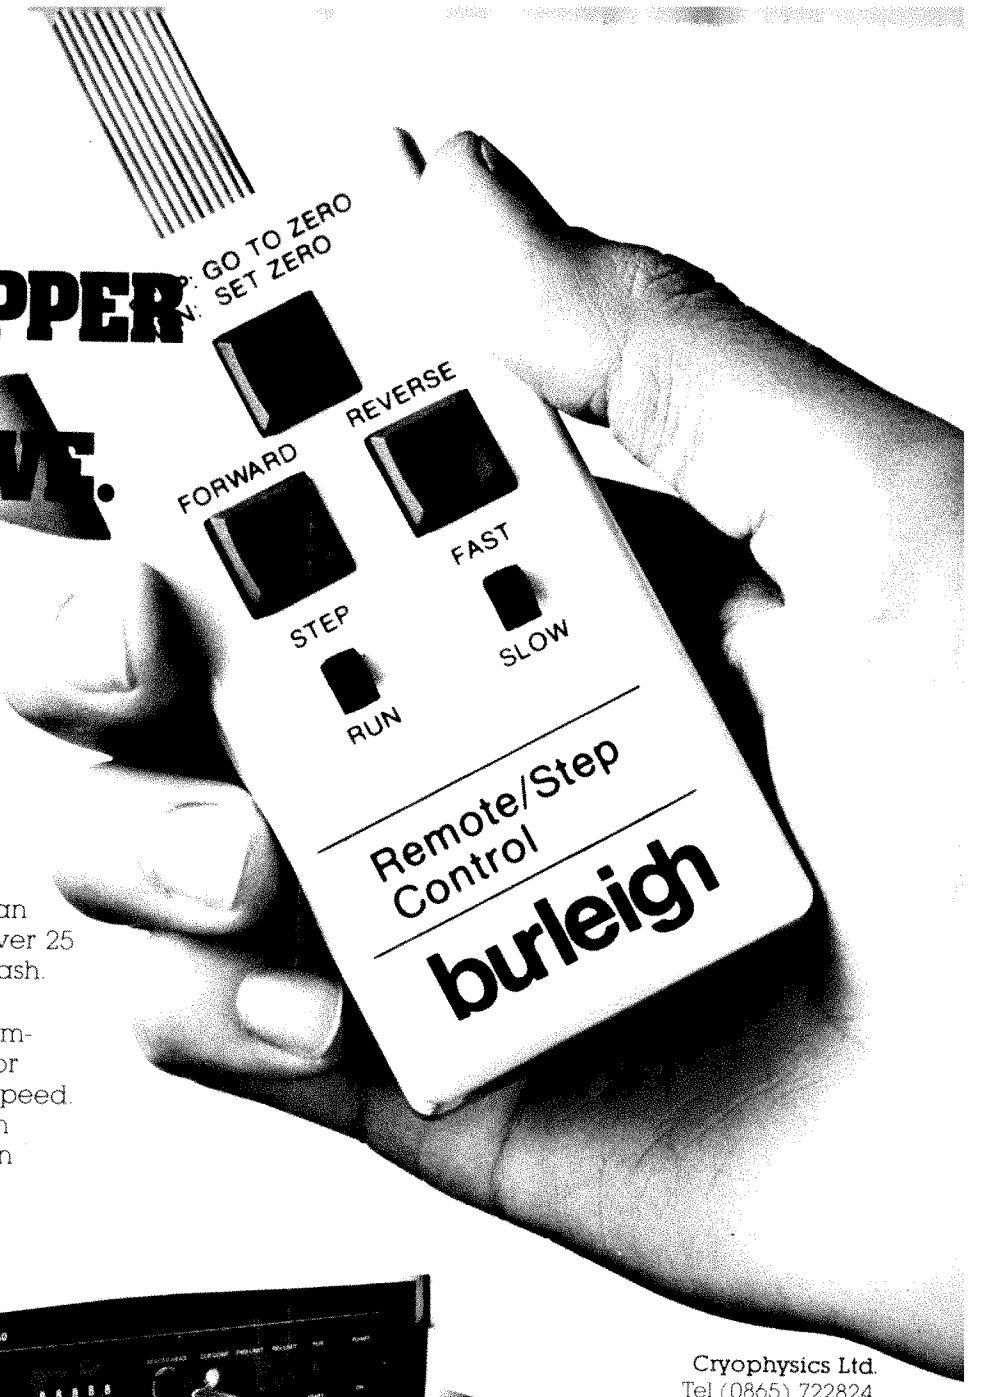
Applications are invited for a 2-year Postdoctoral Research Fellowship for work with Dr D A Ross, in conjunction with the Ministry of Agriculture Cattle Breeding Centre, Reading, verifying the viability of routine assessment of samples of frozen semen, using the new fibre optic Doppler anemometer, and to correlate motility measurements with fertility trials.

Candidates with a PhD in Physics or Electrical Engineering and interest in or direct experience with laser anemometry or photon correlation preferred. Initial salary in range (under review) £5073 — £5650 p.a. (including London Allowance).

Please apply, giving age, qualifications, experience and names of 2 referees, to The Secretary, Queen Mary College, Mile End Road, London E1 4NS. 3809(E)

UNIVERSITY OF WARWICK
CASE Studentship — Kinetics of Diazonium Salt Reactions by Fast Reaction Methods

Applications are invited for a three-year SRC (CASE) Research Studentship in the Department of Chemistry and Molecular Sciences, starting 1st January, 1980; and supervised by Dr T J Kemp in collaboration with Dr J Atherton (ICI Organics). The programme will involve a kinetic study of the decomposition and coupling reactions of ArN_2^+ ions using stopped-flow spectrophotometry combined with a rapid-scanning spectrometer which provides complete u.v. — visible spectra in milliseconds.



Applicants should hold at least an upper second class honours degree in chemistry. Further details may be obtained from Dr Kemp, Department of Chemistry and Molecular Sciences.

Applications should include a curriculum vitae and the names of two referees and be sent to the Academic Registrar, University of Warwick, Coventry CV4 7AL quoting Ref. No: PG/40/79 by 15th December, 1979.

HE HYDRAULIC RIVE/STEPPER)TOR TERNATIVE.

At last. Unprecedented micropositioning capability and low cost. And the nicest thing about Burleigh's all piezoelectric Inchworm™ Translator Systems isn't their compactness and ease of use. Or the unique optical readout accurate to 2μm. Or even their interfaceability with most micro, mini, or mainframe computers. It's the fact that unlike messy hydraulic drives or vibration-prone stepper motors the Inchworm is capable of an amazing 20 nanometer resolution over 25 millimeters of travel with zero backlash.

The Inchworm can be controlled from an optional hand held unit. Command the Inchworm to go forward or backward. Choose the step size and speed. Even select the zero point. And when you're done, the meter reads position relative to the zero point you chose.

Position electrodes. Puncture cells both in vivo and in vitro. Position microelectrodes for intracellular or extracellular recording. Translate the stage in an X-Y microscope for specimen scanning.

The Inchworm is a better alternative to hydraulic drives or stepper motors. The motion is smooth and no conventional micropositioning device can match it for precision and accuracy. It's reliable too with five years of history behind us.

So call Burleigh or the nearest representative to find out why the Inchworm Translator is a better alternative.

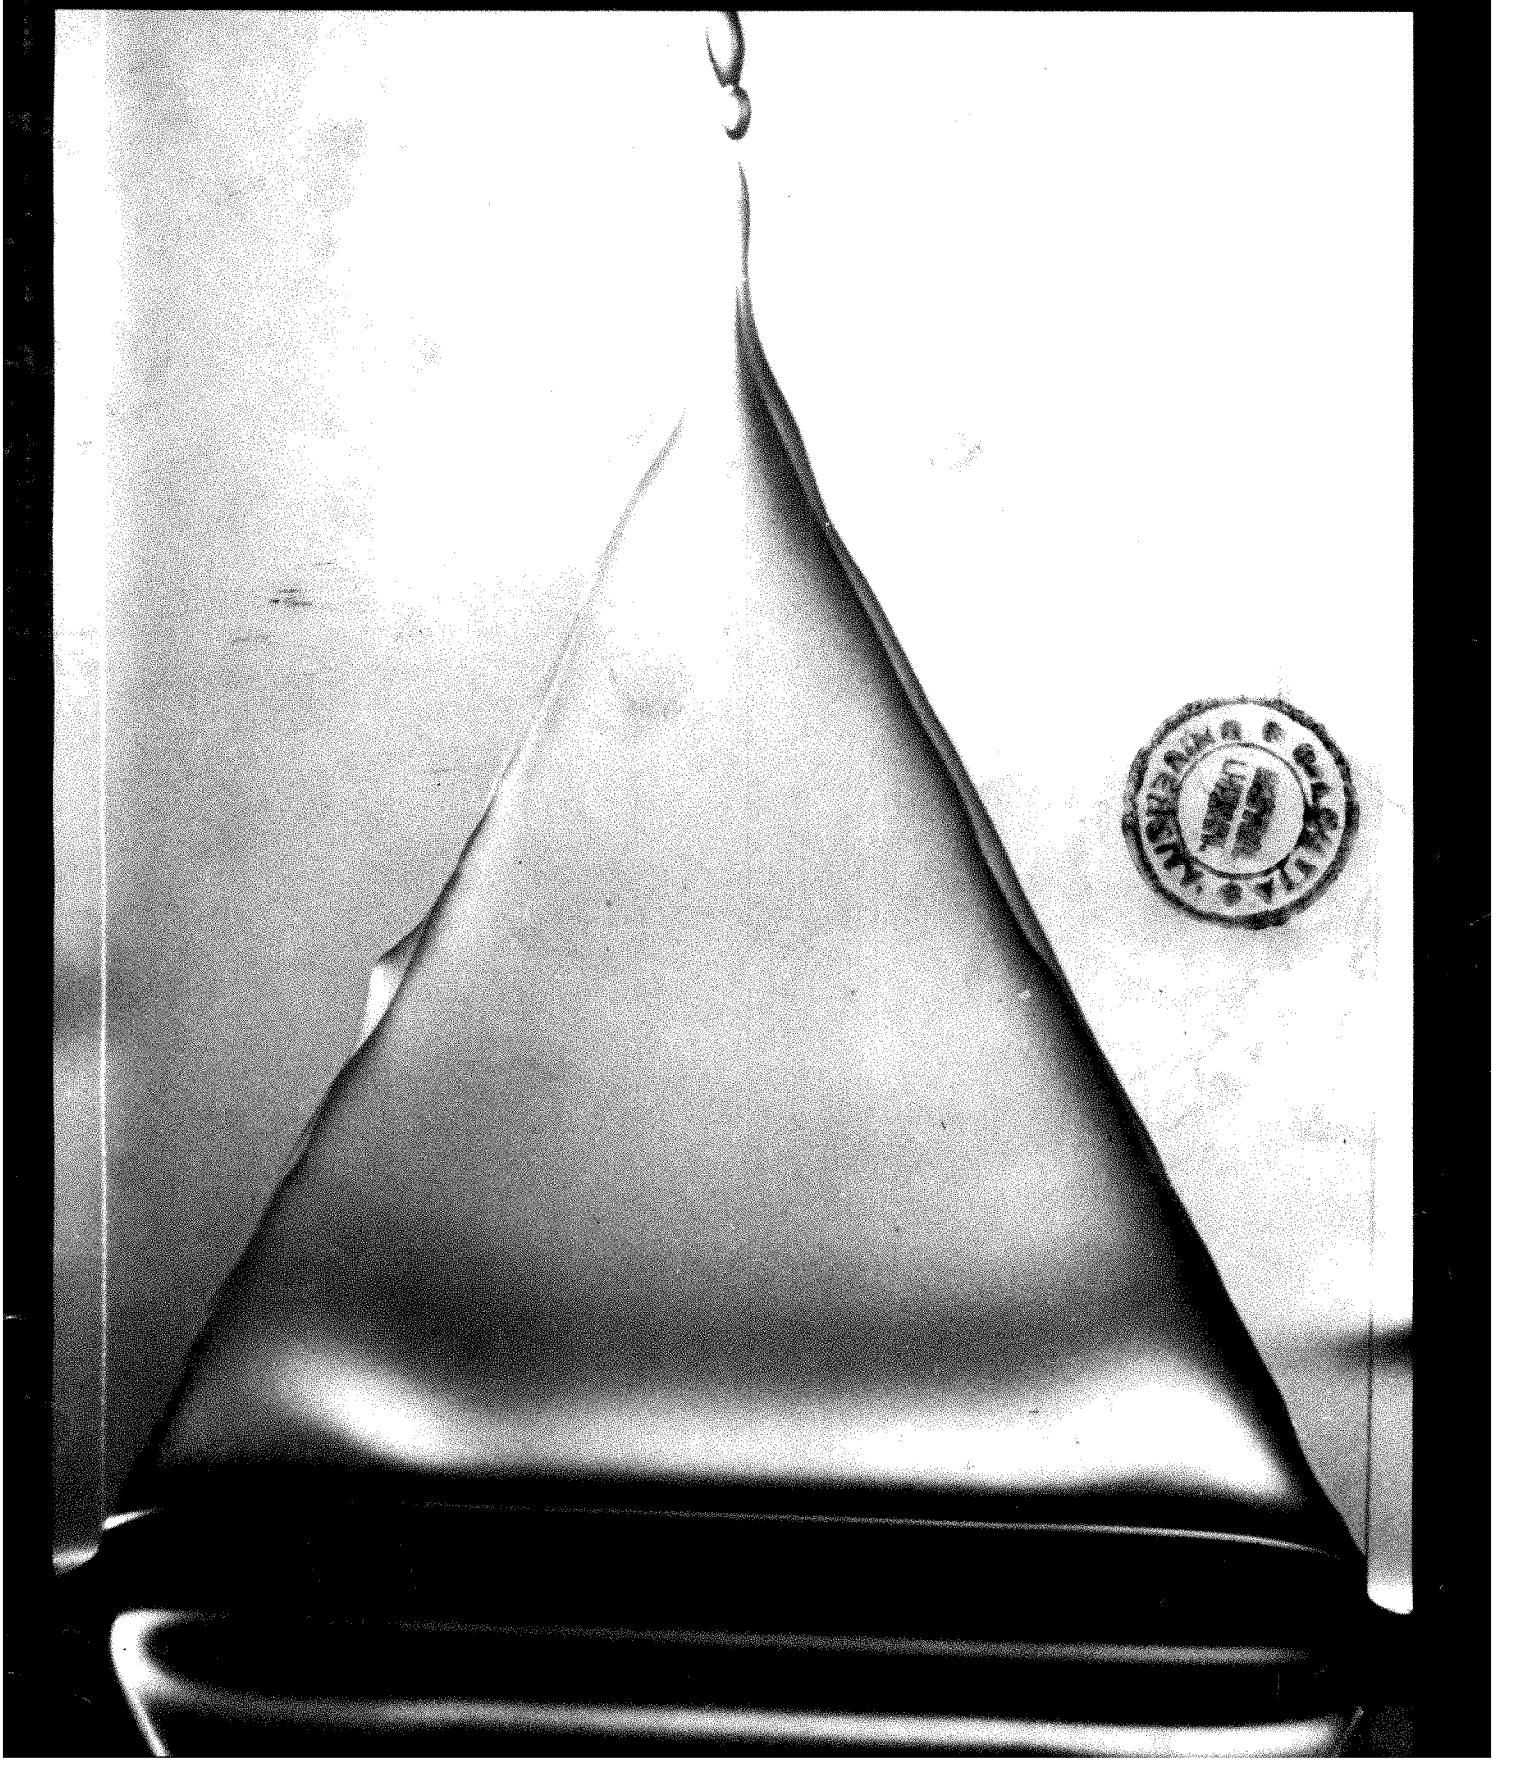
Our new Lysate is out on its own-but is backed by 80 labelled amino-acids

With Amersham's new reticulocyte lysate you just add the labelled amino-acid of your choice and mRNA and incubate. The lysate has been nuclease treated* to remove endogenous mRNA and has been optimised for immediate and convenient use. Each batch is tested for high protein synthesis activity with low background and is available from stock.

Our new lysate is backed by a comprehensive range of about 80 amino-acids labelled with ^{3}H, ^{35}S and ^{14}C, including our very widely used L-[^{35}S]methionine. All are produced to the same high standards of purity.

On its own our new lysate gives you quality, convenience and flexibility.



Together with our range of labelled amino-acids it gives you a complete, high quality translation package you can rely on for protein synthesis.

* based on the method of Pelham, H.R.B. and Jackson, R.S. *Eur. J. Biochem.*, **67,** 247-257, 1976.

The big liberator is here!

A revolution in tissue culture techniques by Boehringer Mannheim!

The neutral protease "Dispase" is the most favourable enzyme in tissue culture techniques for the enzymatic disintegration of tissues into single cells or to keep cells in suspension culture.

The advantages over trypsin are:

* no damage of cell membranes	* increase of the yield of living cells
* no inhibition of cell growth	* no loss in enzyme activity under tissue culture conditions
* tissue disintegration in presence of a complete nutrient medium even with serum	* no contamination by viruses or mycoplasms possible

Commercially available: Dispase, Grade I, Cat. No. 241750
Dispase, Grade II, Cat. No. 165859
Dispase/Collagenase mixture, Cat. No. 269638

HIGH PRECISION. LOW PRICE.

ALZET® minipumps now give you 8 days of precise, round-the-clock drug delivery for only $7.25, or less. And, with a wider range of solvent compatibility, you can deliver some previously difficult-to-solubilize agents.

These tiny, self-powered minipumps can be implanted in laboratory animals to deliver bioactive agents systemically or locally. And since they are small, minipumps can be used easily in animals as small as mice.

The price is now only $72.50 for a 10-pack of Model 2001 minipumps. Enough for a week-long study in 10 animals based on a delivery rate of 1 μl/hour. The Model 1702, which delivers 0.5 μl/hour for up to two weeks, is also available. To order minipumps, or to receive more information, call our toll-free number: 800/227-9953, or send in the coupon below.

Guide to authors

● Review articles should be aimed at a relatively wide readership. Many reviews are invited, but submitted articles may also be accepted; it is advisable to consult us before writing a review article.

● Articles may be up to 3,000 words long with at most six displayed items (figures and tables); they are reports of major research developments.

● Letters are brief reports of original research of unusual and wide interest, not in general longer than 1,000 words; they have at most three or four displayed items.

● 'Matters Arising' permits short discussion (up to 300 words) of papers that have recently appeared in *Nature*.

Articles should be accompanied by an abstract of not more than fifty words. Letters should begin with a paragraph giving the background and main conclusions in terms intelligible to as wide a readership as possible.

Manuscripts may be submitted either to London or New York. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the Système International. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible; exp (*a*) is preferred to e^a if '*a*' is more than one character.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) only one reference number need be used if the reference is to several papers by identical authors.

(ii) first and last pages of references should be cited.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth edn (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished' should be incorporated in text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings should be either photographic prints or in Indian ink on heavy cartridge paper, tracing paper or similar materials. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text, they should contain only essential material. Ideally, an unaltered original and three lettered copies should be provided; labelling on half-tones should, if possible, be avoided entirely. Magnifications quoted should be for the figures as submitted. We are always glad to see artwork for possible use on the cover, but cannot guarantee its return.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

Nature's publishing policy is outlined in **258**,1 (1975) and **264**, v, 11 Nov. (1976).

A maximum speed of wetting	*T.D. Blake and K.J. Ruschak*	489
A CO_2-climate sensitivity study with a mathematical model of the global climate	*S. Manabe and R.J. Stouffer*	491
Carbon disulphide and carbonyl sulphide from biogenic sources and their contributions to the global sulphur cycle	*V.P. Aneja, J.H. Overton, L.T. Cupitt, J.L. Durham and W.E. Wilson*	493
Tidal flexure of ice shelves measured by tiltmeter	*S.N. Stephenson, C.S.M. Doake and J.A.C. Horsfall*	496
A geologically meaningless Rb-Sr total rock isochron	*D. Field and A. Råheim*	497
Visual lateralisation effect in reading Chinese characters	*O.J.L. Tzeng, D.L. Hung, B. Cotton and W.S-Y. Wang*	499

Affinity chromatography – your keys to success!

- high selectivity and low non-specific adsorption for pure product
- ready-to-use for greater time-saving
- porous matrix for high capacity, concentrated product
- excellent flow properties for fast results
- reusable for economical separations

Group specific adsorbents for the key step in your purification

Protein A-Sepharose CL-4B	IgG, antigens, immune complexes
Con A-Sepharose	glycoproteins, glycolipids, polysaccharides
Lentil Lectin-Sepharose 4B	membrane glycoproteins
Heparin-Sepharose CL-6B	plasma proteins, enzymes etc
Poly(U)-Sepharose 4B	mRNA, plant nucleic acids
Poly(A)-Sepharose 4B	mRNA-binding proteins, hnRNA
Lysine-Sepharose 4B	plasminogen, ribosomal RNA
Blue Sepharose CL-6B	serum albumin, nucleotide-requiring enzymes
5'AMP-Sepharose 4B	NAD^+-dependent dehydrogenases
2'5'ADP-Sepharose 4B	$NADP^+$-dependent dehydrogenases

E"E. ' T E SIC OUTFIT OI. 'TS THE WAY TO MAXIMUM MICROSCOPIC PERFORMANCE.

There are many valid reasons why research workers the world over decide in favour of a LEITZ ORTHOPLAN. The most important one is the LEITZ plan-apochromats, which produce images of unsurpassed resolution and edge-to-edge pin-sharpness. They also permit the utilization of a field of view which with large-field eyepieces is up to 140% larger than what has hitherto been possible to observe in a conventional microscope. This means more and better information at a glance, without the need to adjust the object.

There is not a single optical microscopic method of illumination and contrasting for which the LEITZ ORTHOPLAN cannot be adapted very quickly, to be instantly ready for any microscopic problem.

But the possibilities of the LEITZ ORTHOPLAN far exceed the field of classical microscopy.

They make this microscope the central optical component of all quantitative methods of microscope photometry with the LEITZ MPV system, and in electronic image analysis with the LEITZ T.A.S. the LEITZ consultant will be delighted to call on you and to demonstrate in your own laboratory how the LEITZ ORTHOPLAN can solve your special microscopic problems. All you have to do is send us the coupon below.

☐ I should like to know more about the LEITZ ORTHOPLAN and would be grateful for your detailed prospectus.
☐ I should like to arrange a meeting with the LEITZ consultant soon.

At Last! A Reliable Incubator Under $100

Designed for Aerobic or Anaerobic Tissue Culture Experiments

Shown at ASM and FASEB Meetings

With this Modular Incubator Chamber[1] you no longer have to worry about the inherent variability (due to CO_2, temperature and humidity fluctuations) of present day continuous flow and anaerobic incubators.

Simply place your experiment into the sealed chamber, purge the system with the required gas mixture and set in a controlled temperature environment.

Because each chamber is an isolated system you now have the flexibility to design experiments you previously thought were impractical or too expensive.

Chamber and tray components are made from rugged, non-toxic, uv-resistant polycarbonate.

Multi-purpose trays conveniently hold petri dishes, test tubes, T.C. flasks, microtest plates, etc.

Chambers can be stacked and interlocked for agitation or storage.

And now for the best part. The price of the chamber with 3 trays is only $95.- To order or for further information phone or write Billups-Rothenberg, Inc., Dept. N-1, P.O. Box 977, Del Mar, CA 92014 USA (714) 755-3309.

Universities are an international heritage

OVERSEAS students in British universities, whether at the undergraduate or postgraduate level, will have to pay more — much more — for their education from next September. The fees will vary from subject to subject but will range from £2,000 to £5,000 per year; at the same time, sources of assistance for students in developing countries, whose governments are unlikely to be able to find the additional sums, are drying up with the decline in scholarships that the British Council can provide on its trimmed budget.

Not surprisingly, in the weeks since the announcement was made arguments about the folly of the increase have been widely aired — particularly those which point to the financial benefits which accrue to Britain from overseas students. Against these are ranged arguments that if British education is all that good, market-place forces will continue to bring overseas students in droves; and if, on the other hand, it comes off badly in international comparisons, then again the market-place will convey a clear message and we will all have to pull our socks up.

The trouble with the market-place argument is that whilst the prospective purchasers of everything from toothpaste to automobiles can at leisure compare costs and assess values, the specific question of which university in which country is likely to provide the best (whatever that means) education for an individual student is almost unanswerable. Decisions are based as much on tradition and hearsay as anything else. Maybe for this reason, good students will continue to be sent to Britain. No-one yet knows. But whatever happens it is foolish to talk of higher education existing in anything like a market-place.

The real concern over students' fees ought to be the implications they convey, not altogether unjustly, of a developing defensiveness in Britain against foreigners taking any advantage whatsoever of the British taxpayer. Traditionally, British governments have recognised the intagible benefits which come from a generous policy towards students — not least that places of learning are an international, not just a national, heritage and that a leavening of overseas students helps keep them that way. If the present government is seen simply to be milking overseas students for what it can get, then, no matter whether enough rich students can be found from overseas to keep the numbers up, the character of Britain's universities will slowly change for the worse.

Monitoring developments in numbers of applicants is not enough. It says nothing about those who have been frightened off by the price from filling in a form. The government needs to take remedial action now, probably in the form of a scholarship fund, to ensure that deserving students from poorer countries get a chance. □

Threshold treaty would bê a mess

PROGRESS these past few months towards a ban on underground nuclear weapons tests has been glacial. The United States, Soviet Union and Britain continue to meet regularly in Geneva to discuss technical matters such as the number of monitoring stations that each country will have, what instruments the stations will contain and so on. But there seems little sense of urgency, despite the obloquy that nuclear powers are bound to encounter during the Non-Proliferation Treaty Review Conference next year if they have failed to deliver on a treaty which has a high symbolic value to non-nuclear states.

The idea that the treaty might be of indefinite duration has long since been abondoned; a short-term ban of three years with no promise whatsoever of renewal is now the most that will ever be negotiated. But even that now shows danger of being eroded. There are rumours that whilst Britain is at present maintaining an official line that a total ban is still the desirable outcome, privately views are being expressed that a much better treaty would be one which kept the concept of a threshold. A figure mentioned is 15 kilotons. Explosions with yields above this would be forbidden, explosions with lower yields would not.

Technically, this sort of treaty would be next to impossible to police properly. At present the United States and Soviet Union have a threshold agreement that neither will fire devices of more than 150 kilotons, and even at this level there have been occasions when serious questions have been asked about whether particular tests have contravened the limit: such are the vagaries of geology. A reduction of this limit by a factor of ten would cause much greater difficulty, because signal levels recorded by various seismic stations around the world would then be closer to the level of the general noise background. As a consequence the error bars that have to be assigned to yield estimates would expand unacceptably; it would be a foolhardy person who was prepared to say that any particular device was, say, 20 kilotons rather than 15. The consequences of so many false alarms are not difficult to imagine.

There are strong political reasons why a comprehensive test ban should be comprehensive. There are equally strong technical ones. □

US debate heats up over energy conservation strategies

Higher energy prices may encourage more efficient use — but will the poor have to bear an unfair proportion of the costs? **David Dickson** reports

The American poor have little money left for heat or light

THE recent take-over of the US Embassy in Teheran has focused Washington's attention even more sharply on the need to reduce dependence on imported oil. And this in turn has emphasised the gains to be made through measures to increase energy conservation.

Yet the appropriate strategy to achieve energy savings has become a major source of political controversy. At stake is the basic trade-off between energy efficiency and energy equity: if the price of energy is raised to encourage conservation, can this be done without imposing an unfair burden on those who would be proportionately most affected by the higher costs, namely the urban and rural poor for whom energy costs take up to 30 to 40% of the weekly income?

This conflict has been most visible in early sparring between the two main contenders for next year's Democratic presidential nomination. President Carter has made oil price de-control central to his energy strategy, arguing that the price of domestic oil should be allowed to rise to that set by the OPEC countries — and that there should be a 'windfall' profits tax on the oil companies from which the worst effects of the price increase can be mitigated.

In contrast, Senator Edward Kennedy has in recent weeks been arguing strongly against decontrol, suggesting that in current circumstances "it would seriously exacerbate our inflation and produce 'conservation' only as a by-product of a massive recession". Higher prices may in the long run be desirable to encourage economic competition — but in the present economic climate they would be unjust.

Not that the Carter administration has been idle on conservation. Last week, for example, the Department of Energy published proposed building regulations estimated to add 3 to 5% to the costs of new residential and commerical buildings — but to result in energy savings of 20 to 50% through setting overall consumption rates needed to qualify for federal loan guarantees and other benefits.

But after setbacks in other parts of its proposed policy, the administration has recently switched its main focus to energy supply matters, such as the proposed massive programme to develop synthetic fuels. And the conservation ball has been passed back to Congress, where the Senate's Labour and Human Resources Committee is supporting a bill that would provide $2.2 billion within three years to help poor people insulate their homes.

This see-sawing between the administration and Congress reflects the difficulties that surround attempts to devise a strategy for conservation, where the unpredictable effects of policy measures — as well as the complexity of putting them into practice — are even greater than for energy supply decisions.

Indeed it is only relatively recently that the full potential of conservation for reducing energy demand, not only for transportation but also for space heating and other domestic uses, has been accepted in policy circles. And there has been a tendency to lean heavily on the effects of 'price signals' — the expected response of individuals to increased energy costs.

Using such signals, for example, a study prepared two years ago for the National Academy of Sciences' Committee on Nuclear and Alternative Energy Systems (CONAES), produced estimates showing the wide range of energy-use forecasts resulting from different pricing strategies. It predicted, for example, that a four-fold increase in energy costs would lead to energy use remaining approximately constant between 1975 and 2010.

In practice, however, price signals have so far not provided a particularly good guide to the behaviour of car drivers, either in seeking energy-efficient vehicles or in cutting down consumption of petrol. "I am probably less optimistic now about how readily people take to economic signals", Dr John Gibbons, chairman of the NAS panel and now director of the Office of Technology Assessment, said last week.

"I am still convinced that people make rational economic decisions about future choices — but it seems that you still have a lot of social inertia, perhaps because the path to high energy efficiency is complex".

Experience has therefore shown that the relationship between price and consumption is even more elastic than previously thought. This has led to greater consideration of non-price mechanisms, inevitably involving greater federal intervention. At the same time energy problems have become intertwined with broader attempts to cope with inflation.

Here the choice is whether, as Senator Kennedy argues, the government should tackle inflation head-on by trying to keep prices down until the economic situation improves — or to argue that eventually inflation can only be contained by realistic pricing strategies, and that the government's role should be to stimulate the operation of market principles.

"In the long run, it is going to hurt if prices stay down", says Dr Lee Shiffer of the Lawrence Berkeley Laboratory in California, a member of the panel which produced the conservation report for CONAES. "One thing that our study found was that for the majority of consumers, energy standards will only be accepted if . . . the savings are in the same ball-park as the costs."

The panel's calculations show that only when the cost of oil rises to about $30 a barrel do major conservation programmes begin to look attractive. And this strategy is also supported by many environmentalists, who have argued that increased conservation will not only slow the growth of pollution-generating sources, but will also spur the search for more desirable sources of energy, such as solar power.

Such arguments, however, are meeting increasing opposition from community activists and others concerned more directly with social welfare issues. Gar Alperovitz, for example, of the Center for Economic Alternatives in Washington,

0028-0836/79/480432-02$01.00

©1979 Macmillan Journals Ltd

argues that whatever the theoretical principles involved, steps to offset the inflationary impact of increased energy prices are unlikely to prevent the poor from being required to shoulder a disproportionate amount of the burden.

The effects of recent price increases on such groups is illustrated by a survey prepred for the office of consumer affairs of the Department of Energy. This points out that between 1973 and 1977, the median income of poverty-level families increased 34.7%, while the costs of household fuels increased 78%, and has risen even more dramatically since then.

The survey found that for many poor families, food was the first budget item to be cut in order to pay high utility bills. "Since few of them spend much money on anything except housing and food, there is nothing else to eliminate . . . many of them are without heat at all in the winter", the survey says.

If nothing else, current debates have raised a general awareness that energy politics have important equity implications, and cannot be resolved merely by technical arguments. But the tensions between environmentalists and community activists is symptomatic of the disagreement that remains over appropriate strategy.

Many are now demanding a stronger government role in regulating demand, through rationing, heavy energy taxes, and tough conservation standards. They point, for example, to the example of Portland, Oregon, which has recently introduced a statute which requires all home owners to introduce conservation measures if they want to sell or to rent their properties.

"We cannot realistically overcome the inequity of higher energy prices" says one community worker from New York. But with Congress in its current anti-regulatory mood, alternative strategies are unlikely to get very far, and protection for the poor will have to be sought by other routes. □

Canada boosts university research by 32%

THE Canadian government has announced that the budget of the Natural Sciences and Engineering Research Council (NSERC) will be increased by 32% in the financial year 1980-81, to a total of $159.8 million.

The increase is the first of a number of measures expected to be made public in the next few weeks for stimulating Canadian research and development. This is in line with the government's pre-election commitment, reaffirmed two weeks ago by the newly-appointed Minister for Science and Technology, Mr Heward Grafftey, to raise Canadian R & D expenditure from 1% to 2.5% of the gross national product.

The extra money has been provided to the research council, which is responsible for supporting research in Canadian universities, in response to a five-year plan which the council submitted to the government earlier this year.

"We are currently operating with a budget which is 14% lower in real terms than it was ten years ago. This is obviously a very significant increase, although still less than we had asked for", Dr George Macnabb, President of NSERC, told *Nature* last week.

In response to current and projected manpower shortages, the council is planning to introduce a research associate scheme, under which it will provide salary costs and additional research support over a five-year period to post-doctoral scientists at universities prepared to commit 90% of their time to research. About 100 such awards will be made annually.

Another plan is to provide summer support for undergraduates in their second or third year who want to gain research experience. The council is currently working out details on how the extra money for equipment should be distributed. "We are trying to undo the damage of the last decade, and hopefully we can do it in a planned way", says Dr Macnabb.

As for research grants, the precise distribution of awards will not be announced until February, but it is planned that although the major part of the increase will go to basic research, there will be proportionately a larger increase in support for targeted research.

The NSERC'S budget increase has been generally welcomed by Canadian scientists, who in recent months have been lobbying for an end to the decline in federal support for research through groups such as the Canadian Federation of Biological Societies and the Canadian Association of Physicists (CAP).

"The federal commitment to improve support for fundamental research in the universities and to ensure the creation of a healthy and vital university research community is long overdue", Dr Robert Willes of the CFBS commented last week.

Dr John Kucharczyk of CAP, however, warned that scientists still had some reservations. These included: doubts whether the commitment to increased funding would continue for more than one year; doubts whether the provinces and private industry were prepared to provide the support on which the government's strategy depended for research; and concern over the constraints placed on the NSERC by the fact that less than half its requested budget increase had been accepted.

The Canadian government is expected to announce shortly increased funding for both the Medical Research Council and the Social Science Research Council. And the budget to be presented to Parliament in December is likely to include details of tax incentives offered to industry to invest in research and development.

David Dickson

US drops back in biology and maths

THE total number of US papers appearing in the world's leading scientific publications fell by 6% between 1973 and 1977, according to figures released in Washingon last week by the National Science Board, the policy arm of the National Science Foundation.

US prominence dropped particularly in biology and mathematics. In biology, the net number of papers by US scientists in the Science Citation Index's two thousand most influential journals fell by 11%, representing a drop from 46 to 42% of the total biology papers. In mathematics, the proportion of US-authored papers fell from 48 to 41% over the four years.

This decline, which was mirrored but not quite so sharply in almost all scientific disciplines, was partly offset by an increase in the average frequency with which papers published were cited. In 1973 the rate of citation of US papers was 28% above what would have been expected on purely numerical grounds. By 1977 this had risen to 30%.

These figures, based on data gathered by Computer Horizons Inc. from the Institute for Scientific Information, are published in *Science Indicators 1978*, presented to Congress last week by President Carter as the annual report of the National Science Board.

Despite frequent statements to the contrary, the report paints a relatively healthy picture of US research and development, suggesting that an apparent decline in international terms may be largely the result of countries such as Japan and West Germany catching up with the US's previously unchallenged position.

"Among the two major types of research activity — basic and applied — a period of modest growth has persisted for longer than any time since the late 1960s" the report says. Even in industry, it states, expenditure on basic research grew from $719 million in 1975 to $975 million in 1978, an increase in constant dollars of 14% over the years.

The report points out that the "phenomenal growth" which has taken place in energy research and development since 1974 — an occurrence which, contrary to expectations, it says did not take place in other industrialised countries — has slowed down, although perhaps only temporarily. But a shift from military to civilian R & D within the federal budget seem to have been reversed in the last two years. □

Defoliant companies can be sued

A US federal judge ruled last week that five chemical companies which produced the defoliant "agent orange" can be sued by Vietnam veterans. The veterans claim that they were injured by exposure to the chemical, and that their children were deformed. Agent Orange contains the defoliant 2,4,5-T, suspected of containing the toxic contaminant dioxin; it was extensively used in Vietnam between 1962 and 1971.

The veterans want a trust fund to be set up and financed by the five chemical companies — Dow Chemical, Monsanto, Thompson Hayward Chemical Company, Hercules Inc, and Diamond Shamrock — for the benefit of those who, they claim, suffered as a direct or indirect result of exposure to the defoliant. According to the veteran's attorney, claims against the companies could be $40,000 million.

The companies had contended that the 362 veterans are entitled only to veteran's medical benefits, and that the suits should be tried individually in state courts. However, Judge George C Pratt ruled that a suit could be brought against the companies.

The US Defense Department was accused last week of severely underestimating the number of soldiers exposed to Agent Orange during operations in Vietnam. Although the Pentagon has until recently said that all combat zones sprayed with the defoliant were free of army personnel, a report issued last Saturday by the General Accounting Office, the investigatory arm of Congress, said that at least 5,900 marines were within a third of a mile of the areas while or immediately after they were being sprayed. The GAO also says that a further 16,000 marines were within a third of a mile of the sprayed areas within four weeks of the spraying, and it called the army's contention that troops did not enter the area until six weeks afterwards as "inaccurate". In a letter to Senator Charles Percy who had requested the GAO investigation, the Department of Defense admitted that "the chances that ground troops were exposed to herbicide Orange are higher than DOD previously acknowledged". □

UK radical scientists ten years on

THE 10th anniversary of the founding of the British Society for Social Responsibility in Science was celebrated in London last week by a congenial gathering of 200 activists representing a span of 60 years of experience of radical and socialist approaches to science. Five speakers analysed the past and present successes of the "largest single grouping of radical scientists in Europe".

Maurice Wilkins, president of the society, evoked the social atmosphere requiring new approaches to the practice of science by emphasising the turbulent state of world affairs. "Things have changed a very great deal in a very short time. We have seen a continuous disintegration and degeneration of our institutions in modern society over the past 50 years. This disintegration has certain advantages since it increases the possibility of getting outside our conditions. It is difficult to overestimate how strong our social conditioning is and BSSRS correctly has been concerned to show that science cannot escape from these conditions."

Joseph Needham, who is as close to a patron saint as is possible for a political organisation to have, presented a unique mixture of Christianity and socialism with a blessing for BSSRS' past and future work. He affirmed his conviction in the achievements of socialism. "Socialism has been an outstanding success in China which was absolutely medieval in character in the 1940s. I think we have to recognise that India will never get anywhere unless it follows the Chinese way."

Strong continuities exist between the issues of the 30s science movement and those of present groups. Racism, science in war, organising scientific workers, developing links with left wing movements, demystifying science to a larger audience and the position of women in science are all issues that lie outside mainstream "establishment science". One of the great achievments of the 30s movement according to Needham was the campaign leading to the eventual construction of the Anderson air-raid shelters prior to the second world war. "We knew it was important and possible and in spite of government indifference we shamed them into doing it."

Speakers, Dorothy Griffiths, Jonathan Rosenhead and Mike Cooley outlined BSSRS recent history and immediate future plans. In terms of analysis, the group has moved away from the "use-abuse" model of science and technology and is concentrating on developing its understanding of how science is thoroughly integrated into the social fabric through its employment in profitable economic production, its use in social control technology and its use as "a justification for social inequality based on class, race and sex." New activities include a formal Women's Caucus, a working group to criticise the UK government's proposal to count and predict the size of Britain's black population, particularly the proposed introduction of a question on racial origin in the 1981 census, and a working group that will provide an information service to trade unions on the likely impact of the proposed introduction of microprocessor based technologies in particular workplaces. **Joe Schwartz**

London meeting calls for end to psychiatric abuse

THE recent meeting in London of the World Psychiatric Association focused attention, once again, on the use of psychiatry for political repression. Although the 1977 Honolulu Congress of the WPA formally condemned psychiatric abuse, there has so far been little concrete action from its special "Committee to Review the Abuse of Psychiatry". *Ad hoc* pickets at the meeting and Amnesty International in its formal letter to the WPA executive, stressed the need for firm and expeditious action from the Review Committee.

The Amnesty appeal stressed the "consistent pattern" of psychiatric abuse in Romania and the Soviet Union, particularly the latter. Details of over 40 recent Soviet cases were appended, with "symptoms" ranging from Seventh Day Adventism (Eugenius Darguzes) to membership of an unofficial Marxist discussion group (Alehsandr Skobov) and from organising an independent trade union (Vladimir Klebanov) to proposing Academician Andrei Sakharov as a candidate for the election to the Supreme Soviet (Vladimir Tsurikov). In spite of the recent criticism of "Snezhnevskiism" (*Nature* 11 October, page 419) Snezhnevskii-type diagnoses of "sluggish schizophrenia" continue — as does the "treatment" of dissent by massive doses of neuroleptic drugs.

Perhaps one of the most telling comments on psychiatric abuse is the fact that the occasional transfer of a dissident such as M Kukobaka (charged with "anti-Soviet slander") from psychiatric hospital to trial and prison is viewed by Soviet human rights campaigners as a qualified triumph. **Vera Rich**

Galileo formally reprieved

POPE John Paul II has called for a formal reversal of the Catholic Church's verdict on Galileo, who in 1633 was condemned by the Roman inquisition and placed under house arrest for his heliocentric theory of the solar system. The Pope was addressing a special session of the Vatican's Pontifical Academy of Sciences, held to mark the centenary of the birth of Albert Einstein.

He quoted the Pastoral Constitution *Gaudium et Spes* No 36/2 of the second Vatican Council, which deplores "certain habits of mind sometimes found too among Christians, which do not sufficiently attend to the rightful independence of science. The arguments and conflicts which they spark lead many minds to conclude that faith and science are mutually opposed". These words, said the Pope, related in particular to the Galileo case. □

News in brief

US waives air pollution rule for coal-burning power plant: The US Environmental Protection Agency announced last week that it would temporarily waive air pollution rules to allow New England's largest power plant — in Somerset, Massachusetts — to convert from oil to coal two years earlier than planned. The utility had been ordered to convert to coal in 1977 by the Federal Energy Administration, and although the EPA had agreed to the conversion, the need to install pollution-control equipment meant that the conversion was initially planned to be phased in between 1982 and 1984. However the EPA has agreed to a temporary waiver of the pollution rule covering particulate emissions.

Converting most power plants to coal is a key element of the Carter Administration's energy programme, and EPA deputy administrator Barbara Blum said that the waiver, which will not involve the violation of atmospheric air quality standards protecting public health, was an "important milestone" towards energy independence.

British Council of Churches urges abolition of UK nuclear missiles: By a vote of 54-19, the semi-annual Assembly of the British Council of Churches has urged the UK government to abandon its plans to replace Polaris submarine missiles with newer nuclear missile systems. The Assembly resolved that "non-replacement by the UK of its present nuclear strategic deterrent (the Polaris missile system) would strengthen moves for nuclear non-proliferation and urges Her Majesty's government to take a decision to this effect."

In its presentation of the resolution, the Council's Division of International Affairs, argued that "unfavourable consequences" could be minimised by careful implementation of the decision and that there is "no hope of reversing the nuclear arms race until a nuclear weapons state is willing to demonstrate that the arms spiral can go down as well as up. Britain now has a unique opportunity to demonstrate that nuclear non-proliferation is a realistic rather than Utopian goal." At present the UK has four nuclear submarines each armed with 16 missiles which were obtained "at rather advantageous prices" from the US in 1962. Each missile contains three UK manufactured warheads. The US now has 2,141 missiles capable of delivering 11,000 warheads and the Soviet Union has 2,582 missiles with about 5000 warheads.

Jacob criticises new social darwinists: French Nobel Laureate François Jacob has vigorously attacked the "ideological distortions" of biology propagated by social darwinists, racists and others in an attempt to "justify certain models of society". M Jacob is a coauthor of a recent report for the French government on bioengineering and has written a major five part series on biology for the French daily *Le Monde*. In these articles he takes severely to task those who, like the French "new right" or certain sociobiologists, would see in genetic diversity a racial weakness or an excuse to justify inequality and injustice. Indeed, says Jacob, human potential depends on this diversity. "Any effort that aims at the homogenization of the biological properties of individuals — either by hoping to 'ameliorate' them through eugenics or by seeking to encourage one attribute like an aptitude for mathematics or for running — would be biologically suicidal and socially absurd".

Refusnik charged with plagiarism: Dr Vladimir Kislik, a leading figure among Soviet Jewish "refusnik" scientists has been threatened with a charge of plagiarism and breach of copyright. Dr Kislik, whose work has been largely in radiation physics, especially radiation defects in solids, applied for an imigration visa for Israel, in 1973. Permission was refused, on the grounds that radiation physics was "secret", and he was obliged to leave his post at the Kiev Physics Institute. Since then he has worked as a nightwatchman, and as bus-ticket seller, and has been subject to constant police surveillance. Deprived of any way of continuing his scientific career at home, he managed to send abroad a paper on the kinetics of helium release from irradiated samples of austenite steels, which was published in the *Journal of Nuclear Materials* in 1978.

Recently Dr Kislik was warned that a charge is being prepared against him under article 136 of the Ukrainian penal code which deals with plagiarism and patent infringements. This appears to be in connection with a thermokinetic method of He analysis which he developed while at the Kiev Physics Institute, and with the unauthorised publication of his paper abroad.

This is the first time that the smear of plagiarism has been raised against any refusnik scientist, and appears to form part of a new "pre-Olympic" drive against all forms of dissent and nonconformity. Ironically, Kislik himself could have a strong case against the authorities under the said Article 136. As with Academician Veniamin Levich, after being driven out of academic life, Kislik's name "disappeared" from citation of his published papers.

India's wild life projects under spy cloud: Many of the wild life projects which India is currently carrying out in collaboration with western countries have come under suspicion of being convenient covers for espionage in the far-flung, strategic borderland of India. The Public Accounts Committee of Parliament, after investigating various collaborative wild life schemes in India, has implied that a project on migratory birds is involved with the perfecting of biological weapons. The US is the guilty partner in this case and the work undertaken in the swampy, sprawling Sunderban, known for its variety of migratory birds, has come under severe public criticism.

"All the beat produced was three KGB, one MI5 and a brace of CIA!"

Another project that has become a focal-point of public controversy is the "pheasant project" undertaken in collaboration with the International World Pheasant Association of the UK. It involves the selective reintroduction of pheasant in the foothills of the Himalayas in the states of Uttar Pradesh, Himachal Pradesh and Jammu and Kashmir. It is feared that the foreign collaborators might use the pheasant project as a camouflage for spying in the sensitive borderland.

B Radhakrishna Rao

Four thousand in French protest march: One of the largest demonstrations by scientific and technical researchers in the last ten years marched through Paris on 22 November. Responding to a national call from all the trade unions in the scientific sector to demonstrate opposition to the government's reorganisation plan for the CNRS, scientists and workers from this organisation were joined by colleagues representing the medical, agricultural and overseas research institutions of France in a march from the Sorbonne to the Presidential palace. A delegation handed in a protest against a government reform they feel was pushed through without consultation and which will lead to a dismantlement of French research, overdependency on the criterion of profitability and an increasing level of job insecurity for the country's scientists.

Correction: In "UK to tighten asbestos control", (1 November, page 5) crocidolite should replace chrysotile in the second paragraph of the second column. The first sentence of the fourth paragraph in that column should refer to the 0.5 fibre per ml^{-1} limit for amosite.

France faces a cold winter

The discovery of cracks in the tubing of most French nuclear reactors has lead to a strong call for a national debate on nuclear energy. **Jim Ritter** outlines recent events.

TROUBLES, indeed, come not singly but in armies; and over the past two months France's nuclear programme has found itself under siege by a formidable host of them. The leaks of primary coolant which have, for the moment, shut down half of the country's present generation of nuclear reactors, and the discovery of cracks in the tubing of almost all reactors, either under construction or in operation, promises a cold winter for the French people and a series of agonising reappraisals for their government.

The decision was taken in 1969, under the last government of Pierre Messmer, to create an 'all nuclear' electrical power industry. The development programme was placed in the hands of the state electrical generating board, Electricité de France (EDF) which opted for a two-tier, short-term and long-term programme. The short-term programme involves the building of 900 MW pressurised water reactors under licence from Westinghouse. The long term programme involves the development of fast breeder reactors. The present problems lie in the PWR systems.

By the end of August 1979 the EDF had succeeded in putting into operation six PWR reactors, two at Fessenheim, and four at Bugey near Lyons, the latter alone supplying some 10% of present French electrical generating capacity. Three more PWRs at Gravelines, at Tricastin and at Dampierre were due to be integrated into the network by the end of this year, with another 26 to be added over the next five years (some of these to be of 1300 MW capacity).

But on 22 September the two principal French trade unions, the CFDT Confederation Française Démocratique de Travaille (CFDT) and the Confederation Générale de Travaille (CGT), sent an open letter to M André Giraud, the Minister for Industry, signalling the existence of numerous cracks in key components of the cooling system of almost all reactors then under construction and, most likely, in those already in service.

The PWR construction firm Framatome had known of these faults since mid-1978 although neither it nor the EDF had made this information public. This the unions meant to remedy. The government's own report appeared on 3 October and was in substantial agreement with that issued by the unions.

Part of the trouble lies in a metal plate, 3.5 m in diameter and 0.53 m thick, used in the steam generation system between the primary and secondary coolants. The plate is pierced by 6776 holes, each 22.22 mm wide and protected against corrosion by a 10 mm thick layer of Inconel alloy. The alloy is deposited in two stages, both involving the heating of the element to 200°C, generating great thermal stress. It is during the second of these processes, the formation of the Inconel-Inconel bond, that the problem arises. Each plate develops between 30 and 200 cracks from 15 to 20 mm long and 6-8 mm deep. Worse still, it was discovered that similar cracks appeared during the fabrication of the six tubes which connect the reactor chamber with the steam generator, tubes which not only carry the hot, pressurised primary water but also support the entire 400 tonne weight of the reactor itself.

Although these cracks are not dangerous at this stage, Framatone experiments show that they tend to enlarge under the temperature transients of normal operating conditions, leading to possible component failure within 4-6 years, a failure which clearly would have catastrophic consequences involving the total loss of primary coolant.

What then can be done? The steam generating plates are replaceable, though not those in the six reactors already in operation. For these, and for the entry and exit primary tubes, repairs will have to be effected *in situ*. But ambient radiation levels rule out the use of human labour and as yet undeveloped automatic, remote techniques will have to be used. Indeed, the very possibility of such cracks occurring was not even considered in any of the preliminary safety calculations. The only other possibility is permanent shutdown after five years which, given the present cost of 3000 million FF for each reactor, would render the whole nuclear programme economically unfeasible.

These were the facts made public by both government and unions. Along with their report the unions demanded that the loading of fuel elements at Gravelines, Tricastin and Dampierre be halted until further checks were made. The EDF replied 11 days later, in issuing their report, that the loading would continue on schedule. The CGT and CFDT then called out their members in a five day strike which ended in the government's agreement to a cessation of loading and a new investigation. While this second investigation was underway the Ministry for Industry launched a counter-offensive in the media. On 10 October a ministry official said that the government had instituted its investigation long before the unions' announcement, while government spokesman M Marcel Boiteux said during a television interview that "where (cracks) have been found they are not serious; where they might be serious they have not yet been found".

But further trouble had already arisen. On 10 October there was a leak of primary coolant at one of the Bugey reactors, forcing a shutdown. Now under severe pressure, the EDF announced a blanket censorship on any further information on the nuclear programme; all further statements were to be subject to government clearance. In response a petition which had been circulating, calling for a national debate on nuclear energy and the suspension of all work on nuclear reactors until the conclusion of that debate, rapidly gained sponsors and signatures. The discovery of further leaks at two other Bugey plants and the announcement by the EDF on 24 October of their decision to resume loading at Gravelines (followed by a similar decision for Tricastin though not yet for Dampierre) brought things to a head.

The hitherto united trade union front broke. The CFDT, which like the Socialist Party opposes the present form of the nuclear programme, called for a strike at Gravelines to prevent loading. But the CGT, which along with the Communist Party supports an all-nuclear policy, accepted the EDF decision. Since the CGT was the union of the majority of nuclear technicians the CFDT call was heeded by a comparatively small number of workers. Even so, the loading at Gravelines and Tricastin has had to proceed under police protection with technicians brought in from outside the EDF, an unprecedented situation even in security conscious France.

The impact of the national petition for a national nuclear debate, is not yet known. Public opinion polls before the announcement of the cracks showed pro-nuclear opinion ranging from 53% to 62% with an opposition between 24% and 37%. During recent union elections within EDF, however, the anti-nuclear CFDT gained 2.5% while all other groups, including the pro-nuclear CGT, lost ground. Since this swing now gives the CFDT a majority position at Gravelines and Tricastin, any govenrment decision to start up these reactors after loading is completed in a month's time may be expected to spark off further protest.

Meanwhile, with three of its six operating reactors closed down, the EDF is facing difficult choices this winter. It has already called upon industries to help produce part of their electrical needs themselves, and it cannot avoid unpopular power economies in the domestic sector in the months ahead. With the further delays in the commissioning of new PWRs attendant upon the discovery of structural faults, the vulnerability of an 'all-nuclear' policy has become more evident. □

Development: where are the real experts?

This year's expensive jamboree of United Nations conferences on science and technology for development yielded hollow phrases and little else, writes **Sir Ieuan Maddock.** Funds would be better directed to small teams of trouble-shooters who have direct experience of real problems, such as flood control in Bangladesh or health care in Tanzania; the teams would make "blunt appraisals" and recommend practical actions, building up a library of useful prescriptions.

Sir Ieuan Maddock: the jet-setters must be firmly pushed aside

IF noble phrases, robust restatement of the obvious and general amiability of colleagues is the formula for peace on earth and universal prosperity then the sumposium organised by the United Nations' Advisory Committee on the Application of Science and Technology to Development (ACAST) must indeed be regarded as a historic event.

"The New World Economic Order", "Immediate and Total Disarmament", "Free and Open Flow of all Scientific Information", "Global Mobilisation of all the World's Scientists" and many more such phrases crackled and thundered around the chandeliers of the Festsaale of Vienna's magnificent Hoffburg like a Wagnerian overture. The facts that these noble objectives were very far from being achievable, and that none of the world's scientists had even an inkling that they had been mobilised (by whom? for what?) did not deter the faithful. The existence of the Iron curtain, the troubles of the Middle East, the problems of South East Asia, the stresses in Africa, the conflicts in Central and Southern America, the agonies of Northern Ireland and the economic ills of so many countries were brushed aside. Noble declarations were good for the soul.

Down from Olympus

When ultimately the delegates agreed to clamber down from the top of Mount Olympus they proved to be disappointingly mortal. After turning their collective wisdom to such subjects as food and agriculture, health, natural resources, transport, population, and energy, a series of improvised, working groups produced conclusions which were banal in the extreme. Nothing was said which had not already been said far more competently in a multitude of conferences on the same fashionable subjects many times before. The level of originality can be judged by a few quotes chosen at random as follows:

●On natural resources: "Recommends to government that priorities be set for mineral and energy resources, water resources, marine resources and other natural resources in their development policies". "The multidisciplinary nature of the concerned science and technology requires technical cross-sectoral mechanisms for cooperation and co-ordination".

●On transport: "That the integrated policy and planning for transport must be evolved in developing countries, taking into consideration population growth and movement, land use, urban and rural development, agriculture and food production, . . . research and development and comparative study of the development of transport on the international scene in order to avoid errors of the past".

●On communication: "More attention should be given to the value of telecommunications as one of the important instruments for development. The various forms of telecommunications and their usefulness should be investigated. For example radio broadcasts should not be underestimated".

●On population: "Recommend an increase in real terms in the investment in reproductive research and contraceptive development and adoption". "Because population is both a component and beneficiary of development it is recommended that attention be paid to the creation of development models which feature the dynamics of population".

●On human settlements: "Generally there is need for strengthening the scientific, technological and administrative capability for human settlements planning, policies, strategies and implementation to meet the basic needs of the people. This includes re-orientation of architecture, engineering, planning and management of human settlements".

●On environment: "The scientific and technological community is urged to give increased emphasis to interdisciplinarity as an operational concept for tackling the complex land-use problems of ecosystem management".

●On energy: "All possible types of primary energy resources need to be developed including hydrocarbon, coal, nuclear, hydro and solar. When one of these sources is developed even by a few countries it will release non-renewable resources like hydrocarbon for other countries. From this point of view development of coal and nuclear energy appears to be necessary".

●On industrialisation: "These relate to the enormous technological developments of the developed countries as well as the accumulated problems such as unemployment, low productivity, unequal income distribution in the developing countries, posing major challenges to the technological and industrial developments".

Even the strongest digestion tended to become debilitated on a constant diet of this kind of stuff. If one felt prompted to make a comment based on practical realities, one is inevitably felt a bit of a spoilsport. Why diminish the heady delights of playing God.

I came to the conclusion that the ACAST conference was just about the least effective I had ever encountered — that is until I experienced the United Nations Conference on Science and Technology for Development: UNCSTD.

UNCSTD was held in a giant sports hall with some two hundred individual delegations each with its own table, six delegates' chairs, translation equipment and microphone — the minimum kit, it seems, of any serious minded participating country. Several of the larger nations had 'supporters clubs' seated on the sloping galleries around the floor. Each delegation was allotted fifteen minutes to make a statement and these were interspersed by statements from sundry United Nations organisations and a sprinkling of acknowledged non-governmental organisations (NGOs). After the initial ceremonial opening by the Secretary General of the United Nations and by the

Sir Ieuan Maddock is Secretary of the British Association for the Advancement of Science. He represented the Royal Society at the UNCSTD and ACAST conferences. This article has been submitted to the Council of the Royal Society, and it is now published with the Council's approval.

0028-0836/79/480437-02501.00

©1979 Macmillan Journals Ltd

President of Austria, punctuated by two splendid renderings of Beethoven by the Vienna Philharmonic, the procession of statement-makers began.

The distinguished delegate from Ruritania would be invited to the rostrum (we were all 'distinguished delegates') and each would make an almost identical speech. This process started around noon on the first Monday and was still proceeding late on Tuesday evening over a week later. One wit commented that the only worthwhile statement in the whole series had been made by Beethoven on the opening day. It was obligatory to have at least one person sitting at the delegation table — although the hall tended to be embarrassingly sparsely populated by late afternoon, and so there was a process of finding a succession of 'watchkeepers'. Junior staff from the appropriate embassy or academics who chanced to be studying in Vienna were pressed in service.

Action in the corridors

Inevitably most of the action occurred in the corridors and more particularly in the 'groups'. There was the 'Group of 77' which represented an initial gathering of 77 less developed nations (there were by now over 120). Then there was the EEC, the Eastern European Group, and the Western European and other Countries Group (known as 'WEOC'), an Asian Group, an Islamic Group and so on and so on. These were constantly meeting, determining 'positions', negotiating between groups, and colliding with each other in a manner that could have provided a dozen plots for C P Snow. It was small wonder that the only outcome of this much publicised meeting was to be a weak soup of half-boiled ideas and heavily spiced polemics.

Much of the trouble arose from the skew distribution of the interests and outlook of the people who served in the preparatory phase and also the main conference. At UNCSTD the delegates were drawn almost exclusively from the ranks of academia, of national or international research institutes, of bureaucracies and of politics.

It was a remarkable defect of the structure of the delegation that there were so few people present with any direct experience of the application of technology. Why were names like Ford, Siemens, Ericson, Hoechst, Roche, Heinz, Mitsubishi, Massey-Ferguson, General Electric, Brown Boveri, Unilever, and Shell absent? Where were the hospital superintendents, the forest planters, the dam and bridge builders and sewerage plant constructors? Indeed water and sewerage received hardly a mention throughout the conference, presumably because these were hardly fit subjects for eminent scientists to be found to be discussing. Why were consulting control experts absent from this conference? Where were craft-guilds (the analogue of London City and Guilds) the technician training boards (such as EITB in the UK) the inspectorate and the specification bodies (BSI in the UK)? Why were there no farmers, fishery managers, food packaging experts, food inspectorates or catering managers to be seen let alone heard? Should not those with direct responsibility for and experience of operating railways, urban roadways, electricity and gas utilities, ports and harbours, fire fighting and ambulance services or telephone networks be at the forefront of the endeavour to harness science and technology for development?

But the whole conference had been conceived and executed by those who so blinded by the pyrotechnics of research that they failed to see, or to admit to seeing that there were others far more relevant and more experienced than themselves for the task in hand.

Although several speakers pointed to the essentially long time scale between even successful research and its ultimate impact on society on a significant scale, the emphasis on research continued. To point out that there was already one billion people on the planet living at the survival threshold and that this number would at least double and possibly treble in the next twenty years — a mere thousand weeks — could not deflect the research enthusiasts from their course. Indeed it was clear that some of the less developed countries thought that, despite the inescapable validity of the points made, the developed countries were raising these points only wilfully to impede the development of the less fortunate countries.

There was the persistent impression that we were dealing with a 'global R&D fund' and that somehow the developed countries had seized 97% of this. The fact that the R&D figure was nothing more than the aggregate of a great mass of individual and unrelated decisions seemed to be difficult to convey. That economic and social order was a prerequisite and not a consequence of a high R&D expenditure was only vaguely understood.

I feel convinced that this intellectual gap would not have been present had the composition of the people attending both ACAST and UNCSTD been different. If the core of the delegates had been drawn from those with direct responsibility for and experience of *applying* technology then the community of purpose would have bridged the gap of semantics or of doctines. Of the delegates less than 10% could be clearly identified as people with direct industrial responsibility and experience.

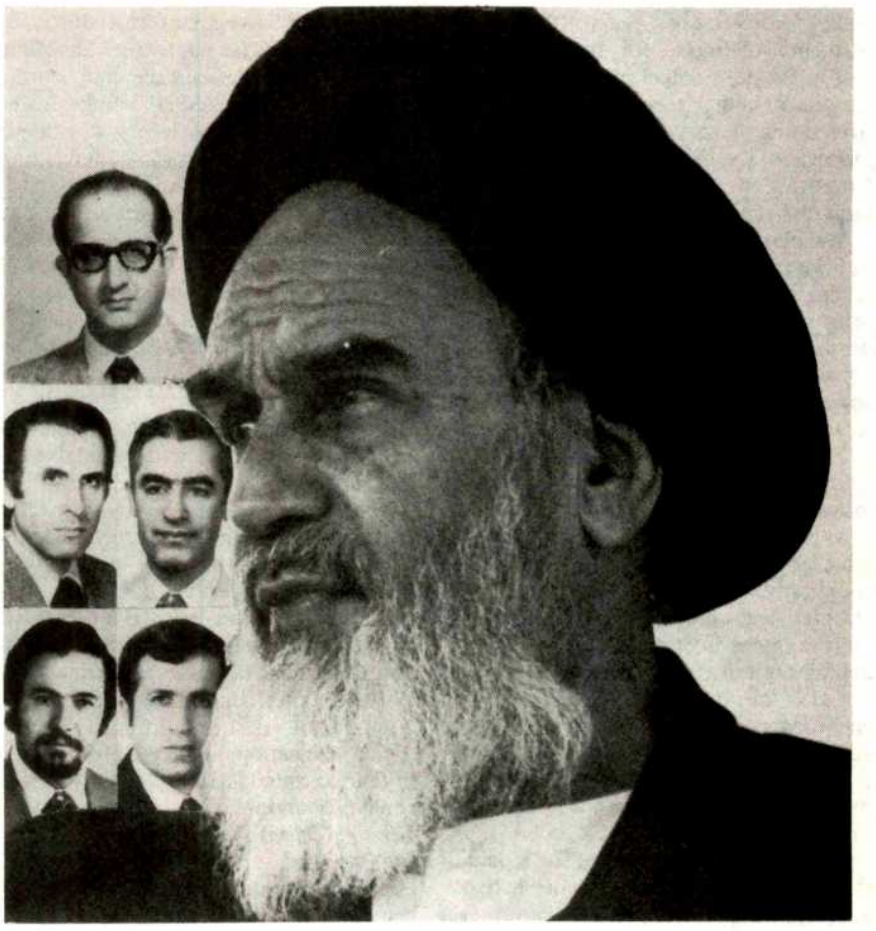
The real experts

Alas! the problems of harnessing the fruits of science and technology to meet the needs of the less developed nations remains. It is a sad thought that in the two years that it has taken to prepare the UNCSTD conference at least one hundred million people have been added to the ranks of the starving and the diseased. It is pointless continuing to hold giant congresses on this or that aspect of the subject and thus providing fodder to that intellectual jet-set who thrive on a menu of agenda drafting and resolution passing. The problem is too urgent and too serious to be left in such hands. All whose who control the aid funds (which in total are quite large if they could be efficiently deployed) should cease to support them.

Instead, small teams of *real* experts, experienced in the technical, human and economic aspects of each subject area, should be brought together. If it is flooding in Bangladesh that is to be discussed, let flood control experts supported by economists, and management experts be brought together to make a long visit to Bangladesh to discuss matters with those directly concerned, give seminars, inspect facilities (including education and training) and to understand the local and cultural constraints. Let such teams write precise and, where necessary, blunt appraisals in cooperation with the local experts and authorities and let them prescribe a plan of action. If it is the health problems of Tanzania, the housing of Peru or communications in Lapland, let the same general procedure be followed. In this way a library of prescriptions would be built up from which both specific and general action programmes would be derived. Above all a network of effective human links would be established between those who are responsible at the national or local level and those who have access to the relevant technologies.

$50 million meeting

Such a scheme would cost money and take time — but the UNCSTD conference took two years to prepare and is reputed to have cost fifty million dollars. The same amount of money deployed over the same time period in the way described above would already have yielded a great fund of exact knowledge on which current and future programmes would be based. The asset would be accumulating as the mosaic of local pictures built up.



It would be easy just to accept their conference as an agreeable if expensive frolic and to excuse it as the price which has to be paid in the struggle to establish some kind of a world society. Time and circumstances do not permit this kind of tolerant cynicism. With one billion people already at the starvation level and the certainty that this number will treble before the end of the century, it is time for action rather than for conferences. The jet-setters must be firmly pushed aside, they should receive no further encouragement by financial grants or assistance in kind and the task must be steered towards those who are realistic and expeditious. There is no shortage of these if only they are given the opportunity and the support. □

Scientific thinking behind Khomeini

Hidden within what appears to the West to be an increasingly anarchic Iranian revolution lie a number of young thinkers and ideologues who are planning a new science and technology for Iran. Bitterly critical of the past, they foresee a science which would respect basic human needs and Islamic values. **Zia Sardar,** an enthusiast for their cause, spoke to them

Right: Ayatollah Khomeini and Iran's science policy makers from top and l to r: F Darvish, A Safai, M N Bahadori, M Roohi, A Barzegar.

How will Iran use science and technology to achieve its aims? And what is the role of science and technology in the realisation of an Islamic vision? "We take it for granted that science and technology are a means to an end, and not an end in themselves", says Dr Mahdi Nejat-Bahadori, Professor of Mechanical Engineering at the University of Shiraz and a member of the sub-committee of the Revolutionary Council on Planning in Science and Education. "So we must ask: what ends do we seek?"

"What we have agreed to do", says Dr Bahadori, "is to redefine development as a compound of economic, scientific, technological and social actions that take the society closer to God. And this is used as a guiding principle in all our planning". Within this principle, activities that promote development will be encouraged. But certain scientific and technological activities are too complex and their impact on society cannot be easily appreciated. "For this reason", says Dr Bahadori, "we want all societal changes to be slow, after due consideration and with full consent of the society. We will not commit ourselves to a particular science and technology policy without full consideration of its impact on the society, debate and discussion by our people of it and of its place in our development goals."

Dr Bahadori emphasises that the Iranian revolution is not an economic revolution. "We are not aiming to have a prosperous or a consumer society. Or to further the interests of a particular class or group. Our aim is to elevate human values and our science policy will reflect this aim in all its manifestations".

Dr Ali Barzegar, Deputy Minister of Higher Education argues that a science and technology which elevates human values and the principles of Islam cannot be imported. "They have to be Iranian through and through", he says. "We are not attracted towards big, conspicuous projects with grandiose goals. We are more interested in small, more humble and humane projects that do not get out of control and that utilise our abilities and resources and develop local capability. We want to use science and technology to meet our basic needs and, as these needs are changing, our planning will be continuous. The important thing to realise is that if you do not want to create a consumer society, or chase excessive profits, production becomes a second order determinant. And you can concentrate on quality".

Within the new scheme indigenous research will become very important. Dr M Zirakzadeh, the former deputy minister responsible for scientific research (now replaced by Dr Syed Mohammad Mahdi Jafari), says that universities, government bodies and private industry will be encourged to tackle local problems and offer viable solutions. Financial incentives will be provided. "But the allocation of funds will be on the basis of projects and their importance to Iran, and not on the basis of organisation and research centres", he says. At present there are some 120 research centres in Iran but, according to Dr Zirakzadeh, more than half of them have either been transferring technology or using foreign consultants to get their job done. "Most of these", says Dr Zirakzadeh, "will either be closed or reorganised on a more appropriate basis."

The old National Research Council, which before the revolution was a special committee of the Ministry of Science under the chairmanship of Queen Farah, has been retained with a new mandate to reorganise and revitalise local scientific research. Fields singled out include agriculture, cottage industry, public health and alternative sources of energy, and the development of links with industry and research bodies.

While the new Ministry of Science (a reorganisation of the old science ministry) has been working on a new science policy, a sub-committee of the Revolutionary Council has been working on the new Development Plan. This plan marks a radical change from conventional development planning, just as the Iranian definition of development differs sharply from the commonly accepted ideas.

It is a sophisticated plan with a 12 year horizon, split into three phases. After a two year transition period, the plan proper begins to unfold. It will operate within fixed limits but there will be considerable scope for change and adjustment. Each phase will start at a presidential mid-term so that changes in details can only be made when a particular government has been in

0028-0836/79/480439-02$01.00

©1979 Macmillan Journals Ltd

power for at least two years. "While there is plenty of scope for rethinking and readjustment, changes cannot be abrupt; and the planning process is continuous and over-riding," says Dr Ataollah Safai, Director of the Centre for National Spatial Planning of the Plan and Budget Organisation.

The plan is based on current predictions of both the needs and requirements of Iran and its resources and potential twelve years after the revolution; and it assumes that during this time oil revenues will decrease considerably. It aims to take Iranian society closer to Islam, and has several strategies running in parallel.

The Development Plan concentrates on four areas. First, the fundamental sector of industry, where the emphasis is put on private small cottage industry. Medium-scale industry will be operated on a cooperative basis with the government and essential heavy industry will be run entirely by the government. "The economy is neither capitalistic nor socialistic", says Dr Safai. "Private industry will be encouraged but monopoly will not be allowed. The state will not interfere with the freedom of the individual nor will it have total control over the means of production."

Second, considerable attention is paid to the distribution of economic activity. Strategies for de-urbanisation and rural development are recommended, and a balance in economic activity is sought between the national, regional and local levels. There will be separate programmes for urban, rural and regional systems.

The third area covered is the development of traditional economic sectors — such as agriculture, industry and services within the context of an Islamic society. Both agriculture and cottage industry are given equal emphasis, but services are limited to a level where they do not interfere with the spiritual and cultural values of society. According to Dr Bahadori, the plan will meet all the basic needs of the citizen while at the same time checking materialism. Finally there is an area covering the environment and the creation of a capacity for future expansion, which are intended to create a physical and spiritual environment conducive to the Islamic way of life.

In the area of science policy, the plan emphasises creativity and originality. Dr Safai says "an environment that encourages thinking, with maximum freedom and inducement for originality and creativity — this is our survival imperative". The plan condemns blind imitation of the Western scientific establishment, and envisages the expansion and reorganisation of the educational system to meet the educational needs of Iran.

For education, the country will be organised into regions which will then receive individual attention. This, says Dr Farrokh Darvish, Director of the Institute for Planning in Science and Education, is already happening. Education in Iran has been mainly a paper chase for better jobs and promotions. "Now we are emphasising education which is geared to regional needs", he says.

Although the Iranian educational system faces many new problems such as an acute shortage of teachers, administrators and text books (most curricula have been changed in content or in emphasis) most of its problems are typical of the Third World: irrelevance to social needs, over-emphasis on higher education and on paper qualification.

Although the new Development Plan has been finalised, it awaits presentation to and approval by the Revolutionary Council. Pending its start, the government has cancelled all technology transfer projects, the nuclear energy programme and heavy industry schemes and has reduced the budgets of the existing educational, scientific and research organisations and frozen all expansions that were planned before the revolution. This has created a certain amount of temporary unemployment and ill feeling in industry and education. But, according to Dr Barzagar there is little else that can be done until the society has direction and the plan comes into operation.

The policies put forward so far in the pre-plan period, have been mostly negative however, and some of them have created an uneasy atmosphere. There is also a real danger of over-reaction to the Shah's extreme policies. The pool of technical manpower created under the Shah is now a major asset which must not be forced into self-exile by over-zealous revenge seekers. The revolutionary leadership should try to preserve all of Iran's human resources.

Most of all, the revolutionary leadership must ensure that balance and clear thinking dominates its policies: zeal can sometimes blind reason and humanity. If Iran can avoid this trap it could become a model for all those who seek to build a society on human and spiritual grounds. □

The multinationals come under scrutiny

THERE is considerable ill feeling in Iran against the American and European multinationals and business concerns. "They have plundered Iran without any ethical or moral consideration", says Dr Barzegar. The sales techniques used in Iran, and no doubt they are now being used in other Third World countries, were a balanced compound of Skinnerian Psychology and gangsterism, he says. "Most of the contracts signed with the multinationals by the Shah are ruthlessly one sided".

There are many examples of such joint ventures and technology transfer agreements. In one case, the Shah agreed that General Motors should set up a subsidiary in Iran with the parent company holding 45% of the capital in the US. The agreement stipulated that all key managerial positions, including managing director, treasurer, sales manager and supply manager would be held by American citizens for an indefinite period and that the US parent company would charge the Iranian company a managerial fee and an engineering fee equal to 15% of the cost of machinery.

Even the track record of Scandinavian companies (Scandinavia is considered to have liberal policies towards Third World problems) is poor. For example, consider the case of the Iranian Ball-bearing Company, established in 1969 as an $8.6 million joint venture with the Swedish firm SKF. Even when the Iranian plant began production, SKF continued to import ball-bearings into Iran. As the local product lacked quality, the Iranian Ball-bearing Company suffered tremendous losses and had to reduce its capital by half. SKF, however, made substantial profits.

Iran's dealings with Electronic Data Systems (ESD) are also notorious. Under the Shah, an imaginary demand for sophisticated computers was created. For example, Dr Shojaeddin Sheikholeslamzadeh, Minister of Health and Welfare under the Shah, was trying to implement a mad drive "to have computer terminals in every village in the country, even the remotest, which will let us know immediately a person is ill, so that a central computer can notify the authorities who will send a helicopter to transfer the patient to the nearest hospital". Similar logic was being followed in the Plan and Budget Organisation, the Social Security Organisation, Iran Air, and other government as well as private organisations.

The EDS signed a contract with the Social Security Organisation to computerise its operations. The company supplied a number of packages, without the necessary manpower. None of the packages, however, could meet the needs of the Social Security Organisation. EDS then asked for its contract to be extended from the original three years to five years and the extension was agreed. After four years and $80 million paid out, it became clear to the Shah's regime that EDS had come to stay permanently. Shortly after the firm quadrupled its original demand, with the project still less than one-third complete, Iran had its revolution.

The firm has now sued the Iranian government for breach of contract and the remainder of its money. The action has been taken in the United States and ESD has succeeded in securing the confiscation of the Iranian government's property in the US.

The nuclear programme of Iran under

0028-0836/79/480440-02$01.00

©1979 Macmillan Journals Ltd

the Shah is another example where the Iranians feel they have been exploited by the multinationals. The programme envisaged a network of 23 reactors, supplying 42% of Iran's electricity needs by 1994. Before the revolution, work on four nuclear plants had started and a further 19 were being negotiated.

According to Mr Mansoor Roohi, Vice-President of the Iranian Atomic Energy Organisation (IAEO) the contracts signed for the four nuclear power plants, two to be built by the German company Kraftwerk-union, an engineering unit of Siemens, and two by the French company Framatome, were "remarkably one sided". He claims that the IAEO were warned not to interfere with the work of the foreign companies in case they used this as an excuse for delaying the work. Framatome charged $2.3 billion to build two pressurised water reactors of 900 megawatt near Ahwaz on the Karun river and Krafstwerkunion charged $3.2 billion for two plants of 1,200 megawatts near Bushehr on the Persian Gulf.

According to the IAEO, in order to meet the demands of its nuclear programme, the Iranian government purchased vast quantities of uranium at inflated prices, and directed it to Germany for enrichment. Once enriched, the uranium had to be stored in Germany till 1994, or until it would be needed by Iran. This had been going on since 1974. The Iranian government paid Germany both for enriching its uranium and storing it.

By 1978 the cost of both projects had more than doubled. 60-70% of work on the German plants had been completed, while the sites for the French plants were still being prepared. When regular payments stopped during the revolution, both companies pulled out. They are now threatening legal action.

Iran has decided not to continue with construction of the four nuclear plants and with plans for the remaining 19. A 50-man special commission concluded that the German company had either failed to fulfill all its undertakings or had done shoddy work.

For example, 400 Iranians were sent to be trained in Germany. The commission claimed that they were given the most rudimentary training not much above the technician level. It also considered that the $7 billion sum demanded by the German company to complete the project was unrealistic and that even the $3.3 billion already paid out was grossly unfair for the work done. Sadeq Tabataba'i, Deputy Prime Minister in the Bazargan government, made it clear that "Iran has no intention of paying the compensation".

Meanwhile, the IAEO is rethinking the long-term energy policy of Iran. "We had to abandon the nuclear energy programme because it was designed to keep us in the hands of the foreign companies for decades. Although we are looking into other sources of energy such as solar energy and hydro-electric power, we have not completely ruled out the nuclear option", says Roohi.

Iran is continuing some of its nuclear research and training programmes and a small power plant of 20-30 megawatts will be kept in operation, so that it can retain some nuclear option for the next 10-12 years by maintaining a certain amount of indigenous capability and manpower. However, Roohi thinks that for the "next decade or so, the time needed for us to explore other alternatives and come up with a new, more appropriate energy strategy, Iran will rely largely on its oil to meet its energy needs." □

Iran faces an environmental crisis

DR Taghi Ebtekar, the newly appointed director of the Department of Environment, says that urgent action is necessary to stop further despoilation of the environment. According to Dr Ebtekar, the Shah's economic policies of rapid industrialisation without any consideration for the environment, as well as rapid urbanisation and a growing population, have resulted in alterations to and destruction of many ecosystems.

Complete river systems, such as those of the rivers Ziandrond and Anzali (formerly Phalavi) in the Caspian, are under severe threat from industrial wastes and emissions. Hard detergents from industrial plants have done serious damage to marine life. The Caspian sea is now heavily polluted with "dangerously high levels of DDT, mercury and other heavy metals". "A recent study carried out after the revolution in the northern part of Iran, reveals that the level of DDT and mercury in mothers' milk is up to five times higher than the accepted critical level", says Ebtekar. The Caspian forests, "unique among the temperate forests of the world" are also in great danger.

Vegetation in the northern part of Tehran, he says, is under heavily polluted water and in Ferozabad natural vegetation is swamped by sewage. Air in Tehran contains up to four times the permitted levels of particulates. In Shiraz and Isfahan, air pollution is attacking cultural monuments and threatening the world renowned Iranian architectural heritage.

Soil erosion and soil pollution are also major worries for the department. In the steppes of western Asia, for example,

Traffic pollution is a major problem.

enormous areas are turning to desert. The situation has become so serious, according to Ebtekar, that unless measures are taken to halt and reverse the process, there will be total loss of vegetation over wide sectors with consequent erosion, floods and dust-storms. In other areas, soil, a scarce and precious commodity in Iran, is being polluted by pesticides, heavy metals and fertilisers.

Ebtekar blames the Shah's economic policies for much of the urban pollution. For example, "the Shah promoted private transport and ignored public transport. As a result we have almost 1.2 million cars in a city of 5 million people. Over 80% of urban pollution is the result of exhaust fumes". The Department of Environment has persuaded the government to introduce new, more comfortable buses and to expand the bus routes. It is planning legislation to limit the use of private vehicles and heavily leaded and poor quality petrol. Iranian vehicles will also require "certain devices" to eliminate hydro-carbon and carbon monoxide fumes.

Legislation is also being prepared to enforce appropriate waste-treatment facilities in polluting industries. Sets of National Emission Standards have been developed for application to most industries throughout the country. The department also plans a wholesale conversion to natural gas both for industrial and domestic fuel. Conversion had already started in Tehran before the revolution and will soon be extended to Shiraz and Isfahan.

The department administers 62 reserves for protection of the floral and faunal resources of Iran, constituting one of the most comprehensive programmes for nature conservation in Asia and the Middle East. A number of endangered species are protected in accordance with the wildlife regulations. Of the animals in this category, only the Caspian Tiger (*Felis tigris*) is genuinely endangered, possibly being extinct in Iran. A number of other species, such as Asiatic Black Bear (*Selenarctos thibetanus*) and two species of gazelle and Onager, once believed to be extinct, are now considered safe.

Conservation and protection of wildlife and natural environment are dictated by Islamic law, says Ebtekar. As such, conservation is being promoted at the popular level. "We are conserving our natural resources for the people", he says. "The people must have access to our wildlife, wetlands and other natural resources. We do not want to isolate conservation areas and preserve them as museum objects. Neither will we limit access to conservation areas to certain privileged classes. Everyone will have access to conservation areas as long as conservation laws are obeyed". □

correspondence

Three Mile Island not "a major disaster"

SIR, — I am writing to comment on the article in your issue of (8 November, page 120) on the Three Mile Island report. In the heading you refer to the accident as "a major disaster". In the text you write "the worst accident in the history of the US nuclear programme". The reader might think there must have been a large number of people killed and injured. In fact there were no deaths and no injuries except psychological. Estimates of the long-term consequences have suggested that a few (less than 10) additional cancers may ultimately develop in the population exposed, an effect likely to be far outweighed by the cancers caused by an extra packet of cigarettes smoked by the same population, or the additional traffic accidents due to the upheaval. How about deaths from bronchitis due to pollution of the air from coal-fired power stations and factories?

A journal of the standing of *Nature* should not be a vehicle of sensational reporting. Many of the recent comments in your columns have shown a total lack of sense of proportion in that the dangers of radiation are never put in the context of the risks we all accept in daily life, nor of the risks attached to not using nuclear power. An irrational fear of radiation has been built up by the popular press and other media; serious journals such as *Nature* should take a more rational and responsible attitude.

Yours faithfully,

D.K. BEWLEY

Medical Research Council, London, UK.

Scurrilous comments belie Egyptian-Israeli cooperation

SIR, — It was difficult to understand the relevance of Dr Galal's comments (11 October, page 424) on the article by Z Sardar (2 August, page 350). The hostile views expressed by the author were in complete defiance of the brave and new approach of Egypt's President Sadat. In spite of Dr Galal's comments I hope that not all the scientific community in Egypt share his views.

It seems that during the twenty years he has been science editor of *Al Ahram*, Dr Galal has adopted the political approaches, but has failed to overcome the psychological gap to which President Sadat has referred many times. What is the relevance of Dr Galal's remarks on "Israeli arrogance in science and technology" to the potential benefit to scientific cooperation? Where did he get his impression of the "superiority complex" of Israeli scientists; or where did he get the idea that Israeli scientists regard their Egyptian colleagues as incompetents who need teaching by us?

I would like to remind Dr Galal that Israeli science has suffered no less than Egyptian science from the continuous wars, and his scurrilous statement on the "colossal funds and privileges that Israel is getting from rich Jewish communities" is far from being "objective, realistic and frank". The money that was given to Israel has been spent to absorb hundreds of thousands of refugees from all over the world, mainly from Arab countries. Was the money from rich oil-producing Arab countries used to improve the condition of the Palestinian refugees? They were kept for more than twenty years in the most miserable conditions and used as a political football. Is that not depriving the Palestinians of their right to live as human beings? The Palestinian problem will be solved only when the Palestinian policy makers stop aiming at the destruction of Israel and recognise the right of the Israelis to live in their homeland. I hope that the Egyptian people, including the scientific community, now agree with their President and recognise the State of Israel, in spite of the problems that still remain to be solved.

Were this to be so, I feel sure that true cooperation between scientists from Israel, Egypt an the world can be achieved, to the benefit of all the peoples of the area.

Yours faithfully,

Z. BEN-ISHAI

Technion, Haifa, Israel.

Antijewishism

SIR, — The style of the letter from Mr Salah Galal (11 October, page 424) is perhaps appropriate for *Al Ahram*, but for *Nature* it seems to be unusual. Though some of the Israeli scientists may have superiority complexes or may be arrogant, the supposition of a national superiority complex and arrogancy of Israeli scientists in general is nothing else than antijewishism. Thus, disregarding their demagogic content, the arguments and statements of Mr Galal have a diminished value because of their motivation by his obviously inherent antijew emotions.

Yours faithfully,

LAJOS ERNST,

Freie Universität Berlin, West Germany.

Distorted interviews in East Germany

SIR, — When I attended the meeting of the Federation of European Biochemical Societies (FEBS) in July 1978 in Dresden, I was invited to give an interview to the Press. This was conducted in German and recorded.

Now, in November 1979 I am surprised to receive "with thanks for my collaboration" a book with contributions to mark the thirtieth anniversary of the GDR (*Of the Birth and Growth of the GDR*, Zeit im Bild, Dresden) in which my question-and-answer interview has been included in the form of a 500-word statement in English. The translation has resulted in a eulogy of the GDR and of GDR scientists, which in its exaggeration is ludicrous. The poetic licence of the translation has caused subtle, and some not so subtle, changes; but when — to give but one example — I am quoted as referring to "a secure existence free from worries of unemployment", I am absolutely certain that I said that I was not competent to answer questions on full employment in the GDR.

I do not blame the colleagues who organised the FEBS meeting in Dresden, of which I still retain a happy memory, but would counsel visitors to the GDR to learn from my experience.

Yours faithfully,

H LEHMANN

University of Cambridge, UK.

Health care in India

SIR,—Anil Agarwal's article on 'barefoot doctors' in India (30 August, page 716) creates the impression that a new health policy was launched in April 1977 after the Janata Government took over. In fact, the community health worker (CHW) made his appearance in the planning of the Ministry of Health of the government of India much earlier. In 1972, he was called the Rural Medical Practioner (RMP). The previous government had hoped to deliver a modicum of health care to the entire country, using RMPs, by 1976. It is apparent that the goal was never reached.

The problem in India at present is not that of an inadequate supply of doctors; it is that of maldistribution. The reason for this geographical lopsidedness in the distribution of health care personnel is that recommendations of the Bhore and Mudlair committees were never fully implemented. Professional isolation, lack of adequate facilities in the practice of scientific medicine and often a lack of personal security are a result of this apathy on the part of successive governments in India in implementing the recommendations of its own specialised committees.

To answer the question with which the article ends: yes, there are alternatives to the CHW scheme. Building physical facilities for health care in the rural areas (as was recommended more than two decades ago) may take another two decades to accomplish. In the meantime, doctors could function efficiently if organised along the lines of the Indian Administrative Service or the Indian Police Service.

The junior-most officers of these cadres very often live in towns, where all the facilities they are used to are easily available, and commute to their places of work in the different villages. Doctors in an Indian Medical Service could do the same.

The children of these doctors could then attend schools which their parents think are reasonable, thereby eliminating one major reason for their reluctance to work in rural areas. Professional isolation would be done away with at the same time, as they could consult with each other on returning to the town after the day's work. Coverage at night could be provided on a rotational basis, akin to the duty hours spent as house-officers in urban hospitals. All this of course implies government expenditure.

Another alternative is completely outside the government. Such a scheme would draw on the private sector — the mini-international companies which Anil Agarwal has described in another of his articles (23 August, page 625).

It has been shown to work on an experimental basis, as the Social Work and Research Centre, at the village of Tilonia in Rajasthan. Why not use it as a model for the other parts of the country as well? Contrary to Agarwal's conclusion, one would hope that CHW scheme or the RMP scheme, call it what you will, does die a speedy death. If not, such half baked medical care will bring untold misery to a vast and gullible public in rural India.

Yours faithfully,

BEHRAM PASTAKIA,

Michael Reese Hospital and Medical Centre, Chicago, US.

news and views

Production and respiration in animal communities

from Robert M. May

A WIDELY-quoted generalisation about natural ecosystems is that the efficiency of energy transfer from one trophic level to the next is around 10%; that is, about 10% of the net production of plants ends up as net production of herbivores, about 10% of this makes its way into net production of the first level of carnivores, and so on. The generalisation is largely based on studies of freshwater lakes and of laboratory aquaria, conducted in the 1950s. One early articulation of this notion is in Slobodkin's elegant and influential *Growth and Regulation of Animal Populations* (Holt, Rinehart and Winston; 1961), where his speculative list of candidates for valid ecological generalities leads off with "Food-chain efficiencies and ecological efficiencies in nature are approximately constant for all species".

Unfortunately, subsequent research on terrestrial and on other kinds of aquatic communities has overthrown this appealing generalisation, showing that the efficiency of energy transfer from one trophic level to the next can vary very widely. This is a pity, for valid 'ecological laws' are thin on the ground, and we can ill afford to lose any of the few we thought we had.

To determine overall efficiencies of energy transfer, two questions must be answered. First, what fraction of the net production at one trophic level is actually assimilated by creatures at the next level? Second, how do these creatures apportion the assimilated energy between net production (growth and reproduction) and respiration (maintenance costs)? The second question is amenable to fairly precise answers, but the first question is messier, as it can involve both particularities about the fraction of material that is assimilated rather than excreted by a given species and generalities about the overall fraction of net production at one level that is actually used (consumed) by the next level. Some of these problems and ambiguities can be made more explicit by considering, say, mice and weasels. If we focus on the weasels, it is in principle straightforward to determine the efficiency with which 1 gram or 1 calorie of mouse eaten is transformed into grams or calories of weasel. If we focus on the mouse population, it is hard to determine what fraction of their total biomass appears as net production in the next trophic level. Indeed, the answer ultimately depends on how we keep the books; the very notion of 'trophic level' does not stand up to close examination (where, for example, do the decomposers belong?).

Humphreys (*J. Anim. Ecol.* **48**, 427; 1979) has recently drawn together a large body of literature, to determine the relationship between annual production P and respiration R in natural populations of animals. This synoptic study sheds light on the general issues discussed above. It also has more immediate practical applications. If a relation between P and R can be confidently established for a given group of organisms, then for a species in this group only one of the two quantities need be measured directly, which can be a helpful short-cut in compiling energy budgets for communities; several people have used the earlier study by McNeill and Lawton (*Nature* **225**, 472; 1970) for this purpose. Humphreys analyses a total of 235 energy budgets culled from the literature, and he emphasises that a great variety of different assumptions and possible biases have gone into the individual studies.

Examining regression relations between P and R, Humphreys shows that homeotherms (loosely, warm-blooded animals) can be separated into four significantly different groups: insectivores; birds; small mammal communities; and other mammals. Poikilotherms (cold-blooded animals) separate into three groups: fish and social insects; non-insect invertebrates; and non-social insects. The invertebrate groups further permit significant separation into trophic categories of herbivores, carnivores and detritus feeders. In no case is the relation between P and R significantly different from a simple linear one. The fruits of Humphreys' analysis are summarised in Table 1, which shows the mean 'production efficiency' $P/(P+R)$ or fraction of assimilated energy ($A = P+R$) that is devoted to net production, for the various groupings.

Several interesting patterns emerge. Both for non-insect invertebrates and insects other than social insects, the production efficiency is significantly lower for herbivores than for carnivores and

Table 1 Mean production efficiency, $P/(P+R)$, for various groups of animals.

Group	Mean production efficiency (per cent)	Sample size
Insectivores	0.9	6
Birds	1.3	9
Small mammal communities	1.5	8
Other mammals	3.1	56
Fish and social insects	10	22
Non-insect invertebrates	25	73
Non-social insects	41	61
Non-insect invertebrates		
herbivores	21	15
carnivores	28	11
detritivores	36	23
Non-social insects		
herbivores	39	49
detritivores	47	6
carnivores	56	5

Nature Vol. 282 29 November 1979

Table 2. The assimilation efficiencies, or percentage of plant production consumed by feeding-animal species, for various systems.

Plant	Consumers	Percentage of productivity consumed
Beech trees	Invertebrates	8.0
Oak trees	Invertebrates	10.6
Maple–beech trees	Invertebrates	6.6
Maple–beech trees	Invertebrates	5.9
Tulip–poplar trees	Invertebrates	5.6
Grass + forbs	Invertebrates	4-20
Grass + forbs	Invertebrates	<0.5
Alfalfa	Invertebrates	2.5
Sericea lespedeza	Invertebrates	1.0
Grass	Invertebrates	9.6
Aquatic plants	Bivalves	11.0
Aquatic plants	Herbivorous animals	18.9
Algae	Zooplankton	25.0
Phytoplankton	Zooplankton	40.0
Marsh grass	Invertebrates	7.0
Marsh grass	Invertebrates	4.6
Meadow plants	Invertebrates	14.0
Sedge grass	Invertebrates	8.0

detritus feeders. A plausible explanation is that biochemical conversion efficiencies are higher for animals eating other animals than for animals eating plants. Other patterns are shown by Humphreys to be conspicuous by their absence: there is no significant correlation between production efficiency and the magnitude of production (that is, no correlation between P/R and P or R); there is no correlation between production efficiency and animal weight; and, with the groups set out in Table 1, species with different habitats (aquatic and terrestrial) do not have significantly different production efficiencies. Humphreys makes the further point that "there is no quantum jump in production efficiency between poikilothermic and homeothermic animals", but I think Table 1 suggests such a distinction is real (with homeothermic production efficiency typically in the range 1-3%, poikilothermic in the range 10-40%). Admittedly the scatter around the mean values for a given group is such that some social insect species have production efficiencies lower than some mammal species, so that there is no 'quantum jump' between homeotherms and poikilotherms, but the tendency for the typical poikilotherm to have a production efficiency an order of magnitude larger than that of the typical homeotherm remains. Warm-blooded beasts pay a noticeable cost, relative to cold-blooded ones, in order to keep their metabolic machinery ticking over at a constant temperature.

For a community of interacting species, we can get some idea of the overall 'food-chain efficiency' with which energy flows from one trophic level (n) to the next ($n+1$), by combining the mean production efficiencies at level $n+1(P_{n+1}/A_{n+1})$ with estimates of the fraction of the productivity at level n that actually is consumed (the assimilation efficiency, A_{n+1}/P_n). Pimentel, Levin and Soans (*Ecology* **56**, 381; 1975) have brought together several rough estimates of the percentage of plant production that is consumed by the animal species that feed upon it; their compilation is summarised in Table 2. As mentioned above, any such estimates of assimilation efficiencies suffer, *inter alia*, from the arbitrariness inherent in a crude classification into 'trophic levels'. Convolving Table 1 with Table 2, we see that food-chain efficiencies can vary over two or more orders of magnitude, from less than 0.1% to more than 10%.

In the early 1960s, the tentative '10% rule' engendered enthusiasm for ecological generalisations. The subsequent collapse of the rule, giving way to the complicated variety of patterns shown in Table 1, has, in my opinion, led to an excessive disenchantment with such generalisations. I think the time is ripe to return to these questions, trying to understand the patterns documented by Humphreys and others, both from 'below' (in terms of thermodynamic constraints on production efficiency in different kinds of animals) and from 'above' (in terms, for example, of the possible constraints that energy flow may impose on food web structure). □

Order in amorphous polymers

from Paul Calvert

THE extent of order in the amorphous state of polymers has been debated for many years. Likening the polymer melocules to strands of spaghetti it is difficult to see how they can be packed to high densities unless the strands are largely arranged parallel to their neighbours. After the Chemical Society's recent Faraday Discussion* on Organisation of Macromolecules in the Condensed Phase the situation seems much clearer than two years ago (see *News and Views*, **271**, 507; 1978).

Two types of order have been postulated for amorphous and glassy polymers, the orientational correlations just mentioned and local density fluctuations with regions of tight packing separated by a less dense matrix or by boundary zones. The latter were apparently demonstrated by Yeh and Geil about 10 years ago. They observed 2.5 nm nodular structures in many glassy polymers with electron microscopy in bright and dark field as well as in fracture surface replicas. At the recent meeting D.R. Uhlmann (Massachusetts Institute of Technology) reviewed his small angle X-ray scattering (SAXS) results which show only enough scattering to be consistent with the small thermal fluctuations in density, frozen in at the glass transition temperature in polymethylmethacrylate, polyethylene terephthalate, polycarbonate, polyvinyl chloride and polystyrene (PMMA, PET, PC, PVC, PS). This does not eliminate the possibility of heterogeneities whose density differs significantly from the bulk density but they must be present in very small quantities. Uhlmann also concluded that the bright and dark field electron microscope observations of small nodules were due to electron diffraction effects.

Thus the 'typical' amorphous polymers are essentially homogeneous. Epoxy resins are not but SAXS cannot distinguish between small quantities of voids and larger quantities of low or high density nodules. G.C. Stevens (CEGB, Leatherhead) said that small aggregates could be detected in unreacted liquid epoxy resins by light scattering. P.H. Geil (Case Western Reserve University) pointed out that he had seen annealing of nodular structures in amorphous polyethylene (PE) and in plasticised and unplasticised PVC. It does seem reasonable that crystallisable polymers such as PE should form crystalline nodules at low temperatures. PVC is frequently partly crystalline and its structure is most dependent on the polymerisation conditions, so any strange behaviour is plausible, and important, in this polymer.

Thus there are heterogeneities in some systems and possibly in small amounts in

*Held at the University of Cambridge, 25-27 September, 1979.

0028-0836/79/480444-02$01.00

©1979 Macmillan Journals Ltd

'typical' polymer glasses, which could still affect the fracture and optical properties. The nodules often seen on fracture surfaces seem to be an artefact.

Most of the evidence presented at the discussion was against orientational order but most of it was on PE and paraffins which are atypical in that the chains are very flexible. E.W. Fischer (University of Mainz) and P.J. Flory (Stanford University) reviewed a range of techniques which point to a lack of regular order. Small angle neutron scattering shows that chains have the same radius of gyration in the glass and melt as for the ideal random walk found in θ-solvent. This result seems quite general, having now been seen for PS, PMMA, PE, polypropylene and polyoxymethylene. Orientational order would be expected to lead to chain expansion, whereas if anything this random coil is a rather contracted state. Infrared and Raman results show that probabilities of *trans* and *gauche* conformations are similar in the glassy, liquid and solution states.

Magnetic birefringence and depolarised light scattering, new techniques in this context, both suggest that chains are not parallel for more than about three carbon atoms as opposed to the strong orientation seen in liquid crystals. According to Fischer polystyrene is similar to polyethylene in this respect. A.H. Windle (University of Cambridge) described the impossibility of fitting wide angle X-ray scattering data using models with straight, parallel polyethylene chains where random arrays of straight chains of four or five carbons worked quite well. On the other hand for polytetrafluoroethylene, a very stiff chain polymer, bundle models worked better. These results used scattering beyond 3 $(Å)^{-1}$ which are mostly attributable to interactions of neighbouring groups within chains and so are not really a reliable guide to packing between chains.

The weakness of the available data was demonstrated, perhaps unintentionally, by W. Pechold (University of Ulm). His meander model, in which bundles of chains fold into cubic arrays, came in for much criticism and is unrealistic, but does fit most of the available data. Also no alternatives were presented in such detail; most workers prefer to avoid committing themselves on the exact nature of the packing. Thus the chain is random in terms of its radius of gyration and the local bends and curves are the same in glasses as in solution. As for how they actually fit together we can either look more seriously at spaghetti or ignore the question as unimportant. □

Paul Calvert is a lecturer in the School of Molecular Sciences, University of Sussex.

Replication dissected

from Barry Holland

AT a recent meeting on the control of replication of bacterial chromosomes and plasmids* a mass of genetic evidence was presented that initiation of DNA replication of several plasmids is negatively controlled — that is, through removal of repressor. Even in the case of the high copy number plasmid R6K, where it is known that a plasmid-determined protein (π) is required for initiation both *in vivo* and *in vitro* it was argued that synthesis of this protein is also under autoregulatory negative control (R. Kolter, University of San Diego).

Although the genetic evidence for the repressor is now overwhelming its nature remains elusive. Several participants reported that a DNA fragment coding for a *trans*-acting control substance has been cloned from a number of plasmids but *in vitro* protein synthesis has not yet identified the regulatory substance. This may simply reflect the very small amounts of repressor synthesised, due in part to tight autoregulatory control.

In the past there has been some question of whether plasmid size is a primary determinant of copy number, as plasmids with high copy numbers tend to be smaller. However, there was agreement at the meeting that, providing the primary control of initiation is intact, increasing the molecular size of the plasmid does not in itself affect copy number; however, if plasmid copy number rises substantially in so-called 'copy mutants' copy number is inversely proportional to size and this indicates that total plasmid DNA then becomes the limiting factor (B. Polisky, Indiana University). Discussion of the multiplicity of potential and active origins found in naturally occurring replicons (for example in *B. subtilis*, F and R6K plasmids) exposed a difference in emphasis between participants concerned with understanding what Nördstrom called the 'basic replicon' (the smallest fragment of self-replicating DNA which maintains the copy control of the wild-type replicon), and others, concerned more with the identification of specific sequences which identify regions of chromosomes capable of interacting with replication complexes to promote initiation. As a step towards defining such regions on the *E. coli* chromosome, W. Messer (Max-Planck-Institut, Berlin) has found a 100 base pair fragment of the origin region (*ori*-C) which when integrated into plasmid ColE1 will drive its replication in mutants in which ColE1 replication does not normally occur. On the other hand, Y. Hirota (National Institute of Genetics, Mishima, Japan) reported that a 245-base-pair sequence covering *ori*-C, was the minimum sequence sufficient to rescue ColE1 in similar conditions. Hirota also announced that alteration of even a single base by directed mutagenesis was sufficient to abolish biological activity of the sequence and further studies of this kind should greatly illuminate structure and functional relationships in the *ori*-region.

The presumed significance of the secondary structure identified in all *ori*-regions so far cloned was constantly reiterated and D. Smith (University of California, San Diego) presented new data showing the impressive conservation of possible secondary structures but not necessarily of precise base sequence when the origin regions of *E. coli* and *S. typhimurium* are compared. Overall comparison revealed 88% of conserved bases, and one contributory factor suggested to explain conservation was the presence of 17 GATC sequences, the site of methylation by the *dam* gene, which could therefore be particularly prone to mismatch repair of any incorrect bases in newly synthesised daughter strands.

Some controversy remains over the precise role of the *dnaA* product in the temporal sequence of initiation in *E. coli*. T. Atlung (Institute of Microbiology, Copenhagen) reviewed evidence that the *dnaA* gene product (now convincingly demonstrated to have a subunit molecular weight of 54,000) is an autoregulated, rho-like protein which controls the frequency of initiation, at the primary level, by modulating the rate of transcription in the *ori*-C region. E. Orr (University of Leicester) agreed that the *dnaA* gene product affects transcription but presented evidence in favour of its action at a later step in initiation, subsequent to the primary control step operating in wild-type cells.

Concerning the role of a specific RNA primer at an early stage in initiation, Messer reported that the so-called 'ori-RNA' described previously in his laboratory, does not hybridise with DNA from or near the origin region. Despite this setback there was still general agreement that transcription of a specific ori-RNA primer and/or transcriptional activation to open up the *ori* region, must be an essential early step in initiation. Perhaps indicating the need to unwind the *ori* region, several reports suggested an important role for the enzyme DNA gyrase in initiation. Orr *et al.* and N. Fairweather *et al.* (University of Leicester) described a thermosensitive gyrase mutation mapping in the *cou* (*gyrβ*) gene which prevents colony formation. Nuclear organisation, initiation of DNA replication and placement of septa are all apparently defective in the mutant although, intriguingly, the rate of DNA chain elongation is not significantly affected,

*The 2nd EMBO Conference on the control of replication and the partition of bacterial chromosomes and plasmids was held on 20-24 September in Leicester and organised by Kurt Nördstrom and Bob Pritchard.

thereby raising doubts about previous assumptions that this enzyme is essential for replication fork movement.

The long haul towards the characterisation of specific components involved in the association of *ori*-C with the cell envelope took an important step forward with the identification of a 65,000 molecular weight membrane protein by A. Jacq *et al.* (University of Paris) and H. Lother *et al.* (Max-Planck-Institut, Berlin) which binds to at least two specific single-stranded DNA sites on the cloned *ori*-C region. Although the precise localisation of this protein in the envelope remains to be established, other findings (H. Wolf-Watz, Umea University; M. Schaechter, Tufts University) that different outer membrane proteins are apparently present in isolated origin-membrane complexes continues to complicate ideas on the actual organisation of such complexes. N. Sueoka (University of Colorado) reported that mutations in a *B. subtilis* gene *dnaB1* (coding for a 35,000 molecular weight membrane protein) block initiation at high temperature, an event which seems to coincide with the loss of chromosomal origins (or plasmids formed from cloned origins) from the membrane fraction both *in vivo* and *in vitro*.

The problem of the relationship between the phenomena of incompatibility of related plasmids and the replication functions of such plasmids was clarified considerably by the general agreement that incompatibility is due to the existence of a *trans*-acting mechanism controlling copy number which fixes the average number of plasmid copies per cell. However, although incompatibility based on competition for a few membrane sites as suggested originally by Jacob, Brenner and Cuzin, was not generally accepted, most participants were still reluctant to concede that random assortment of plasmid molecules at division is sufficiently precise to explain the very low frequencies of plasmid-free clones which are observed even with low copy number plasmids. Several segregation or partition mechanisms were therefore proposed. In particular, the suggestion (T. Hashimoto-Gotoh, Max-Planck-Institut, Berlin) that one pair of plasmid molecules was attached to the cell membrane and partitioned accurately whereas other copies partitioned at random seemed attractive to many.

K. Nördstrom (Odense University) described *par* mutants of plasmid R1 in which copy control is maintained but a few per cent of plasmid-free clones arise in each generation. The wild type *par* function was cloned separately from *rep* functions and since the fragment failed to complement *par*⁻ mutants in *trans*, *par* may be a *cis*-acting DNA sequence essential for membrane binding and hence partition. The novel suggestion by N. Sternberg and M. Yarmolinsky (Frederick Cancer Research Center) that site-specific recombination might also play an important part in plasmid stability or partitioning was received with considerable interest. On the basis of their studies with phage P1, Sternberg and Yarmolinsky proposed that a site-specific recombinational hot-spot ensures that plasmid dimers or higher multimers created through the strong pressures for homologous recombination are likely to be separated and therefore efficiently partitioned. In support of this C. Barton (University of Wisconsin) reported the apparent impossibility of isolating dimers of the large plasmid NR1 *in vivo*.

On a related theme J. Broome-Smith (University of Leicester) described the site-specific, *recA* independent, recombination

How to make a drumlin

from Ian Smalley

THOSE streamlined whale-back hills of glacial till (boulder clay) first recognised and named by M.H. Close in Ireland in 1867 still present problems. Drumlins have fascinated geomorphologists perhaps more than any other glacial landform — or so claim Whittecar and Mickelson (*J. Glaciol.* **22**, 357; 1979) — their symmetry, spatial groupings, and the variability of their lengths, heights and materials have led to a variety of theories of drumlin formation. In general they are believed to have been formed by the moulding action of the ice-sheet on newly-deposited moraine.

Whittecar and Mickelson have investigated the Waukesha drumlin field which contains about 650 drumlins and related streamlined features surrounding Waukesha, Wisconsin, about 20 km west of Milwaukee. The field was formed by ice advancing out of the Lake Michigan basin approximately 14,500 years ago and it abuts the Kettle interlobate moraine to the west and is overlapped by a younger set of moraines to the east.

On the basis of the internal structures of the drumlins Whittecar and Mickelson propose a sequence of five events involved in their formation. The particular structures may be unique results formed by special situations in ice temperature regimes, groundwater flow, stratigraphy, and sediment bulk densities. Whatever the features shown, however, they often indicate that material was being moved into the drumlin from below. A growth relationship may exist that is based on the rates of material moving into the drumlin from below and rates of erosion of the drumlin form.

J. Menzies of Brock University, Ontario has also proposed a new theory of origin (*Earth Sci. Rev.* **14**, 315; 1979). He suggests that the new proposal might point the way to some fruitful field research and have a unifying effect on the diverse disciplines involved in the drumlin problem. He notes that it is commonly observed that subglacial debris emerging into the proglacial zone from beneath an ice mass is slurry-like, having a very high water content. Such material would not be capable of developing into a drumlin-like obstruction at the base of an active ice mass since it tends to be rapidly removed due to its extremely low shear strength (the result of a high pore water content) in relation to the basal shear stresses of the ice.

For such material to survive at the ice/glacier bed interface a marked change in its shear strength must occur, and the most likely process to bring about such a change is pore water dissipation. With stresses applied to the material at the interface the pore water will, if routes are available, dissipate away from points of high pressure. The rate of dissipation can be expected to vary depending on the lengths of the routes and on the size of the voids and thus on the texture and consolidation characteristics of the materials. If the water can escape from the interfacial material a relatively rigid structure might be formed which could become a drumlin. Thus the essence of the Menzies theory is that drumlin formation is controlled by variation in pore water pressure in the glacial till material.

The pore water theory bears some similarities to the dilatancy theory of drumlin formation (dilatancy is the expansion of closely packed granular masses with change in shape — in this case under ice pressure) but invokes a different mechanism to provide critical stress levels within the drumlin material. According to Menzies the dilatancy theory still holds a certain sway; he divides drumlin theorists into those who concur completely with dilatancy theory and those who do not reject the theory but who have alternative hypotheses. Crozier (*Can. Geogr.* **14**, 181; 1975), studying the Peterborough drumlin field in Canada, devised a test for the dilatancy theory and claimed convincing support for it.

In a second paper (*J. Glaciol.* **22**, 373; 1979) Menzies gives more details of his formation mechanism. Two mechanisms of pore-water removal are possible. First, pore water may be removed from localised patches within a mobile layer of till at the ice/glacier bed interface, thus creating nuclei of higher-strength till around which deforming till may adhere. Second, removal of water, initially from the thin water film at the base of a glacier, may result in increased pressure melting of the ice leading to till melt-out and subsequent loss of pore water from the deposited till. Menzies rather favours the first mechanism. □

of ColE1 (and ColK) with a comobilisable plasmid during transfer. It was suggested that such recombination is a consequence of the normal mobilisation process, involving strand cutting at, and rejoining of, the similar transfer origins. M. Masters (Edinburgh University) also described the *recA* independent integration of plasmids bearing *ori*-C into a specific site near the origin of the bacterial chromosome and suggested that this event might also involve a site-specific endonuclease, perhaps involved in this case in initiation of chromosomal replication. Finally, R.H. Pritchard (University of Leicester) recalled the puzzling findings, discussed at the previous workshop, that several high copy number 'synthetic' plasmids (for example, λdv,) and copy mutants of Clo DF13 were extremely unstable in *recA*$^+$ but less so in *recA*$^-$ hosts. Many participants therefore left the meeting intending to search for site-specific recombination mechanisms, perhaps hitherto recognised as *par* functions, evolved by plasmids either to reduce recombination between plasmid molecules or to resolve multimers when they occur. □

Transposable elements and chromosomal rearrangements in cancer — a possible link

from Ruth Sager

THE existence of transposable genetic elements which can insert into different chromosomal sites and thereby modulate gene expression was first described in maize by Barbara McClintock more than 25 years ago. More recently, similar elements — insertion sequences, transposons, and the mutation-inducing phage mu — have been found in bacteria; the molecular basis of transposition is under investigation in bacterial systems and in maize. The likelihood that the non-random chromosome changes associated with particular kinds of cancer might also be mediated by transposition events was the subject of a recent workshop entitled 'Chromosomal Transpositions as Causal Agents in Cancer'.*

Chromosome changes

Consistent chromosome changes affecting specific chromosome segments have now been revealed in banding studies of chromosomes from thousands of patients with a variety of haematological malignancies, and similar associations of chromosome aberrations with other kinds of cancer are being found with increasing frequency. J. Rowley (University of Chicago) described the chromosome gains, losses, deletions, and translocations associated with leukaemias, especially chronic myeloid and acute nonlymphocytic leukaemias; these chromosome changes arise in bone marrow cells. In the inherited form of retinoblastoma, however, patients have an abnormality of chromosome 13 in every cell. A. Mark (Central Hospital, Falk, Sweden) reported that chromosome 22 is regularly lost in human meningiomas, and that many 'double minute' chromosome fragments are present in astrocytic gliomas. In non-malignant lymphomas, short segments from other chromosomes are inserted into a particular region of the long arm of chromosome 14 (14q+); and trisomy for chromosome 3 is also found. A similar 14q+ chromosome was also seen in B cell acute lymphocytic leukaemia.

G. Klein (Karolinska Institute, Stockholm) reported that the 14q+ chromosome seen in Burkitt's lymphoma is a reciprocal translocation with chromosome 8, and is found in tumour cells but not in the peripheral circulation. In recent studies, constant break points have been identified in both translocated chromosomes 8 and 14.

Klein proposed that the 8;14 translocation results from random changes followed by cell selection occurring in stem cells made hyperplastic by infection with Epstein-Barr virus and by additional mitogenic stimuli such as malaria. He stressed the importance of host chromosome changes in the development of virus-associated cancer. Rowley proposed that the evident specificity of break points and rearrangements in cancer-associated chromosome aberrations might result from preferential pairing of homologous DNA regions or from random rearrangements giving rise to cells with a proliferative advantage. Transposable genetic elements like those in maize have the properties that could determine the rearrangements seen in cancer progression.

Assays for tumorigenicity

Interpreting the phenotypic expression of particular chromosome changes requires cellular assays of the malignant phenotype. A. Pardee (Sidney Farber Cancer Institute, Boston) compared growth control in normal and tumour cells transformed by DNA viruses, RNA viruses and chemicals. In normal cells, growth is controlled externally by cell-cell interactions and by growth factors (proteins and small peptides) supplied by the vascular system. Tumour cells no longer respond completely to external growth controls; considerable variation is seen from one tumour type to another in the particular responses that have been lost. Pardee proposed a unified theory of growth control in which a key protein, the 'restriction protein', regulates an on-off switch that permits or blocks entry of cells into a new round of the cell cycle. He further proposed that the rates of synthesis and degradation of this protein vary such that tumour cells generally have a higher level than normal cells but variation also exists among tumour types.

J. Ponten (Uppsala) proposed three requirements for normal cell growth: low molecular weight components; growth factors; and the solid substrate. In the presence of one of Ham's recent new media for human cells, the growth factor most clearly required by glial cells is PDGF, the platelet-derived growth factor. With respect to substrate attachment, Ponten has used circular palladium islands of controlled size to which cells attach to show that normal glial cells require a minimum of 500 square micrometres for growth regardless of growth factor availability. This result is consistent with Folkman's evidence that cell shape is of controlling importance in growth, but does not distinguish between shape and anchorage.

Ponten stressed that with glioma cell lines established from human tumours, no single phenotypic trait correlated well with tumorigenicity *per se*. He proposed that population immortality is the only reliable qualitative distinction between normal and tumour cells.

Additional cellular changes leading to metastatic potential were discussed by M. Burger (Biozentrum, Basel) who proposed that specific surface carbohydrate changes may influence the degree to which some tumour cells metastasise. Starting with the B16 mouse melanoma cell line, he used resistance to wheat germ agglutinin as a selective system to recover mutants with altered surface glycoproteins. Some variants that 'home' preferentially to the liver were also isolated for analysis on the basis of organ selectivity.

In summary, loss of growth control and immortality were taken as the best cellular evidences of transformation, and further changes were considered necessary for establishment of tumorigenicity. The relation of cell shape and anchorage to tumorigenicity remained unclear.

Chromosomal changes and malignant phenotype

Genetic analysis of cells in culture provides a means to link chromosomal changes with specific phenotypic alterations involved in malignancy. R. Sager (Sidney Farber Cancer Institute, Boston) described a new Chinese hamster cell line which is a stable diploid (22 normal

*Held in Sils Maria, Switzerland on 8-12 June, 1979 and sponsored by the International Union against Cancer and the Swiss National League against Cancer.

©1979 Macmillan Journals Ltd

chromosomes) and non-tumorigenic. Transformed and tumorigenic mutants have been recovered and genetic differences between normal and mutant cell lines have been examined by cell fusion and subsequent chromosome loss from the tetraploid back to the diploid level, during which reassortment of parental chromosomes occurs. Evidence has been found for suppression in cell hybrids of the anchorage requirement and of tumorigenicity, confirming and extending the original studies of Klein and Harris. In some reduced hybrids with 22 chromosomes, anchorage independence and tumorigenicity were re-expressed independently indicating that these traits are under separate genetic control. In addition, fusions of transformed cells with enucleated normal cells to form cybrids have shown that cytoplasmic genes are involved in tumorigenicity. The importance of examining early stages in tumorigenicity in order to identify the initial key changes that occur was stressed.

The methodology of cell hybridisation has been developed and applied by B. Ephrussi and his students to the analysis of differentiation. M. Weiss (CNRS, Gif-sur Yvette) described the extinction of sets of phenotypic traits of rat hepatoma cells following fusion with normal or malignant mouse cells, and the subsequent re-expression of individual phenotypes coincident with loss of various chromosomes. For example, when rat hepatoma cells that produce albumin are fused with pigmented mouse melanoma cells that don't, the resulting hybrid clones are unpigmented and do not produce albumin, but they give rise to hybrid subclones that have lost chromosomes and segregate for pigmentation and albumin production. Stable mutants have been recovered from the hepatoma line that have lost some or all of their differentiated liver functions; and revertants from these mutants have regained the full set of enzymes. The reversion process is not increased by X-ray or chemical mutagens.

The extinction of sets of phenotypes in cell hybrids followed by full or partial regaining of activity, in parallel with chromosome elimination, strongly resembles suppression of tumorigenicity and its reappearance in reduced hybrids. Both systems can be interpreted in terms of regulatory signals that can turn on or turn off expression of sets of genes. As with tumorigenicity, the genetic basis of extinction and re-expression needs to be examined at the DNA level.

The relation between cancer and normal cell differentiation was stressed by E. Gateff (University of Freiburg) who described twelve unlinked *Drosophila* mutations which are larval lethals. The mutant genes interfere with development of specific tissues or cell types in a stage-specific way and thus are developmental mutations affecting rates of cell proliferation and morphogenetic processes. In addition, neoplastic sublines have been derived from wild-type imaginal disks maintained in prolonged subculture *in vivo*. One of these lines has shown a capacity for reversal to the differentiated state, suggesting the regulation by genetic on–off switch. The wealth of descriptive detail that Gateff has produced over the past few years makes this material a valuable resource and a challenge for anyone who can develop a molecular approach to its analysis.

The possibility that the cell cycle might be regulated by one of the enzymes involved in initiation of DNA replication was raised by B. Alberts (University of California, San Francisco). He suggested that eukaryotic DNA replication might profitably be approached by looking for eukaryotic enzymes with functions analogous to the prokaryotic ones. Alberts also discussed the possibility that gene regulation might occur in some instances at the supra-DNA level of chromosome organisation.

Transposition and carcinogenesis

Of central interest to the workshop were molecular aspects of gene organisation such as the eukaryotic split genes described by P. Chambon (Strasbourg) and mechanisms of transposition in bacteria described by N. Kleckner (Harvard University, Cambridge), A. Toussaint (Brussels), and H. Saedler (Freiburg), subjects previously reviewed in *Nature*.

Despite the differences between prokaryotes and eukaryotes in gene and in chromosome organisation, unanticipated similarities have been discovered with respect to the existence and roles of transposable genomic fragments.

Saedler connected the prokaryotic and eukaryotic systems by a brief account of the discovery of chromosome transpositions in the corn plant *Zea mays* by Barbara McClintock (who unfortunately was unable to attend). McClintock discovered the existence of gene-control elements capable of inducing chromosome breaks and rearrangements and of modulating gene expression both qualitatively and quantitatively. She characterised several classes of these elements and showed that their transposition from one chromosomal location to another can be stimulated by chromosomal breakage. Whether transposition is a regular feature of their function in normal development is not known, but the transposition process is clearly under genetic control, since its time and frequency of occurrence is highly non-random and is inherited as a property of the controlling element.

The similarities in behaviour of the controlling elements in maize and the more recently discovered insertion elements and transposons of bacteria was a principal factor in the design of this workshop. In McClintock's words: "Should a genome-disturbing event appear, such as by a cancer-inducing agent, the result could be induction of transposition of elements that can serve to control gene action. The insertion of such elements at given gene loci could initiate those genomic changes that lead to a cancerous state of the cell."

According to this view, initiation of tumorigenicity by a chemical or a virus might result from a subtle chromosome change which would precipitate subsequent chromosomal instability. Progressive development of malignancy might then depend on random karyotypic reorganisation and selection of new cell types that have lost growth control and gained other traits that facilitate growth in the given environment.

This approach to carcinogenesis may be particularly fruitful in suggesting new kinds of experiments in which the process of tumorigenesis is analysed in terms of transposition and chromosome rearrangement. Understanding the underlying karyotypic alterations that occur during tumour cell selection may provide new insights into the choice of effective anti-cancer drugs, both clinical and prophylactic. □

Pollen problems

from Peter D. Moore

WHEN interpreting the fossil pollen content of past lake sediments in terms of the contemporaneous, pollen-producing vegetation, one needs to consider the spatial origins of the pollen assemblage. Some will have arrived from the atmosphere directly, either blown from nearby plants, or carried down by drops of rainwater which effectively 'forage' for particulate matter in the atmosphere (McDonald *Science* **135**, 435; 1962). Other pollen will have been transported into the lake by the input streams.

Stream-borne pollen may itself be derived from a variety of sources. Some may have been washed from leaf and other surfaces in the catchment, where it had become impacted from the atmosphere (Chamberlain & Chadwick *Ann. appl. Biol.* **71**, 141; 1972). Some may be derived from other types of deposit, such as peat or undecomposed humus and litter from soils in the catchment. This latter source is of particular concern to the palynologist, for such pollen could be considerably older than the remainder of the pollen load in the stream and would distort the general pollen record within the lake basin. Some attempts have been made to separate this inwashed pollen component within fossil

Peter D. Moore is a Senior Lecturer in the Department of Plant Sciences, King's College, London.

0028-0836/79/480448-02$01.00

©1979 Macmillan Journals Ltd

pollen assemblages (for example Birks *New Phytol.* **69**, 807; 1970) on the basis of the different types of damage which such grains will have suffered during transport, but generally little is known of its importance.

An experimental approach to this question has been conducted by Bonny (*J. Ecol.* **66**, 385; 1978) making use of the large tubes inserted into Blelham Tarn in the English Lake District by Lund (*Mitt. Int. Verein. Limnol.* **18**, 71; 1972). These tubes are 45 m in diameter and extend from the surface to the bottom of the lake (11-12 m) and thus effectively isolate a body of water from the remainder of the lake. Bonny established pollen traps at the lake surface and underwater, both inside and outside the tubes; traps inside the tube would be expected to receive the atmospheric pollen component, but to lack the pollen transported into the lake by streams. She found that the annual catch of pollen within the tubes was only 15% of that caught outside. This suggests that as much as 85% of the pollen submerged in the lake may have been brought there by stream transport, though this figure may be inflated by the input from marginal, eroding banks and organic deposits.

Pennington (*New Phytol.* **83**, 189; 1979) has now approached the problem from a different angle, by comparing the pollen record within the sediments of an enclosed basin lake with no inflow streams with one into which streams flow. Blelham Tarn was again taken as an example of the latter, and Whinfell Tarn, a 5.5 hectare basin also in southern Cumbria, as an example of the former. Sediment cores were extracted and the pollen stratigraphy determined using absolute techniques, covering about the past 7,000 years.

The general course of vegetation history as recorded by the pollen was similar in the two lakes. There were fewer irregularities in the enclosed basin, perhaps as a result of the smaller influence such processes as local forest clearance would have had upon erosion and pollen input. On examining absolute pollen influx into the two lakes over the past 7,000 years, however, considerable differences were apparent. Current pollen sedimentation in the surface muds of Blelham Tarn are about nine times greater than those at Whinfell Tarn. Differences between the two basins, however, have not always been so great. About 5,000 years ago, before the local deforestation of the two sites, the stream-fed lake received only twice the pollen influx of the closed basin. Following catchment deforestation this rose to about four times and the difference has been rising rather erratically ever since. This seems to be due to the erosion of organic, mor humus from the cleared forests of the Blelham catchment and the stream-borne input of this older pollen into the lakes, raising the pollen influx values by about five times. This effect is not seen in the enclosed basin. The subsequent erratic behaviour of the influx curves at Blelham Tarn can be correlated with further soil disturbance by such processes as ploughing and cultivation.

The conclusion, therefore, is that the stream contribution to a lake's pollen content will vary with the vegetation and soils of the catchment. Where this consists of stable forest, stream-borne pollen may be less than 50% of the total pollen influx. Forest clearance or soil cultivation releases any acidic organic matter into streams and may inflate this source of pollen to about 85% of the total input.

Such contamination with old pollen is a serious disadvantage when trying to interpret pollen data and indicates that a closed basin provides a more reliable pollen record than an open one. The alternative, of course, is to choose an ombrotrophic (rain-fed) peat site in which all pollen input is atmospheric in origin. □

Chemical recognition in biology

from James Ofengand

SPECIFICITY of reaction is the hallmark of all biological processes. In order to achieve specificity, biological molecules have learned how to recognise one another. Understanding the chemical basis for recognition has been the goal of biochemists and molecular biologists for many years, and none has been more persistent in its pursuit than Fritz Lipmann, whose 80th birthday recently was marked by an EMBO Workshop on Concepts of Chemical Recognition*. Many of the participants were former associates of Professor Lipmann, and while their interests have diverged widely over the years, the approaches taken still reflect in a characteristic way their common exposure to the view that the behaviour of biomolecules can ultimately be explained in terms of the laws of physics and chemistry.

The meeting opened with a series of talks on protein–ligand interactions. C. Walsh (Massachusetts Institute of Technology) discussed suicide substrates, structural analogues of a substrate which carry a latent reactive group capable of being exposed only by the catalytic action of the enzyme. Since these compounds are only unmasked and activated when at their target enzyme, they are well suited for *in vivo* studies as well as for consideration as chemotherapeutic agents. An example of the latter possibility is clavulanic acid (Fisher *et al. Biochemistry* **17**, 2180, 2185; 1978). This is a penicillin analogue which inactivates the β-lactamase responsible for most of the penicillin resistance encountered in pathogenic organisms. Walsh also pointed out the importance, *in vivo*, of a low partition ratio. This is the ratio of activated product which diffuses away from the active site to that which reacts with the enzyme and inactivates it. One substrate cited whose partition ratio approaches zero is the naturally occurring cyclohexadiene amino acid, gabaculine, which inactivates various GABA transaminases. The development of suicide substrates for pharmacologically important enzymes should be a rational approach to chemotherapy.

M. Perutz (MRC Laboratory of Molecular Biology, Cambridge) drawing primarily on X-ray crystallographic data, described how haem proteins recognise their substrates. Haemoglobin and myoglobin prefer O_2 over CO because of steric interference of the side chain of HisE7 which blocks linear addition of the CO molecule but not the angular addition of O_2. This conclusion was verified using Hb Zurich, in which HisE7 is replaced by Arg. Similarly, cytochrome b_5 is an electron carrier rather than an O_2 carrier in this case because HisE7 is only 2 Å from Fe^{2+} instead of the 4 Å in haemoglobin or myoglobin so that even O_2 is sterically excluded.

Protein–protein recognition was discussed by M. Kamen (University of California, San Diego), using the recognition of cytochrome *c* by cytochrome oxidase as the paradigm. Kamen concluded that a pattern of positive surface charges produced by exposed lysine residues on one face of the cytochrome *c* molecule determines the nature of the interaction with the oxidase. Although the overall net charge on both proteins is negative, the concentration of positive charges on one surface allows electrostatic forces to pull the two molecules together, and the specific pattern of these charges determines the strength of the interaction and hence the specificity.

The complex bicyclic system for the regulation of glutamine synthetase (GS) activity was discussed by E. Stadtman (National Institutes of Health). This 12-subunit enzyme exists in an adenylated (inactive) and non-adenylated (active) form with each subunit able to accept one AMP residue. The interconversion requires ATP and adenyl transferase (AT), which can both adenylate GS with release of PP_i, and de-adenylate by phosphorolysis to yield ADP. Which of the two activities is catalysed by AT is determined by yet another protein, PII. PII is required for adenylation in addition to AT but does not induce de-adenylation. The latter reaction requires AT, P_i, and the uridylated form of PII, PII-$(UMP)_4$. The interconversion of PII and PII-$(UMP)_4$ is accomplished by a fourth protein, uridyl transferase, which when stimulated by α-ketoglutarate, adds

*Held at the Institut National Agronomique, Grignon, France, on 18-20 July, 1979.

0028-0836/79/480449-02$01.00

©1979 Macmillan Journals Ltd

the UMP group of UTP to PII, and when glutamine is present hydrolyses PII-$(UMP)_4$ to PII. The net consequence of this elaborate system is that the α-ketoglutarate/glutamine ratio determines the activity of glutamine synthetase, although as Stadtman was careful to point out, the complexity of the system allows more than 40 different metabolites to modify the overall GS activity level. When GS is partially adenylated, 12mers with varying degrees of adenylation and varying specific activities are produced rather than a mixture of fully adenylated and nonadenylated 12 mers.

The subject of the Lipmann Lecture, given by Y. Nishizuka (Kobe University, Japan), was protein kinases. After reminding the audience that Lipmann was also a pioneer in the field of protein phosphorylation (Lipmann & Levene *J. biol. Chem.* **98**, 109; 1932; Lipmann *Biochem. Zeit.* **262**, 3, 9; 1933), Nishizuka described a new class of multifunctional protein kinases discovered in his laboratory. These kinases (molecular weight 77K) are found in various mammalian tissues and require both Ca^{2+} and membranes for activity instead of cyclic AMP or cyclic GMP (Takai *et al. J. biol. Chem.* **254**, 3692; 1979, *J. Biochem.* **86**, 575; 1979). The membrane component can be replaced by certain purified phospholipids or, even more effectively, by the neutral lipid diolein. Ca^{2+} stabilises the enzyme-phospholipid complex as its removal by chelating agents dissociates the protein–lipid complex and destroys kinase activity. Interestingly, dibucaine, a local anaesthetic known to interact with phospholipids, also blocks the activity of this kinase, although it has no effect on cyclic AMP or cyclic GMP-dependent protein kinases. After proteolysis the catalytic fragment (molecular weight 51,000) is fully active without Ca^{2+} and phospholipid. The specificity of the lipid-protein interaction described here should be a fruitful area for further study in addition to the obvious possibilities for transmembrane control implicit in a Ca^{2+} regulated membrane-associated protein kinase.

Protein–nucleic acid recognition was discussed by several speakers. G. Hartman (University of Munich) described some of his group's recent work on the recognition of promoter sequences by RNA polymerase. Although subunits from *M. luteus* and *E. coli*, two taxonomically distant species, are freely interchangeable in reconstituting overall activity, the promoter sequences recognised depend both on the source of enzyme and of the DNA, and vary from no to complete discrimination; analysis of hybrid molecules shows specificity for promoter recognition is due to the sigma subunit.

Recognition of DNA by the protein antibiotic, neocarzinostatin (NCS) was described by I. Goldberg (Harvard University). This antibiotic, which inhibits both bacterial and mammalian cell growth, has been used clinically as an anti-tumour agent. It is a compact protein of 10,700 molecular weight and introduces single strand breaks in DNA at T or A residues probably by splitting the deoxyribose sugar between C_3' and C_4'. A chromophoric group (molecular weight 600) in NCS may be a cofactor.

Specific recognition of satellite DNA by protein was suggested by some recent work from the laboratory of H. Zachau (University of Munich). Each long repeat unit (2,350 base pairs), is made up of four segments, each consisting of variations on the theme of a basic 23 base pair unit which is itself made from a 12 bp and a related 11 bp sequence. Analysis of the complete sequence showed that the extent of divergence as well as the frequency of base substitution at specific positions was characteristic for each segment. A high incidence of symmetry was also found, and provided the basis for Zachau's suggestion that proteins might specifically recognise certain satellite sequences.

Recent experiments on the control of replication of SV40 were described by D. Nathans (Johns Hopkins University) (Shortle & Nathans *J. molec. Biol.* **131**, 801; 1979). Using their localised mutagenesis technique (*Proc. natn. Acad. Sci. U.S.A.* **75**, 2170; 1979) they isolated mutants in the origin region of SV40 DNA, which fell into four classes corresponding to differences in rates and requirements for DNA replication, and were not correctable by complementation with wild-type gene products. Sequencing established the exact nature of the base changes and Nathans proposed that mutants in the *ori* region alter a sequence which is recognised by the T antigen, a viral protein involved in the initiation of viral DNA synthesis. This hypothesis is supported by the isolation of second site revertants some of which were mutants in the T antigen gene.

Various aspects of protein-nucleic acid recognition involved in protein biosynthesis were considered. A. Rich (Massachusetts Institute of Technology) presented some recent experiments (Wrede *et al. Proc. natn. Acad. Sci. U.S.A.* **76**, 3289; 1979) which revealed unexpected and characteristic differences between the anticodon loop structure of the initiator methionine tRNA, $tRNA_f^{Met}$, and the elongator tRNA, $tRNA_m^{Met}$ in the pattern of cleavage by the single-strand specific endonuclease S1. Both prokaryotic and eukaryotic initiator tRNAs were split at two sites in the anticodon, residues 34 and 35, while elongator tRNAs of prokaryotes and eukaryotes were split at residues 33, 34, 35, and 36 (34–36 are the anticodon). The reason for this characteristic difference in splitting pattern is not known. Rich speculated that the three G-C pairs found in the anticodon stem of all initiator tRNAs, and the only sequence feature common to all initiator tRNAs, might somehow give the anticodon loop a characteristically different structure from that of elongator tRNAs.

H. Wittmann (Max-Planck-Institut, Berlin) summarised the current state of knowledge of the *E. coli* ribosome. The primary sequence of 47 of the 53 ribosomal proteins is now known, and their shape is being studied by a variety of physical methods. A number (S1, S18, S7/12, S21, S5) are very elongated with axial ratios of 7-10:1. Several are modified by acetylation or methylation on side-chains or N-termini and three distinct N-terminal acetylases have been identified, but the purpose behind these elaborate modifications has yet to be determined. The architecture of the ribosomal particle is being studied by chemical cross-linking techniques and by immunoelectron microscopy. Two previously described crosslinks have now been precisely identified, the 8Å link between Lys93 (S8) and Lys166 (S5), and the 0 Å crosslink between Met114 (S7) and Urd1239 (16S RNA). Ultimately, the Berlin group expects to map out most of the contact sites in the ribosome in this way. New immunoelectron microscopic results were the localisation of the 3'-end of the 16S RNA, and of the chloramphenicol binding site at the peptidyl transferase centre.

Y. Kaziro (University of Tokyo) reviewed the way that the energy of hydrolysis of GTP is used to do mechanical work in protein synthesis. Both in A site binding and in translocation, the energy comes from the participation of a protein-GTP complex which induces a change in state such that the reaction proceeds. GTP hydrolysis occurs only subsequent to the mechanical process to release its carrier protein from the ribosome by producing a conformational change in it. Kaziro suggested that this concept of work first, hydrolysis later, might be extended to other biological systems where work is done such as muscle contraction, transport, and other polymerisation reactions. Kaziro has also nearly completed sequencing of the EFTu gene, *tuf*A.

Chemical recognition is being used in cancer chemotherapy to direct antimetabolites to the desired site (N. Kaplan, University of California, San Diego). 6-aminonicotinamide, a potent antimetabolite, has been coupled to polylysine to prevent it crossing the blood–brain barrier, the major cause of its toxic side effects. Polylysine coupling to methotrexate has been used to fool a methotrexate-resistant cell line in which resistance was due to a failure to transport the drug. A third example was the coupling of daunomycin, an inhibitor of DNA and RNA synthesis, to melanotropin in order to concentrate the drug specifically in the melanoma cell. This idea of chemically addressing drugs which normally have no capacity to recognise specific cell types should be a fertile ground for new approaches to chemotherapy. □

review article

Redshifts and distances

G. Burbidge
Kitt Peak National Observatory, Tucson, Arizona

Evidence concerning the associations between QSOs and galaxies with similar redshifts, and pairs with very different redshifts is reviewed. It is concluded that both kinds of associations are likely to be real.

FOR more than 10 years there have been doubts over whether all redshifts of extragalactic objects are associated with the expansion of the Universe and can be used to indicate distances. The arguments have centred largely on the nature of the redshifts of the QSOs, although Arp[1] has given evidence which suggests that even some galaxies have non-cosmological redshifts, and Tifft[2] has suggested that the redshifts of the galaxies in clusters, in particular, the Coma and Perseus clusters, are correlated with their nuclear magnitudes and has suggested that distances derived by the usual assumptions cannot be valid.

Because there has been no realistic theory which would account for non-cosmological redshifts, the majority feel that there is no good case for this point of view and strenuous efforts are made to disprove the existing evidence. At the same time, some evidence in favour of the cosmological interpretation has been found, and this evidence is regarded more highly.

I have previously attempted to summarise the evidence on both sides of the controversy[3]. Here I will concentrate on findings made largely since then on one aspect of the problem—the apparent associations between QSOs and galaxies—the first assumption being that the redshifts of the galaxies give good measures of their distances.

The investigations fall into several categories:

(1) The programme of looking for QSOs near bright galaxies which has been carried out by Arp and his colleagues.
(2) Searches among specified samples of pairs of QSOs.
(3) Attempts to find associations between QSOs and faint galaxies on the assumption that the redshifts are cosmological.
(4) Studies of the correlations between galaxy samples and QSO samples without any assumption being made as to the nature of the QSO redshifts.

Before summarising the results of these different investigations a few comments should be made. The average QSO redshift z is close to 1 and only a very small fraction of the known QSOs (~5%) have redshifts ≤ 0.2. On the other hand, practically all of the galaxies in the published catalogues are thought to be at distances such that their cosmological redshifts are ≤ 0.2. Thus, except in special cases in which faint galaxies are deliberately sought out and observed, in any associations that are found between QSOs and galaxies, the QSO redshifts will be much greater than that of the galaxies. A further point concerns Arp's samples. The frequent criticism is that while much is made of the peculiar objects, there must be many galaxies whose fields have been searched and in which no QSOs or anomalous redshift galaxies have been found. The implication is that the cases he describes are rare, and thus may be accidental. In fact the limits on observing time and the exacting nature of the photographic work means that this is not true. To carry out such investigations on a large number of fields would take decades at the rate at which dark time is now available on the large telescopes. I believe that the fact that Arp finds so many of these cases suggests that the phenomenon is widespread, and that more cases are not found because no other astronomers are looking.

QSOs near to bright galaxies

Arp[4] has listed 23 cases of QSOs found near bright galaxies. Of these 20 are NGC galaxies, two are IC galaxies and one was not catalogued. The objects are of two types: QSOs which have been found near to bright galaxies such as the 3C QSOs studied many years ago[5], and QSOs which have been found in conjunction with fainter galaxies which are themselves thought by Arp to be associated with bright galaxies with very small redshifts. In such cases the fainter galaxies generally have redshifts much greater than those of the bright galaxies.

Since 1976 several new examples have been found by Arp and his colleagues. A list of all of the systems of galaxies and QSOs which are known has been published elsewhere[6]. Both QSOs associated with galaxies with much smaller redshifts, and fainter galaxies found around QSOs which in some cases have the same redshifts are included.

The list includes 94 large-redshift QSOs close to 55 NGC or IC galaxies with $m_v \leq 13$ and 10 fainter galaxies, several of which are in the Zwicky catalogue. All of these cases involve highly discrepant redshifts. The remainder are nearly all very faint galaxies near to QSOs with $z < 0.45$ chosen by Stockton[7] who was looking for cases in which the redshifts agree. We shall return to them later. Among the pairs with discrepant redshifts, a few have been found accidentally, some by deliberate searches involving a limited sample of bright galaxies and radio QSOs (the 3C QSO galaxy-pairs[5] and the PKS ± 4° QSOs and Zwicky catalogue galaxies[8]) and the majority by looking in the vicinity of galaxies chosen because detailed radio studies indicated some possible peculiarity or because Arp found a peculiar fainter galaxy in the vicinity of the brighter one.

Table 1 shows all of those QSO–galaxy pairs which have separations $\leq 10'$. This table is abstracted from ref. 6. (The separation is either between a bright galaxy and a QSO or between a QSO and a companion galaxy close to a bright galaxy. These latter cases are all due to Arp.) There are 68 QSOs and 54 galaxies in Table 1. Of these, 57 are QSOs associated with NGC or IC galaxies and 11 are QSOs associated with fainter galaxies, five of which are brighter than 15.5 mag.

Given the heterogeneity of the data, the best way to evaluate the results statistically is to ask, if one looks within a range of angular distances of a chosen set of points, how many QSOs would be expected to be found by chance.

The information that we need to evaluate the result is the surface density of QSOs, and the number of cases (points) that have been examined.

It is generally agreed that the number of radio-quiet QSOs is far larger than the number of radio-emitting QSOs. The surface density of QSOs given by Sandage and Luyten[9] and Setti and Woltjer[10] down to $B = 20$ mag are 10 and 8.5 per square degree. Arp, Sulentic and de Tullio[11] obtain 7 ± 4 per square degree. Savage and Bolton (quoted by Wills[12]) obtain values of 0.2, 1.0 and 3.0 QSOs per square degree to $B < 18.0$, 19.0 and 20.0, respectively. Wills[12] has criticised the problem and has concluded that a value of 20 per degree down to $B = 20.5$ mag is indicated with a very considerable uncertainty. All of the surface densities mentioned above are in good agreement so that we conclude that values of 0.3 QSOs per square degree to 17 mag, 1 QSO per square degree to 18 mag, 3 QSOs per square degree to 19 mag, and 10 QSOs per square degree to 20 mag can be used. At the bright end this number is obviously conservative.

How many fields have been searched? Only Arp has looked extensively, sometimes after a pecularity in the galaxy or companion has been recognised. For example, his study of the vicinity of NGC1073 began after Condon and Dressel[13] reported the discovery of a compact radio source associated with a blue stellar object in the galaxy. The object was found to be a QSO, but it is the only example they found in a study of ~200 galaxies for compact radio sources. Thus this might well be a chance effect. On the other hand the discovery of two more (radio-quiet) QSOs by Arp and Sulentic[14] may be highly significant.

The observing time required to obtain adequate photographic material compared with the limited dark time available for this work leads me to conclude, with Arp, that a maximum of 100 fields have been studied by him and his colleagues. Some of the other objects have been found by accident, and we shall assume at first that the total number of fields that have ever been looked at is 200.

Let $\Gamma(<m)$ be the sky density of QSOs brighter than m. Then the expected number lying within an angular separation θ of arbitrary points is

$$\langle n \rangle = 2.4 \times 10^{-7} N \Gamma(<m) \theta^2$$

where N is the number of tries, Γ is expressed in (arc deg)$^{-2}$ and θ in arc s.

Table 2 gives the number of QSOs expected by chance, as a function of separation from the galaxy and as a function of magnitude of the QSOs, compared with the total number found (N_0). The number that has been found by Arp is designated N_{0A}.

Table 2 shows that the number found within 1, 2 and 3 arc min is far greater than the number expected by chance and thus the result is highly significant.

It may well be argued that the number of tries used to calculate $\langle n \rangle$ can only reasonably be compared with N_{0A}, the number of pairs discovered by Arp and that comparison of N_0 with $\langle n \rangle$ is unfair, because N_0 includes QSOs found close to galaxies in other surveys and more than 200 tries are involved. If we take this more conservative point of view the result has

Table 1 All QSOs known to lie within 10 arc min of bright galaxies or their companions

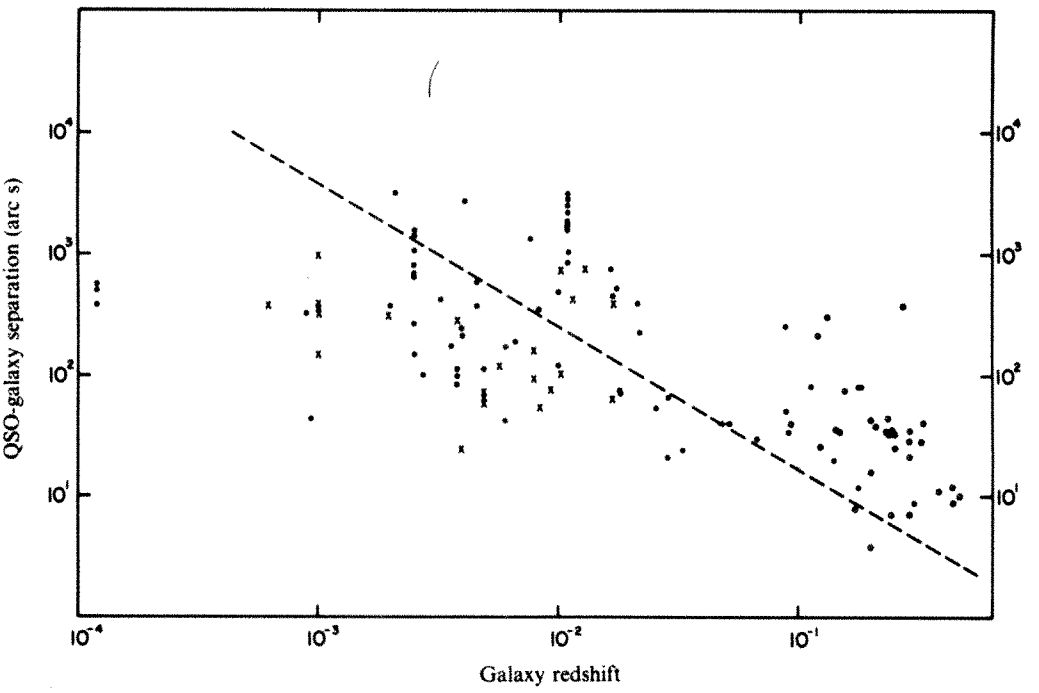

Fig. 1 A plot of log z_{galaxy} against log θ for all apparent QSO–galaxy associations listed by Hewitt and Burbidge[6]. The low redshift QSOs marked with a separate symbol are the QSOs close to galaxies investigated by Stockton[32]. The line is the least-squares solution which has the form log $\theta = -1.17$ log z_{galaxy} + constant. The range of slope at the 99% confidence level lies between −0.93 and −1.56. ●, Main galaxy; ×, redshift (main) versus θ (companion); ○, low redshift QSO.

obviously less statistical weight. Note that N_0 also includes the five 3CR QSOs found near to bright galaxies[5,8,15] which were shown to be highly significant[5] as a separate sample. These associations were found by studying galaxies in the vicinity of about 50 3CR QSOs. Thus only 50 tries were involved and our total of 200 tries assumed above can reasonably include that sample. Also included are the associations between Parkes QSOs and Zwicky catalogue galaxies[18]. Here about 90 QSOs were involved. The other sample which is included in N_0 are the cases recently found by Weedman[16] who has looked for associations between 259 QSOs found by objective prism techniques and 62 bright galaxies in the same area of the sky. He found that the apparent associations lay within one standard deviation of what one would expect by chance. The numbers that are seen as one goes to larger distances ($\sim > 5'$) are comparable with or even less than the numbers expected by chance. This may be because Arp has not searched as hard for QSOs further out. Alternatively it may be that the mean surface density of QSOs that we have used is too high. If the latter is correct, the result based on the number of close QSOs is enhanced.

What about NGC1073 where three QSOs are found to lie within 2′ of the centre of that galaxy. Let P_m be the probability that a single galaxy has m QSOs within θ arc by chance. Then

$$P_m(\mu) = \frac{\mu^m e^{-\mu}}{m!}, \qquad \mu = \frac{\langle n \rangle}{N}$$

From Table 2 we find that there are 34 galaxy–QSO pairs with separation $\leq 3'$. Because in the case of NGC1073 it was the first radio QSO which drew attention to the galaxy, we evaluate the probability that two QSOs are found within 3′ of a point which already has one QSO within 3′. Then $P = 0.0028$, and the probability that any one of the 34 galaxies with one QSO within 3′ will have two more there by accident is 0.095.

Alternatively we might ask what is the probability that any of the ~2,000 galaxies in the revised Shapely Ames catalogue has three QSOs lying within 3′ of its nucleus by chance. If $m = 3$, $P_m(\mu) = 7.22 \times 10^{-5}$. Thus the total probability is 0.144. This assumes that the vicinities of all of the bright galaxies have been searched for QSOs but only a very small number, perhaps 100, have been studied in this way.

Note also that the redshifts of the three QSOs associated with NGC1073 are 1.945, 0.599 and 1.411 (Table 1). This might be another accident, but it is striking that these values are exactly at the peaks of the redshift distribution discussed over many years (see ref. 17).

Many of the QSOs found near to bright galaxies by Arp and his colleagues are not close enough to be statistically significant if we estimate the probabilities in the normal way. But in many of these cases alignment of pairs of QSOs across the nucleus of a galaxy and the similarity of the redshifts of the QSOs makes physical association very likely. Alignments of this type include the QSO and two other compact radio sources associated with the radio galaxy B20925+30 (refs 4, 18), the QSOs around NGC3384 (ref. 19), QSOs around NGC2639 (ref. 20) and the pairs of aligned triple QSOs without a bright galaxy present found by Arp and Hazard[21]. All of the systems of this type have been listed elsewhere[6].

Given that there is some statistical evidence of association of galaxies and QSOs for close separations, and that alignments and similarity of redshifts of several pairs of QSOs around bright galaxies suggest physical association, we can look for further evidence by making a plot of the redshifts (proportional to distance) of the galaxies against angular separations of the QSOs from the galaxies. When this was originally done for the 3CR QSOs[8] it was found that the slope of the log z galaxy–log θ relationship was very close to −1, suggesting that the QSOs were at approximately a constant projected distance from the galaxies. Figure 1 shows a similar plot for all of the galaxy–QSO systems listed by Hewitt and Burbidge. Included are 94 QSOs associated with 65 galaxies. Obviously some of these may be accidental and because in many cases several QSOs at different distances are associated with the same galaxy, we expect considerable scatter in the relationship. However, a least squares solution gives a best fit line for log z given log θ of the form

$$\log \theta = -1.17 \log z + \text{constant}$$

The range of slope for this line at the 99% confidence level is between −0.93 and −1.56. The correlation coefficient associated with the (log θ, log z) pairs is $r = 0.68$. This correlation is significant.

Pairs of QSOs

Stockton[22] found the first close pair of QSOs separated by 35″, with very different redshifts. He calculated *a posteriori* that the probability that this was due to chance was 6×10^{-3}. The next pair that was found was 1548+114a and b, with a separation of 5″ (ref. 23), *a posteriori* probability calculation gave the probability of a chance superposition $\sim10^{-2}$. Bolton *et al.*[24] carried out a systematic search of 100 fields centred on flat spectrum radio-emitting QSOs from the Parkes 2,700 MHz survey. They found eight candidate QSOs within 1.7′ of the radio-emitting QSOs, and have confirmed that there are at least four and probably five pairs of which at least four and probably five pairs have different redshifts. As the plate limit in these studies was $B=19$–19.5 mag, the number of QSOs per square degree is about three, and thus the number of pairs expected by chance is 0.76. Since four or five pairs are found, Bolton *et al.* consider that the probability that this is due to chance lies in the range of 6×10^{-3}–10^{-4}. Wills and Wills[12] then did a similar survey in the north, searching within 2′ of 100 QSOs identified in the NRAO 5,000 MHz surveys. They found two pairs and one is expected by chance. Thus from the two fields together, seven pairs have been found against the 1.76 expected by chance.

Several new close pairs or triplets have recently been found. They include a pair with separation 5.7″ with precisely the same redshift[25] which must be a physical pair, or a single object which appears double due to an intervening massive object[25], and the triple system of QSOs near M82[26] with separations of 75″ and 125″. Each QSO has a redshift close to 2.04.

Perhaps we are seeing several phenomena in the close groups, including chance effects, physical pairs with the same redshift, physical pairs with different redshifts, and physical pairs or triplets with similar large redshifts ejected from nearby bright galaxies. Only further observations will clarify this situation.

Associations between QSOs and galaxies at the same redshift

The first successful attempt to find a galaxy at the same redshift as a QSO was made by Gunn[27], and Robinson and Wampler[28] who found one or two normal galaxies lying near the QSO PKS2251+11. One at least has a redshift very close to 0.323 which is the redshift of PKS2251+11. Gunn made statistical arguments *a posteriori*, concluding that there was a very low probability that this association was accidental and this result was heralded as evidence that the redshifts of the QSOs are of cosmological origin. Several other similar cases were found[29–32]. However, there was no reliable way of estimating the statistical significance of these associations[33].

Recently Stockton[7] has carried out a much more significant study. He chose all of the known QSOs (27) with redshifts ≤0.45, $m_v<19.2+5\log z$ and at declinations $-15<\delta+55$ and attempted to obtain spectra of all galaxies visible on the red Palomar Sky Survey plates lying within 45″ of the QSOs. Of the 29 galaxies he identified, he obtained spectra of 25 and has reported that 13 galaxies in eight fields (out of 27) have redshifts, cz, within 1,000 km s^{-1} of the redshift reported for the QSO. He has estimated that the probability that this could occur by chance is less than 1.5×10^{-6}. Stockton[30] also has found a galaxy at the same redshift as 3C273, although it lies further away than 45″.

These results provide strong evidence that some QSOs at least lie at cosmological distances.

General studies of correlations between faint galaxies samples and QSOs

Several attempts have been made to look for correlations between the positions of QSOs and faint galaxies contained in the Abell catalogue and the Lick catalogues. The maximum redshift for any of these galaxies is $z\sim0.2$.

Bogart and Wagoner[34] found marginal but not convincing evidence for an apparent correlation between the positions of QSOs with large redshifts ($z\geq0.3$) and Abell clusters ($z\leq0.2$). Recently Roberts *et al.*[35] investigated the positions of all QSOs with measured redshifts (498 objects) in the area of the sky containing the Abell catalogue of rich clusters. It was found that there is no statistically significant evidence that either low- or high-redshift QSOs lie preferentially close to Abell clusters. This is in contrast to the highly significant evidence that 3CR radio galaxies lie preferentially close to Abell clusters.

This result probably supersedes the early result of Bogart and Wagoner because much larger samples are involved. It does not contradict the work of Stockton as the galaxies he found close to his sample of low redshift QSOs are rarely, if ever, in rich clusters.

Seldner and Peebles[36] have found statistically significant evidence of a correlation between the position of 382 QSOs at $|b|\geq40°$ $\delta>-23°$ and the Lick counts of galaxies, $m\leq19$. They find on the average 1.45 ± 0.39 more galaxies within 15′ of a QSO than would be expected if the QSOs were placed at random. There seems to be no trend with QSO redshift or apparent magnitude and the effect is not apparently due to a few QSOs at the same redshifts or the galaxies of the type found by Stockton. Again this result does not conflict with the absence of correlations with Abell clusters as the majority of the galaxies in the Lick counts lie in small groups and more extended distributions.

From these results and those of Stockton we conclude: first, that QSOs are not present in rich clusters; second that QSOs are sometimes physically associated with small groups of galaxies. In some cases they may have the same redshifts, with no significant non-cosmological component, while in others they may be a large non-cosmological component.

Conclusion

Based on the evidence discussed here some QSOs apparently have redshifts which are completely cosmological in origin, but others have redshifts of largely non-cosmological origin. It is hard to deny either the evidence of Stockton, or the evidence of QSOs found close to bright galaxies or their companions.

The results therefore imply either that there are two distinct classes of QSOs with very different physical redshift mechanisms operating, or that the Doppler effect is still always responsible. In this latter situation both cosmological Doppler shifts and those due to high speed ejection of QSOs from galaxies must be involved.

A theory of terrestrial catastrophism

W. M. Napier & S. V. M. Clube
Royal Observatory, Blackford Hill, Edinburgh, UK

The time sequence of terrestrial catastrophes and other Solar System phenomena is apparently stochastic but with an underlying galactic modulation. A mechanism is proposed involving the capture of planetesimals as the Sun passes through spiral arms.

THE radial separation of galactic spiral arms and the epicyclic frequency of the solar orbit imply quasiperiodic intervals between crossings of a few 10^7 yr. Should galactic evolution involve the formation of successive generations of spiral arms (see ref. 1), the intervals will be modulated by an additional quasiperiodicity of a few 10^8 yr. If spiral arms were to contain planetesimals, each Solar System passage would lead to the capture and formation of a temporary 'Oort cloud' which would be rapidly dissipated by planetary encounters and hyperbolic ejection. We shall argue that the cratering flux record, the current distribution of comets and the existence of many dynamically short-lived bodies in the Solar System, are each best explained as consequences of this single mechanism. With this viewpoint, comets and most asteroids and satellites are temporary survivors of one or more capture episodes. The impacting planetesimals can be shown also to cause, *inter alia*, water erosion on Mars, intermittent biostratigraphically recognisable events in Earth history (including mass extinctions) and ice ages. The latest rapidly declining series of events follows our passage through the Orion spiral arm. As the Gould Belt complex, at a mean distance of ~250 pc, is the nearest appendage of the Orion arm to the Sun (see ref. 2), and has a relative velocity of ~25 km s^{-1}, this capture episode ended ≤10 Myr ago. The most recent spell of ice ages, within the past ~20 Myr was preceded by a more temperate period[3] lasting ~40 Myr. Furthermore, assuming the Orion arm has a typical mass content (~10^6–10^7 $M_\odot$ kpc^{-1}), the calculated remaining flux of low mass planetesimals agrees with the observed 'short period' (Apollo) asteroids and an impact rate inferred from very recent terrestrial events.

Cratering flux history

The record of impact cratering on the Moon and inner planets[4] shows the planetesimal flux to have declined steeply for the first 2,000 Myr of the Solar System's existence, and then to have attained a constant value over the past 2,500–3,500 Myr. Superimposed on this trend are quasiperiodic bombardments, of uncertain magnitude and duration, separated by time intervals characteristically a few 10^8 yr. A similar periodicity is evident in the deposition of micrometeorites on lunar soil[5].

Dynamical studies[6] indicate that the steeply declining phase of the cratering history can be understood in terms of a sweeping-up, or hyperbolic ejection, of primordial debris by the planets. Rapid depletion of the inner Solar System debris occurs so that after ~10^8 yr, bodies entering the inner Solar System have semi-major axes primarily ~10^5 AU. The existence of these high initial flux rates is clear evidence that the Solar System has been immersed in a cloud of planetesimals in the past.

Two important features of the cratering history remain to be explained: the brief periods of enhanced bombardment; and the remarkable constancy, in the mean, of the planetesimal flux taken over the past ~3,000 Myr.

There are numerous perturbing sources in the interstellar medium. Thus the Solar System has passed through ~15 nebulae of radii a few pc and $n_H > 10^3$ in the past 4,500 Myr, and experienced ~60 close encounters (say with impact parameter $p < 8$ pc) over the same period[7]. Such nebulae have masses $M \sim 10^4 M_\odot$, and encounters with them would result in drastic perturbations of the planetesimal cloud and consequent flooding of the inner Solar System. This could account for the bombardment episodes. However, the very efficacy of the process raises

difficulties for the survival of a cloud virtually intact for half the lifetime of the Solar System, as is implied by the constant flux.

Numerical trials have been run in each of which 2,500 massless bodies bound to the Sun were perturbed by a passing nebula idealised as a point mass of prescribed (M, p, V), where V represents the flyby velocity. The orbits were randomly orientated and the semi-major axes a lay in the range $10^4 \leq a \leq 2\times10^5$ AU, with eccentricities e in the range $0 \leq e < 1$: the test particles were therefore on the outer fringes of the hypothetical Oort cloud. The results of the three-body integrations are shown in Table 1. Clearly the outer part of the Oort cloud, from which long-period comets are supposed to derive, would be very efficiently cleared by passing dense nebulae, and it does not seem likely that the comet-producing regions of the cloud could survive ~30 such encounters, let alone yield a constant cratering flux for the past ~3,000 Myr.

Even if we disregard these difficulties, the hypothetical Oort cloud as currently envisaged is unlikely to be the source of impacting planetesimals. Thus, its mass is supposed to be a few $m_\oplus$ based on a comet mass of $\sim10^{17}$ g and the likely number of comets[8,9]. The crater size distribution[10] reveals a mass function $\propto m^{-1.6}$ with a typical upper limit of $m > 10^{20}$ g (for example the Tycho crater was formed ~400 Myr ago[11] by a mass of $\sim10^{19}$ g). The bulk of the mass of the system must therefore be concentrated in the few largest bodies whereas the 'characteristic mass' of a comet is inferred from the more common bodies at the low-mass end of the spectrum. Note that some observers[12] give independent reasons for supposing a maximum cometary mass $\sim10^{20}$ g. It follows that the mean mass of a comet should be increased by a factor ~40 giving 80 $m_\oplus$, say, for the present Oort cloud. The process which fed comets into the Oort cloud would have thrown the bulk of the material into hyperbolic orbits[13]. Thus 80 $m_\oplus$ represents a total ejection of >1,300 $m_\oplus$ and probably >2,700 $m_\oplus$. These amounts are much too large to be dynamically possible for the current Solar System configuration.

These results indicate that the cratering flux must comprise two components: one a decaying part due to the primordial swarm of bodies bound to the Sun, the other a constant part which has become dominant over the past ~3,000 Myr as the first decayed. The main belt asteroids fail by a factor of ~10 to supply the impacting planetesimals[14] and would in any case be a decaying source. The only other possible location for the constant flux source is interstellar space. In this view, the long period comets have to be identified as the most easily visible component of the captured planetesimals. (The idea that comets are interstellar in origin was first suggested by Laplace[15].) The fact that there are few certain hyperbolic orbits amongst the long period comets indicates the Sun is not currently immersed in a significant interstellar source[16]. The observed flux is thus the residue of captures effected in the recent past.

The hypothetical Oort cloud should be thermalised by weak stellar encounters[17] on a time scale ~1 Myr. The perihelia q should thus be uniformly distributed both over the sky and in distance from the Sun. The perihelion distribution of long period comets in fact increases as $q^{1/2}$ in the inner Solar System[18], lies in a preferred plane ~20° from the Milky Way, and concentrates ~7° from the solar apex[19]. There is thus good evidence amongst the comets favouring a capture mechanism related to the Sun's motion through the local galactic environment.

Probably the dominant capture mechanism is through entry of planetesimals into Jupiter's sphere of influence: thus Radzievskii and Tomanov[20] have shown that Jupiter can capture $\sim10^5$ planetesimals of mean mass 10^{15} g during the passage, lasting 0.1 Myr, through a cloud whose planetesimal component has a smoothed-out mean density 10^{-20}–10^{-22} g cm^{-3}. For mean mass 4×10^{17} g the required densities are 4×10^{-18}–4×10^{-20} g cm^{-3}. These densities are high but not unreasonable; and if planetesimals are widely distributed through spiral arms rather than concentrated in dense clumps, the requisite densities are correspondingly relaxed.

Yabushita[21] has shown that the energy distribution of comets in the Solar System evolves to a form which, after 3–6 Myr, is almost independent of the initial distribution and is concentrated in the range $2\times10^4 < a < \infty$ AU. To be consistent with observation, capture must have taken place between 3.6 and ~9 Myr ago. Within the errors, this agrees satisfactorily with the emergence ≤10 Myr ago of the Sun from Gould's Belt.

We conclude that the constant average flux of planetesimals during the past ~3,000 Myr is ultimately of interstellar origin, and that the fluctuations in the bombardment rate reflect passage through successive spiral arms, the most recent of which is responsible for the currently observed declining flux of comets.

Some implications of interstellar planetesimals

If our hypothesis is correct, then planetesimals, possibly up to at least lunar size, must occur in abundance in spiral arms. Note that a depletion of C, N and O observed in the interstellar medium has been ascribed to the existence of interstellar comets[22] and has certain implications.

First theories of the origin of the Solar System involving accumulation of blobs rather than, say, condensation of a solar nebula, become more plausible. Star formation as a process of aggregating small masses rather than fragmenting large ones is then probable. Although such ideas[23,24] have never found favour, the alternative of Jeans collapse is proving unsatisfactory[25]. The hypothesis is *a priori* consistent with star formation occurring predominantly in spiral arms. The planetesimal mass function indicated by the crater size distribution is developed in a fragmenting–accreting regime[26] and must be consistent with the presence of dust in spiral arms. Cold 'globules' have been observed[27], and these provide evidence that dusty protostellar objects of the kind implicit in this scheme of star formation do actually exist. These objects are also notable sources of CO emission[28], and not only is CO emission generally very concentrated in the galactic plane where spiral arms lie[29], but it is commonly detected in regions of intense star formation[30]. We emphasise therefore that although the existence of planetisimals is not generally considered to be an essential requirement for any theory of how stars are formed, it is, nevertheless, consistent with observation.

A deeper problem arises when we consider the origin of the planetesimal material. The interstellar accretion processes stu-

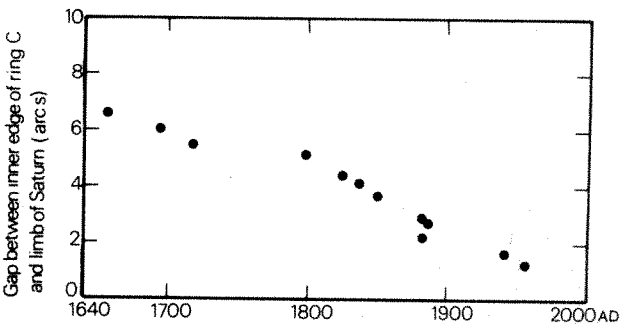

Fig 1 Gap between inner edge of ring C and limb of Saturn, measured in arc s and normalised to a mean opposition. Secular evolution of the whole ring system on a time scale a few 10^4 yr seems probable.

Table 2 Short-lived or recent Solar System phenomena

Object	Phenomenon	Time scale (yr)	Probability*	Comments	Refs

died so far[31] give growth times of ~100 Myr to attain particle diameters $\sim10^{-5}$ cm. Some forced diffusion mechanism (see refs 32, 33) of remarkable efficacy is required if, say, density waves were the prime agency in forming spiral arms. But if spiral arms were the result of some exotic process, say involving recurrent (galactic) nuclear explosions, then one might look for the origin of planetesimals in that same exotic process. Seyfert events may be the result of such explosions at 10^{8} yr intervals[34], and these can be understood in terms of very massive stars ($\geq10^{8}\,M_{\odot}$) evolving through and beyond a nuclear burning phase[35]. On this hypothesis therefore, planetesimals are suddenly cooled fragments of central highly evolved, very massive stars[1].

Recent events and anomalous phenomena in the Solar System

One might expect to find manifestations of interstellar capture events among the small body population of the Solar System. Indeed we propose that in addition to the comets, many asteroids and satellites form a temporary population in a state of relatively rapid (10–100 Myr) dynamic evolution, being the survivors of one or more capture episodes.

Table 2 lists some short-lived Solar System phenomena. Qualitatively, these find a unified explanation in terms of a temporary capture scenario; taken cumulatively, they seem otherwise inexplicable. For example the probability, on a conservative view, that we happen to simultaneously observe the Triton, Phobos and Chiron events is $\sim2\times10^{-10}$. Singer[49] has argued that all the regular satellites of the major planets were captured after the formation of the planets themselves. Currently, direct orbits predominate because retrograde orbits decay more rapidly. The slope of the satellite mass function is similar to that of asteroids, in agreement with a common origin hypothesis. The largest satellite masses are also close to that which comes within the capture radius of Jupiter during spiral arm passages.

A fundamental problem of the asteroid system is that it has much more internal kinetic energy than can be fed into it by jovian perturbations. Jupiter can induce eccentricities of at most a few hundredths in the asteroid system, substantially less than those observed (which are up to ~0.40)[50]. Another manifestation of this problem[51] results from application of Tisserand's criterion to Pallas: it has been shown that this large asteroid (and others) cannot have been perturbed by Jupiter from the invariable plane into its high-inclination orbit—yet conventionally, accretion could have occurred only in the quiescent conditions supposed to pertain in the invariable plane[52].

These problems do not arise on the capture hypothesis, according to which the asteroid zone represents a relatively stable region of phase space, and the asteroids are, in part or whole, interstellar planetesimals which have accumulated during successive bombardment episodes. One therefore expects the asteroids to occupy every available stable niche of phase space, as is observed. The observed chemical differentiation is then a matter for conjecture: the outer, carbonaceous asteroids may simply not yet have lost their surface coating; or we may be observing the products of successive capture events from interstellar regions with locally different properties.

Short-period comets are regarded as deriving from intermediate and long-period comets through jovian perturbations[56]. As they have lifetimes of only a few centuries then one expects dynamic equilibrium to be established in time scales of that order. A recent study[18] of the number density of long-period comets in the Solar System indicates that this is constant throughout the inner regions, and is ~0.09 AU^{-3}. With this figure only 1 comet per 11 yr is expected to enter the 'capture region' around Jupiter. The probability that a comet, entering the capture region, will actually be captured[57], is $\sim7\times10^{-3}$. One therefore expects an interval ~1,600 yr between captures of long-period comets into short-period orbits. Since the lifetime[58] before disintegration of a short-period comet is ~500 yr, then there is an expectation on the 'steady state' model of observing ~0.3 short-period comets. The number actually observed ~80.

The explanation may be that a moderately large comet (say diameter 20 km) disintegrated due to tidal forces while in the process of being captured into a short-period orbit. The maximum fragment size would be determined by the tensile strength of ice and the closeness of passage to Jupiter: fragmentation into say $\sim10^{3}$ pieces of diameters ≤2 km is feasible.

This discussion implies that the intermittent capture hypothesis provides a single, simple explanation of diverse phenomena which otherwise require a variety of *ad hoc* theories.

Planetary impacts

The terrestrial cratering history of the Phanerozoic[10] indicates that the smoothed interval between formation of craters of diameter $D\geq20$ km, is $\delta t\simeq5.7\times10^{5}\ (D/20)^{2}$ yr, with D

measured in kilometres. The kinetic energy E of impact is related to D by $E = 2.4\,D^{3.4}$, valid for $D \geq 14$ km. (It is convenient here to measure energy in megatons equivalent of TNT: one megaton $\equiv 1$ MT $= 4.2 \times 10^{22}$ erg.) Given E, a density of 3.3 g cm^{-2} and a r.m.s. impact speed of 24.6 km s^{-1}, the projectile diameter d follows. Hence (δt, d, E) can be calculated in terms of D and are listed in Table 3.

The actual frequency of impact is bunched into episodes of spiral arm immersion; hence from Table 3, the Earth is expected to suffer one impact of energy at least 1.6×10^8 MT during each passage of the Sun through a spiral arm; an impact with $E > 5 \times 10^8$ MT during a passage is expected with probability ~0.5; and an impact of energy $\geq 10^9$ MT is expected sometime during the Phanerozoic. These intervals should be compared, for example, with the mean duration of a biostratigraphic period (~50 Myr). These large impacts must inevitably have global consequences, directly through the effects of blast (see ref. 59), and indirectly through the injection of dust[60] and NO into the stratosphere.

For land impacts, the smallest overpressure likely to be experienced anywhere on Earth is ~0.25 kg wt cm^{-2} when, for example, $E \sim 5 \times 10^8$ MT. Peak overpressures of this magnitude completely destroy forests[61]. As large land vertebrates of small strength/weight ratio would be preferentially killed[62], such a blast wave could have been the prime cause of the Cretaceous–Tertiary extinction[63,80]. The survival of animal life associated with underground habitats and the rapid regeneration of vegetation from roots and seeds would be consistent with this hypothesis. An impact of this energy would also excavate $\sim 10^{18}$ g of material much of which would reach the stratosphere as a fine dust and block out sunlight, with catastrophic effects on food chains[63]. If the settling time were ≥ 10 yr, the build up of ice could be ~0.3 km in depth and continental glaciation might be initiated[64]. Analogy with nuclear explosions suggests that $\geq 10^{15}$ g of NO would be injected into the stratosphere[66], thereby destroying the ozone layer. The biological effects of the UV deluge to be expected as the sky clears are likely to be drastic[67]. Ocean impacts, causing waves up to 8 km amplitude, will generally be more common than land impacts, and through simultaneous flooding of the land and obscuration of the upper atmosphere are likely to be an extremely efficient cause of sudden ice ages. An impact in the Palaeozoic Pacific at the close of the Frasnian explains[68] all the major aspects of an event which included the sudden extinction of shallow sea life.

Impacts of the sort expected at ~50 Myr intervals therefore produce an abundance of deleterious effects, the consequences of which are catastrophic extinctions. The situation is likely to be more complex for lesser impacts but the gradual extinction of taxa might be initiated indirectly: thus the widespread brachiopod extinctions near the Ordovician–Silurian boundary are correlated with general glaciation and withdrawal of the sea from continental platforms[69]. A quasi-periodicity in the numbers of taxa is clearly evident[70] and is ~50 Myr. Geophysical consequences are more conjectural, but the correlation between extinction events, field reversals and rotation period[71] may have impacts as a common cause. It is possible that frequent ice ages so alter the mass distribution on plates as to raise or lower land levels[72], precipitate orogenic activity at their perimeters, and even provide a driving force for tectonics. Urey[73] suggested that impacting comets might induce the termination of geological periods and pointed out a correlation with tektite ages. Table 4 lists the ages of the known tektites, and all known craters of diameter >50 km, against the ages of the geological periods. As the record must be grossly incomplete, it is surprising that, within the uncertainties, tentative correlations can be made, agreement becoming poorer the more remote the epoch.

Table 3 Interval δt between impacts with planetesimals of diameter $\geq d$, with impact energies $\geq E$ and producing craters of diameter $\geq D$

D (km)	δt (yr)	E (MT)	d (km)
80	9.2×10^6	7.1×10^6	3.9
100	1.4×10^7	1.5×10^7	5.0
200	5.8×10^7	1.6×10^8	10.9
500	3.6×10^8	3.6×10^9	30.8

Table 4 Ages of geological periods compared with tektite ages and ages of all known Phanerozoic craters > 50 km diameter

Biostratigraphic interval	Age at beginning (Myr)	Tektite/ crater age (Myr)	Tektite/ crater
Pleistocene	1	0.77 ± 0.10	Australites
		0.88 ± 0.93	Ivory Coast
Pliocene	13	14.7 ± 0.7	Moldavites
Miocene	25	28.6 ± 2	Libyan desert glass
Oligocene	36	34.7 ± 2	Bediasites
		38 ± 9	Popigai, 100 km, USSR
Eocene	58	57	Kara, 50 km USSR
Palaeocene	63	?	?
Cretaceous	135	?	?
Jurassic	181	183 ± 3	Puchezh-Katunki, 80 km, USSR
Triassic	230	210 ± 4	Manicougan, 70 km, Canada
Permian	280	?	?
Carboniferous	345	365 ± 7	Siljan, 52 km, Sweden
Devonian	405	?	?

Comets may comprise ~40% water ice by mass[74], and this may hold for a proportion of the larger planetesimals: the low densities of the saturnian satellites, for example, may indicate an icy constitution. The impact hypothesis therefore offers a natural explanation for the extensive water erosion on Mars, which is known to have arisen from one or more catastrophic flooding events[75].

A prediction of the hypothesis is that anomalous isotopic and abundance anomalies should occur, because of global dust settling, at biostratigraphic boundaries. Thus Pt, Ir and Os are typically 10^3 times more abundant in extra-terrestrial than crustal material. W. Alvarez *et al.* (personal communication) have found that, in a 1-cm clay layer marking the Cretaceous–Tertiary boundary at Gubbio, Italy, the Ir abundance jumps by a factor ~20, decaying upwards with a half height of 8 cm. The absence of ^{244}Pu, at ~0.1 of the level predicted by nucleosynthetic theories, seems to preclude a supernova source.

Discussion

Clearly the picture presented here needs clarifying. In particular the implications of large amounts of planetesimal material in spiral arms, and the terrestrial consequences of large impacts, need to be explored further. Nevertheless, starting from (and justifying) the interstellar capture hypothesis, we have been able to unify a wide range of galactic, Solar System and terrestrial phenomena; and we have identified the most recent capture event as having ended ≤ 10 Myr ago with the emergence of the Solar System from Gould's Belt.

Our theory enables the flux of planetesimals on the Earth at present, corresponding essentially to the short period core of the Apollo asteroids (ref. 14) to be calculated. This flux results in one $10^{3\pm1}$ MT event every ~10^4 yr and one of these may well have been responsible for initiating the short ice age from which Earth emerged some 10^4 yr ago. (There is a 20% probability that the event lies in the upper half of the stated range.) For comparison, the Krakatoa volcano[76] had an energy of 50 MT and the Tunguska meteorite[77] ~10 MT: these caused ~10% and ~1% drops in the solar constant respectively over ~1 yr. A stochastic distribution of similar ice ages over the preceding ~10^7 yr is implied, although with additional modulation by the Milankovitch process (see ref. 78). With the usual planetesimal mass function, the flux also corresponds to one $10^{2\pm1}$ MT event per ~1,000 yr, each with possibly detectable consequences.

Thus, we might expect these to produce a temporary hemispheric climatic cooling and, following calculations by Brown and Hughes[79], a correlated enhancement of ^{14}C. Discrepancies in ^{14}C chronology during the past several thousand years are known to occur and may coincide with 'mini' ice ages[65]: a common cause for such effects seems probable. Planetesimal impacts have not been previously suspected in this context, and yet their impact frequency is apparently such that historical records are a potential source of data for testing our hypothesis.

Cooperative effects in simulated water

P. Barnes, J. L. Finney, J. D. Nicholas & J. E. Quinn

Department of Crystallography, Birkbeck College, University of London, Malet Street, London WC1, UK

Computer simulation calculations on liquid water, aqueous solutions and biological interfaces have been made almost universally assuming pair-additive interactions. Experimental and theoretical evidence implies this is a serious oversimplification. The development and testing of a different approach is reviewed in which many-body forces are specifically taken into account through molecular polarisation. Solution and interfacial properties of aqueous systems are particularly sensitive to such forces.

DURING the past decade there have been significant advances in our understanding of the molecular structure and dynamics of the liquid state. This has been due largely to the development of computer simulation techniques such as Monte Carlo and molecular dynamics methods[1–3] by which we avoid the problems remaining in analytical theories of simple liquids[4].

The success of these methods applied to the simple liquids of the theoretician (such as liquid argon) has encouraged applications to more complex liquids. In particular, the universal relevance of water in chemistry and biology, coupled with the fascination of its 'abnormal properties', have made aqueous systems a popular target for simulation methods[5–9]. But if results are to have more than a hypothetical relevance to the real liquid, the potential we use must model adequately the behaviour of real water molecules. We discuss some of the difficulties facing realistic simulations of 'water-like water' which are unavoidable if solution effects and the operation of biological systems are to be understood properly. We pay special attention to the nature of water–water hydrogen bonding and argue that the long suspected cooperative nature of this interaction[10] must be taken into account.

Pair additivity

A variety of potentials has been used to model the water–water hydrogen bonding interaction, such as the four-point-charge ST2 (ref. 11) potential which was derived from an earlier effective pair potential (BNS)[12], which was itself fitted to the measured second virial coefficient of steam. Other potentials in use include central-force models (CF) such as that of Lemberg and Stillinger[9] which treats the hydrogens and oxygens as separate charged units, and one developed by Clementi by

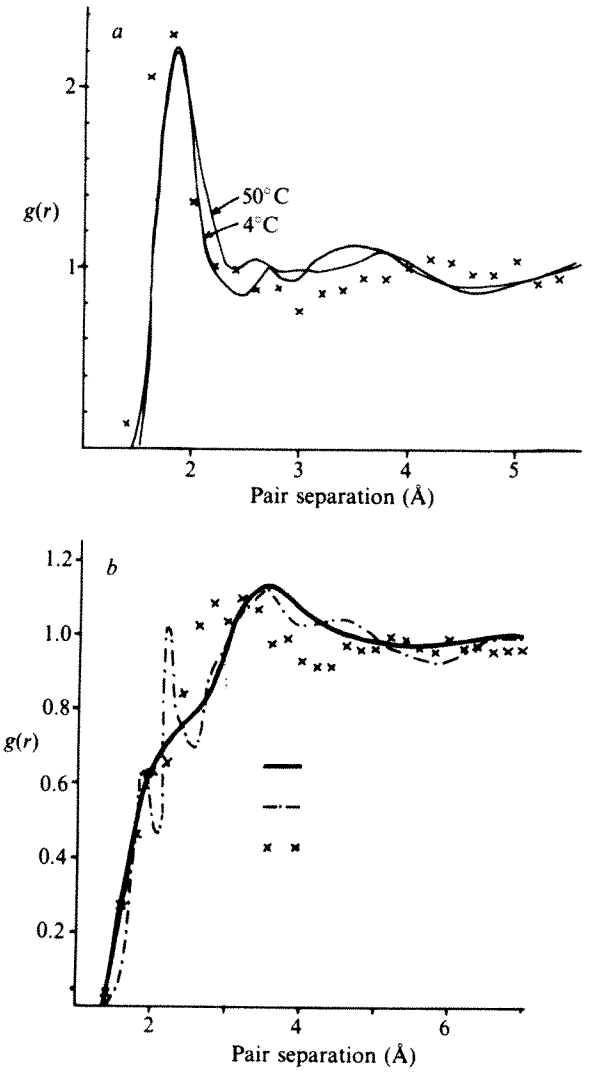

Fig. 1 *a*, Pair distribution functions, $g(r)$, obtained from X-ray scattering data[46] on water at 4 °C and 50 °C (——) and from simulated PE-water (×). The starting configurations were generated from an assembly of 216 molecules (previously equilibrated under the ST2 potential) with 40,000 Monte Carlo steps using a cubic box length of 18.62 Å, normal periodic boundaries and a cut off of 7–7.5 Å. *b*, A comparison of the neutron pair distribution function of D_2O at 11 °C (——) with simulation predictions using the central-force (CF) model of Stillinger and Rahman[51] (- · - ·) and the polarisable electropole (PE) model (×). The PE model reproduces the low-r shoulder and is notably free of the strong peaking incorrectly predicted by the central force model (which indicates the over-tetrahedrality of the latter potential).

fitting an analytical form to quantum mechanical calculations on the water dimer[7].

All these potentials are pair-additive: the energy of a given assembly is expressed as a sum of interaction energies between all pairs of molecules in the assembly. In other words, the interaction between an isolated pair of molecules is assumed to be unaffected by the intrusion of a third molecule. This is a universal assumption when dealing with simple liquids, where it is an excellent approximation. For water it has been argued that non-pair-additive effects, although accepted to be greater than in simple liquids, can be either neglected or somehow averaged[12].

However, it has been stressed[13] that none of these pair potentials can account for both gas and condensed phase properties of water, and recent neutron diffraction data[14,15] on D_2O demonstrates that current four-point charge and central-force models predict an overstructured liquid. Moreover, the known failure of these simple models to account for dielectric properties is a serious drawback to understanding solvent effects in real aqueous chemical or biological systems. The following observations underline the inadequacy of pair-additive potentials: (1) Isolated water molecules are poor hydrogen donors and acceptors; in the gas phase, water is less acidic than toluene, less basic than formic acid[16]. This strongly implies that its celebrated acid/base properties must relate to its bulk phase, rather than to the isolated molecule. (2) Quantum mechanical calculations on, for example, water trimers and tetramers, suggest that hydrogen bonding in these clusters is stronger than in the dimer by 20–30%[17,18]. (3) The dipole moment of the isolated water molecule is 1.85 D (ref. 19), yet the average value for hexagonal ice I is between 2.6 and 3.0 D (ref. 20). Such a large dipole moment enhancement is highly relevant to dielectric and solution properties.

One might argue that an effective pair potential might be constructed to reproduce such condensed phase effects; in view of the known extent of the non-pair additivity, such a procedure is not only artificial but is incapable of reconciling gas and liquid phase properties and therefore most unlikely to be able to predict localised effects such as at interfaces. This evidence forces us to take the cooperative effects into account specifically, and to examine their consequences.

The polarisable electropole water model

The electronic charge distribution of an isolated water molecule is represented by a multipole expansion as described by Buckingham[23] using the known dipole and quadrupole moments plus a spherically symmetric Lennard–Jones function. In developing a polarisable electropole (PE) water model[21,22], an electropole formalism (see Table 1 legend) was chosen in preference to a four-point charge model, (1) to avoid the need for artificial switching devices[11] necessary to prevent charge overlaps, (2) to ensure the correct sign and magnitude of the quadrupole moments (ST2, for example, yields a quadrupole moment of the wrong sign), and (3) to minimise the need to fit adjustable parameters. The non-pair additivity is handled using a classical polarisability tensor.

The use of this classical device requires explanation, considering that any significant covalency would result in appreciable charge transfer between two hydrogen-bonded molecules. However, as the size of the basis set used in *ab initio* quantum mechanical calculations on the water dimer is increased, the amount of charge transfer predicted falls to a degree where electronic cloud distortion into the hydrogen bond region is high but actual intermolecular electron transfer is small[28]. A polarisation algorithm can reproduce the major effects of this charge distortion.

In performing polarisation calculations, the resultant electric (dipole + quadrupole) field acting on a given molecule will induce an electron cloud distortion quantified by the product of the field and the polarisability. This polarisation gives rise to corrections to the previously calculated fields and hence to a further change in the calculated polarisation, and so on. The total polarisation is thus determined in an iterative fashion

Table 1 Comparison of second virial coefficients

Temperature (°C)	Stockmayer*	Model CI†	BNS‡	ST2†	PE§	Experimental ($cm^3\ mol^{-1}$) Refs 34	56	33

*Ref. 32. †Ref. 57. ‡Ref. 12.

§The present model uses an isolated dipole moment of 1.855 D (ref. 19), absolute (not derived[23]) quadrupole moments ($Q_{xx} = -7.482$, $Q_{yy} = -4.180$, $Q_{zz} = -5.939$ D Å, axes as defined by Glaeser and Coulson[26]) from quantum mechanical calculations[24] and an isotropic polarisability ($\alpha_{xx} = \alpha_{yy} = \alpha_{zz} = 1.444$ Å^3) obtained from extrapolated[25] refractive index data. The Lennard–Jones parameters ($\sigma = 3.024$ Å, $\varepsilon = 0.764$ kcal mol^{-1}) were chosen to fit the equilibrium dimer[27] properties.

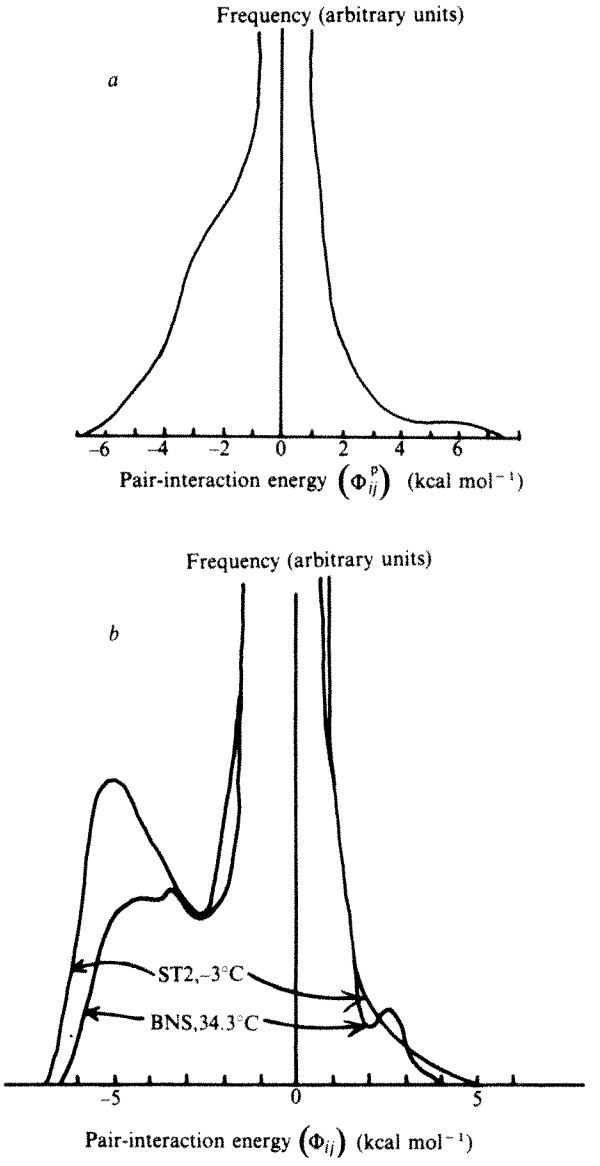

Fig. 2 The population distributions of interaction energies between all pairs of molecules in simulated configurations obtained using: *a*, the polarisable electropole: and *b*, four-point charge models. The four-point charge data (BNS[6] at 34.3 °C, ST2 (ref. 11) at −3 °C) show a definite low energy peak or shoulder at −3 to −6 kcal mol^{-1} which has been identified with 'hydrogen-bonded' pairs. In contrast the PE model indicates merely a broadening consistent with a picture of continuously-varying hydrogen bond energies rather than one in which bonds are discretely formed or broken.

(essentially a self-consistent field approach) and 2–5 iterations are typically necessary to achieve a constancy of better than 1% in the final charge distributions. Once this is completed, the energy is calculated by summing the pair interactions of electric fields with the resulting instantaneous dipole moments and field gradients with quadrupoles. The relevant equations are given elsewhere[42].

The model has the following advantages: (1) The non-pair-additivity calculations are exact. No effective averaging is used. Consequently this potential can be used for gas, liquid and crystal calculations as well as interfacial and mixed aqueous systems. (2) No adjustable electrical parameters are used, in contrast to other models[7,9,11,12,29] where parameters are adjusted to one or two sets of data. (3) Artificial devices such as switching functions[11] are not necessary. (4) Problems of generalising the switching functions to polarisable water molecules do not exist; electrostatic polarisation catastrophes are not experienced in practice except in cases of pathological configurations. (5) The properties of the isolated water molecule are by definition correct. In particular the quadrupole components, in contrast to four-point-charge models, are correct in both sign and magnitude.

Tests of the model

Before using any potential in expensive liquid-phase simulations it is only sensible to test it against known properties which are easily quantified[13,30]. If such tests give poor agreement with experiment, then the potential is clearly inadequate. One cannot overstress the need to be critical at this stage. Thus, we have preferred to gain confidence in the predictive ability of a potential function over a wide range of densities before testing it on expensive liquid, solution and biological interface calculations. The following is a selection of the tests made so far.

The second virial coefficient of steam $B(T)$: this two-molecule property, exploring the interactions of an isolated pair of molecules, can be written for a temperature T as

$$B(T) = -\frac{1}{16\pi^2}\int (\exp - \phi_{ij}/kT - 1)\,d\tau$$

Here, ϕ_{ij} is the interaction energy of the pair, and k the Boltzman's constant. The integration, ideally performed over all possible configurations, raises sampling problems which are discussed elsewhere[31]. Table 1 shows $B(T)$ for several potentials. The BNS and Stockmayer potentials were obtained by fitting adjustable parameters to $B(T)$ whereas the ST2, CI and our PE model values are predictions made without such adjustments. Of the latter set, only the PE model gives a satisfactory fit, especially at low temperature.

The equilibrium water dimer: the polarisable electropole (PE) predictions are in excellent agreement with the equilibrium configuration and force constants from both quantum mechanical calculations[7,17,18,28,36] and experimental measurements[27] (see Table 2).

Small water clusters: as agreement between different quantum mechanical calculations is poor, we discuss only the relative stabilities of the different cluster geometries, and the overall trends in their respective non-pair-additivity energies rather than the less reliable absolute values. Referring to Table 3, the most stable arrangements are the sequential (OH—OH—OH—) form with a distinct preference for the more closed chain varieties, and (except for the trimer) for cyclic clusters over chains. The PE model reproduces the same relative trends in equilibrium geometry and non-pair-additivity. The hydrogen-bond energy increases from −6.09 to −10.35 kcal mol^{-1} as the cluster chain grows from two to five molecules; the enhancement of some 70% is more than a mere perturbation. Water is clearly cooperative, and the PE model reproduces structural and energetic consequences well within the variations found between different quantum mechanical calculations.

Ices: theoretical estimates of the average dipole moment $\bar{\mu}$ in ice Ih suggest a value of 2.6 D (ref. 37)—an enhancement of 40% over the isolated molecule value—while a recent experiment proposes values between 2.45 and 3.0 D (ref. 20). The PE model predicts an average value of 2.88 D, with a half-width spread of about 0.3 D. (The PE model tests were performed on an enlarged unit cell of 432 ice molecules using normal periodic boundary conditions and a cut-off distance of 11 Å. Canonical Pauling arrangements for hydrogen positions were obtained using a disordering 'loop generation' technique described elsewhere[11,22].)

Compared to the experimental value of −11.3 kcal mol^{-1} for the internal energy of ice Ih (refs 38, 39), the PE model gives a value of −11.8 kcal mol^{-1}, of which −17.1 kcal mol^{-1} comes from electrostatic contributions. Although this agreement is encouraging, we regard it as largely coincidental in view of the unoptimised repulsive core parameters. The model is also consistent with the non-existence of a ferro-electric phase of ice

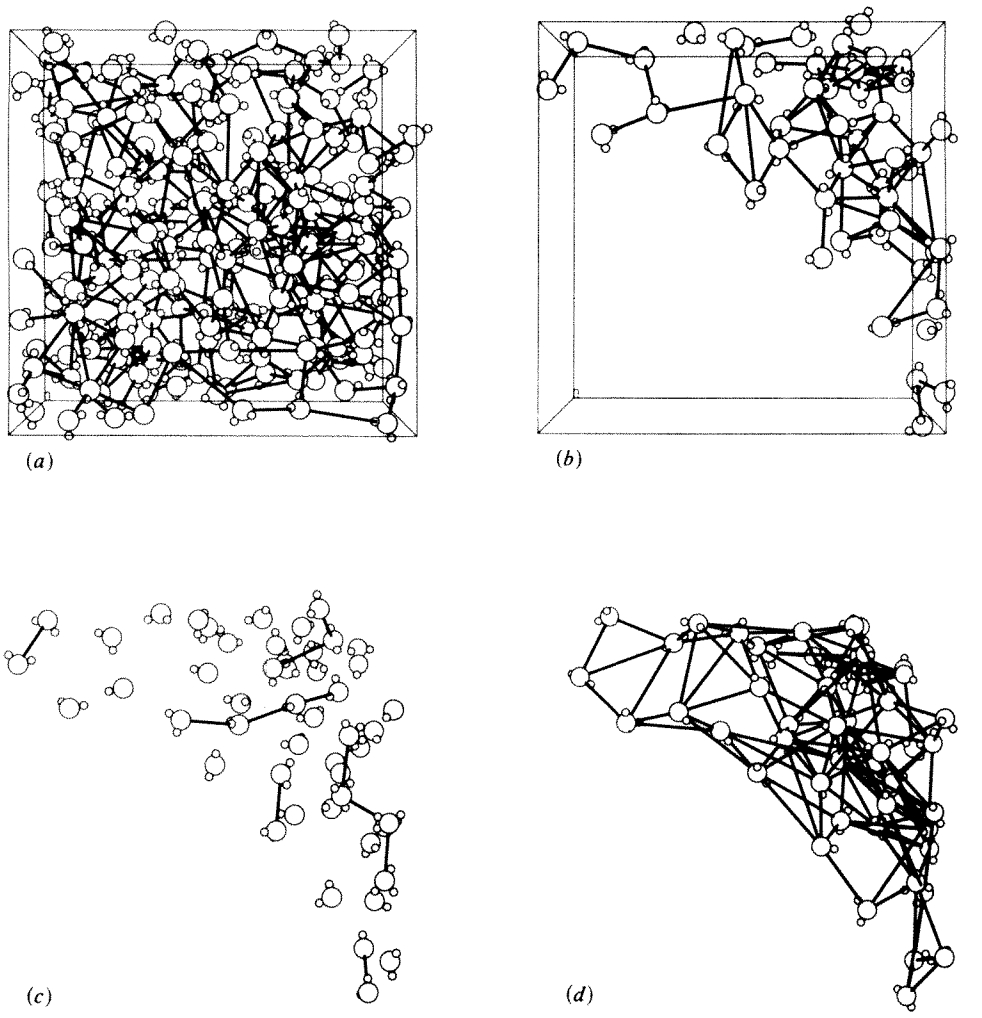

Fig. 3 Computer-drawn models of PE-simulated bulk water (*a*) and a cluster of 50 water molecules (*b–d*). The intermolecular links are notional hydrogen bonds chosen using an energy interaction criterion (cutoff at -2.0 kcal mol^{-1}, using polarised electropole pair-interactions) to give an average coordination of 4.0 in the bulk. The 50 molecule cluster was chosen from a bulk configuration (b-bulk molecules not shown), then removed from the bulk environment (*c*), and then allowed to move freely under the Monte Carlo process (*d*). The initial isolation from the bulk drastically changes the bonding patterns from that of *b* to *c*, strikingly demonstrating the effects of cooperativity at an interface. Pair-additive models would be unable to distinguish between the bonding of *b* and *c*.

Ih (ref. 40), in which the hydrogen positions would be ordered. Such an ordered phase would have a predicted potential energy marginally higher (0.4 kcal mol^{-1}) than the disordered phase. Although the difference is small ($\sim kT$), this alliance of increases in both entropy and binding energy is unusual. The high stability of the high pressure-hydrogen ordered ice VIII is also shown[41] by the PE model to be almost wholly due to dipole–quadrupole interactions, underlining again the need for the correct sign of the quadrupole moment.

Liquid water

We have begun to examine some consequences of non-pair-additivity for the liquid phase of 'PE water'. We stress the preliminary nature of these results, in particular the short chain length so far generated (see legend, Fig. 1a), and that the model is being refined. Nevertheless, some of the results make very interesting comparisons with those from standard pair-additive potentials.

The reconstructed instantaneous configuration shown in Fig. 3*a* is consistent with a picture of the liquid as a non-crystalline disordered network. Closer examination, however, shows considerably lower tetrahedrality of local coordination than found in ST2, BNS or Rowlinson-water[5,6,11,44]. Although surprising at first, this result is consistent with both the degree of tetrahedrality indicated in crystal hydrate studies[45] and the less structured picture of water given by recent neutron diffraction data[14,15] (Fig. 1*b*).

Figure 1 compares radial distribution functions of PE water with experimental X-ray[46] and neutron[14,15] results. There are evident deficiencies in the PE results (as there are deficiencies with pair-additive calculations[8]) which suggest, among other things, an inadequate treatment of the short-range repulsion; the improved agreement with the 50 °C curve suggests that our notional temperature is too low for the potential (repulsive part) used. The comparison with very recent neutron data is particularly interesting (Fig. 1*b*). Whereas ST2 and CF (ref. 51) both predict too much close-range structure (a consequence of over-tetrahedrality), the PE results are much more consistent with experiment. This less-structured picture is also borne out by studies[22] of the distribution of effective pair interaction energies as seen in Fig. 2*a*. The lack of definite bimodal distribution on the negative energy side should be compared with the definite maximum observed for ST2 and BNS water[46] (Fig. 2*b*) which was used to support the idea of a well-defined hydrogen bond. In contrast, the PE model is consistent with a picture of a continuously varying hydrogen-bond energy rather than formation (or breaking) of discrete hydrogen bonds. This suggests that it may be dangerous to identify hydrogen bonds from the purely geometrical considerations of distances and angles. In some cases, a second-nearest neighbour geometrically is found to be a first-nearest neighbour energetically and vice versa.

Table 2 Water dimer predictions

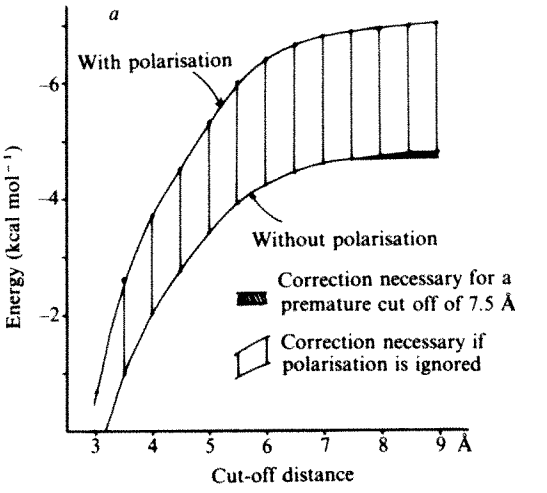
Table 3 Water cluster energies and non-pair additives (kcal mol^{-1})

Water cluster	Quantum mechanical	Polarisable electropole (PE)
DBP-trimers		
Double donor	−9.33 (+1.87)	−13.58 (+0.24)
Double acceptor	−10.14 (+2.05)	−13.66 (+0.55)
Sequential	−14.66 (−2.06)	−16.77 (−0.83)
Polar-cyclic	−16.83	+10.51 (−1.74)
DBP-tetramers		
Open	−23.45	−26.02 (−1.8)
Closed	−24.55	−27.25 (−2.2)
Polar-cyclic	−37.91	−32.62 (−7.55)
DBP-pentamers		
Semi-open		−36.25 (−3.12)
Closed	−41.39	−43.70 (−5.24)
Polar-cyclic	−53.15	−73.61 (−16.75)
DBP-hexamer		
Polar-cyclic	−64.53	−93.67 (−23.66)



Non-pair additives are given in parentheses. The DBP-cluster configurations and the quantum-mechanical values are those given by Del Bene and Pople[18,36]. The PE values contain just the electrostatic portion—the Lennard-Jones contribution is irrelevant to non-additivity.

The distribution of instantaneous dipole moments yields an average (enhanced) value of 2.50 D with a half-width spread of about 0.7 D. The relevance of cooperativity to dielectric, and hence solution effects, is strongly underlined. The internal energy is −6.8 kcal mol^{-1}, of which −9.0 kcal mol^{-1} is electrostatic. The comparison with experiment[38] (−9.9 kcal mol^{-1}) is not good, but the above discussions of notional temperature and the sensitivity to the repulsive core should be borne in mind.

The significance of non-pair additivity at a free water interface is underlined by a Monte Carlo calculation in which a droplet of 50 water molecule centres (chosen with a large surface area) was instantaneously removed from a bulk simulated water configuration. The evolution of the removed cluster is shown in Fig. 3*b–d*. Note that the initial destruction of hydrogen-bonding interactions depends solely on removal of the remaining aqueous environment, and the rapid re-establishment of a new hydrogen-bonding scheme as the droplet adjusts to its isolation. Pair-additive potentials would be unable to differentiate between the bonding in the first two states (Fig. 3*b*, *c*). Hence we stress the inadequacy of using pair-additive potentials in looking at any aqueous interface, such as protein–water interactions[47,48].

The effects of truncating the energy calculation at a short distance, normally 7–9 Å, have been widely discussed for dipolar fluids[49,50]. The concept of a reaction field, whereby the back-reaction of the forces from the fluid outside the cut-off radius are considered, has been proposed[52,53] as a possible way round the problem. However, all these discussions have been within the framework of pair-additive potentials. When non-pair-additive effects are considered, there are significant changes in the nature of the problem.

Figure 4*a* shows the correction necessary to the energy of the 'water' assembly using different cut-offs, with and without polarisability. Clearly a premature truncation gives rise to a far

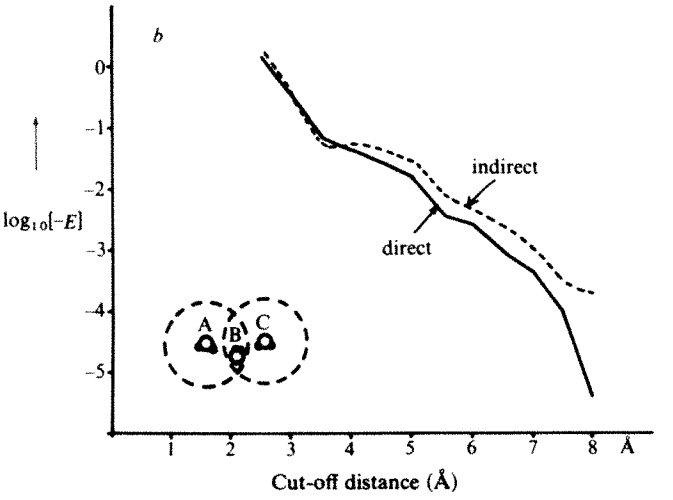


Fig. 4 *a*, The total energy of simulated PE-water as a function of the cut-off distance, with and without polarisation. The finely shaded portion represents the errors arising from using a cut-off distance of 7.5 Å (a common value), whereas the coarser shading indicates the errors arising from ignoring the cooperative effects of polarisation. Ignoring polarisation is clearly the dominant error. *b*, The variation with separation (r) of direct (——) and indirect (- - - -) interaction energies (E) between pairs of PE-water molecules in a bulk simulation. The indirect interactions arise from mutual polarisations through intervening molecules as illustrated by the three-molecule motif; the two molecules A and C (possessing cut-off spheres indicated by the larger circles) are separated so that no direct interaction exists between them, but a third molecule B common to both spheres provides, via mutual polarisation, an indirect link between A and C. Note that the indirect (A–C type) interactions overhaul the direct (A–B, B–C type) interactions for separations above 4 Å. This probing of long-range effects cannot be realised using pair-additive potentials.

smaller error in energy than does the neglect of the non-pair-additivity. A more subtle—and perhaps more dramatic—point is that within the framework of a non-pair-additive potential, we do in fact probe extensively those interactions beyond the cut-off radius via intermediate (polarised) molecules.

Figure 4*b* illustrates the point with three water molecules, A, B, C, placed so that A and C lie outside each other's formal cut-off distance. However, although A and C are considered to be unable to interact directly, the polarisation effects via molecule B provide an indirect link. We now define an indirect AC interaction as the difference between the potential energy of A with and without C present: clearly, only non-additive models will give non-zero values for this indirect contribution. Figure 4*b* compares the direct and indirect interactions as a function of the cut-off radius, and shows in our bulk water calculation that the indirect interactions are generally of greater consequence than direct interactions, even at the larger cut-offs.

Conclusions

It is necessary to abandon the use of pair potentials for aqueous systems. Although a parametrised effective pair potential reproduces 'homogeneous' properties such as the internal energy, we would have little confidence in its ability to predict properties depending on local effects, for example, the dielectric constant which depends significantly on the enhanced dipole moment. For interfaces, the removal of even a small part of the homogeneous fluid, for example by the presence of a solute molecule or a protein surface, will upset the indirect interactions severely (compare Fig. 3). We might draw a comparison with liquid metals, where we can devise an effective pair potential for a given density; change the density, and we change the effective potential. A bulk-derived potential would not be used for a liquid metal surface or for gas. Water should be thought of in a similar way. Interface calculations, be they simple solutions or protein crystals, based on pair-additive potentials would seem very premature.

Our approach to handling cooperative effects is probably only one of several which could be useful[54,55] and is clearly capable of further improvement. We would urge more effort be made towards developing alternative approaches, rather than continuing with applying known inadequate potentials[13,15] to more complex systems.

We thank Dr C. Moser of CECAM, under whose auspices part of this work was carried out, Dr J. Dore for neutron data, Dr B. C. Whalley and Dr C. J. Wormald for helpful discussions. J.E.Q. is supported under SRC grant GR/A 50368. We acknowledge the computing facilities of ULCC, SRC (Daresbury), and Birkbeck College.

Subduction, the geoid, and lower mantle convection

Clement G. Chase
Department of Geology and Geophysics, University of Minnesota, Minneapolis, Minnesota 55455

Geoid models show that net uncompensated masses in subducting lithosphere are less than thermal models predict, and do not require elevation of mantle phase changes in the slabs. The largest deviations from hydrostatic equilibrium ignore plate boundaries and may be ascribed to lower mantle convection uncoupled to plate motions.

THE EARTH'S gravity field gives the most direct evidence on the distribution of mass in its interior. In particular, areas of anomalous density associated with thermal convection—cold subducting slabs, mantle upwellings, deflection of internal density boundaries—should be reflected in the global gravity potential. Some surface tectonic features have characteristic large scale gravity anomalies[1,2], especially the oceanic subduction zones with their associated geoid (Fig. 1) and gravity

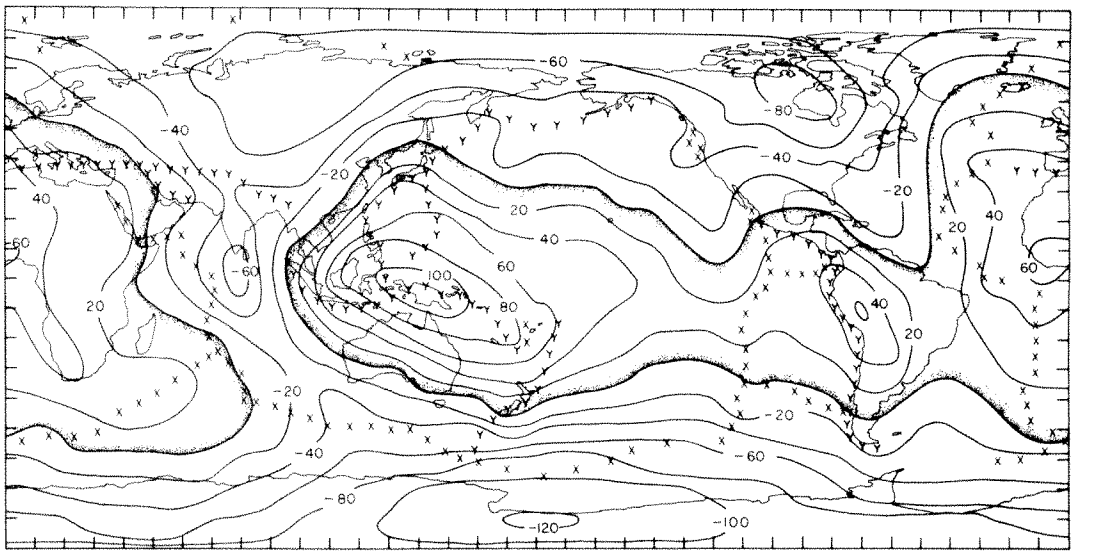

Fig. 1 Contours of the GEM8 geoid relative to a hydrostatic figure of flattening 1/299.75. In all the figures: solid contours are at 20-m intervals; dashed contours at intermediate 10-m intervals; uphill side of the zero contour stippled. Geoids were synthesised from coefficients of degree 2–20. Y, point on subduction zone; X, point on spreading centre. Cylindrical equidistant projection.

highs. However, most of the observed variation in the gravity field is not closely related to plate boundaries. Here forward modelling is used to match the observed field, thereby placing limits on the size and depth of some of the anomalous regions. Most previous quantitative interpretations of global gravity[3–9] have used direct or statistical inversion of the gravity potential.

The geoid

It proved advantageous to work with the geoid rather than with global gravity anomalies, which amplify the higher degrees of the spherical harmonic expansion of the potential. In geopotential models those coefficients are not as well determined as the lower degrees. Thus the geoid, which weights the harmonics evenly, is less subject to errors of measurement. The geoid also 'sees' deeper than the gravity field, because the effect of a mass on the geoid decreases directly with depth, while the gravity effect decreases with the square of the depth. Because the geoid is not as sensitive to the exact depth of perturbing bodies, their masses can be estimated more reliably without knowing the details of their vertical distribution.

All departures from hydrostatic equilibrium within the Earth must be supported by the strength of rocks or by viscous stresses, so the appropriate geoidal reference surface for tectonic purposes is the hydrostatic rotational figure of the Earth. Figure 1 shows the elevation of the nonhydrostatic geoid for GEM8[10]. The shortest wavelength represented is ~1,000 km.

Subduction zone model

It seems to be accepted that excess (uncompensated) mass of the subducting slabs is important in causing oceanic slabs to move (see ref. 11 and refs therein). Watts and Talwani[12] inferred from gravity models of outer rises that the cold slab was somehow regionally compensated. However, Grow and Bowin[13] have criticised their method and conclusion. Uncompensated slabs are used here since large averaging depth causes the geoid to respond most strongly to net excess or deficit of mass.

The starting point was the thermal slab model of McKenzie[14] as modified for finite slab length by Molnar and Gray[15]. The slab's down-dip length was taken as length of the seismic zone[16], except for Patagonia and the continental collision zones, where slabs to 200 km were assumed. Approximating points (Figs 1, 2) were then assigned masses determined by the local subduction rate from a global relative motion model[17] and the area of slab they represent. Behind-arc spreading was not taken into account. Depths of the point masses are shown in Table 1. Spherical harmonic coefficients of the point mass potentials[18] were then calculated and summed.

The simple thermal models markedly overestimate the net excess mass localised in most subducting slabs, turning positive anomalies into negative ones. An empirical subduction zone model (Fig. 2) was derived by independently adjusting the amount of excess mass for each subduction zone, usually downwards (Table 1), until the residual geoid (Fig. 3) showed as

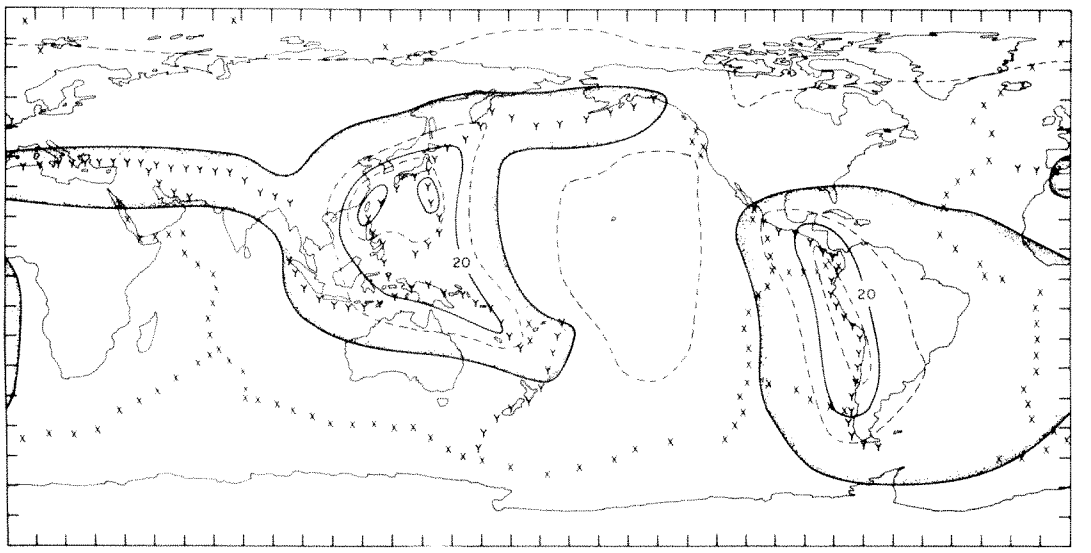

Fig. 2 Model of geoidal undulations due to excess uncompensated masses localised in cold subducting slabs (Table 1). Note the broad, low amplitude high in the South Atlantic. This is a 'farside' effect caused by displacement of the centre of mass towards the subduction zones in the Pacific. Centre of mass offset is 16 m towards 23° N, 165° E.

Table 1 Subduction zone (cold slab) and deep source models

Feature	Depth (km)	Length (km)	Excess mass (10^{15} kg km^{-1})	Cold slab theory (10^{15} kg km^{-1})*
Subduction zones				
Middle America	200	2,864	1.10	1.03

Arabia	1,200	(only 1 point)	8.36×10^{18} kg	

* Calculated from slab model of Molnar and Gray[15] using down-dip length of seismic zone from Isacks and Molnar[16], lithospheric thickness 100 km, $T_1 = 1{,}200$ K, $\rho = 3{,}300$ kg m^{-1}, $c_p = 1{,}050$ J kg^{-1} K^{-1}, $\alpha = 3\times10^{-5}$ K^{-1}, $\kappa = 3.77$ W m^{-1} K^{-1}, convergence rates from ref. 17.

little correlation with the position of the subduction zones as possible.

The subduction zone model (Fig. 2) has positive masses only but negative anomalies in some places, and positive values in places where there are no anamolous masses. The omission of zero and first degree terms from the gravity field means that a positive excess mass will have a positive geoid anomaly directly over it, negative values at greater distance, and a gentle positive on the opposite side of the Earth. This 'farside' effect is caused by displacement of the centre of mass towards the perturbing body.

There may be several reasons that the final model required less mass than theory suggested. The thermal model may not account for all important processes of heat transfer and generation. Because the topography of the oceanic trenches is probably not locally compensated, a trench can contribute up to 0.5×10^{15} kg km^{-1} of mass deficit to counteract the slab's contribution. There may also be local phase boundary deflections caused by convection, and thermal anomalies beneath back-arc basins that partially compensate the cold slab. Elevation of the olivine–spinel phase transition within the cold slab[19,20], increasing its excess mass, would worsen misfit of the thermal model. Sung and Burns[21] suggest that sluggish kinetics will delay transitions in the cold heart of the slab to greater depths, reducing or reversing the effect of the phase change.

A modest amount of uncompensated slab was permissible for continental collision zones of the Himalaya, Zagros and Mediterranean areas. This is surprising considering the importance of the Himalaya in development of isostatic theory, but there is some support from surface gravity studies[22].

The subduction zone model does not remove all geoidal highs located near the trenches, leaving broad positive anomalies on the continental side of the East Asian and Peru–Chile trenches (Fig. 3). These may reflect the pressure gradient necessary to drive asthenospheric counterflow from trenches to ridges. Global models of the flow[23–25] suggest that geoidal elevation should be roughly symmetrical about most convergence zones, but the residual highs are not. However, cooling of the oceanic lithosphere can reduce the elevation on the ocean side of the trench[26].

Another possibility has been pointed out by F. M. Richter (personal communication). Mantle cooled by the subducting

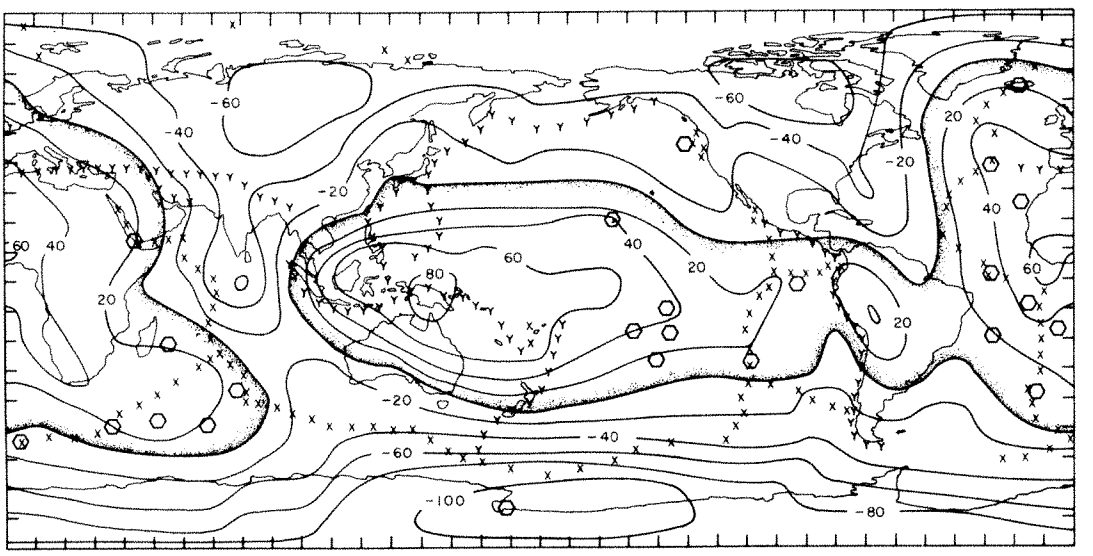

Fig. 3 Residual after subtraction of subduction zone model (Fig. 2) from observed geoid (Fig. 1). Large amplitude and wavelength anomalies remain. ⬡, The location of selected hotspots, mostly oceanic. They cluster strongly about the positive anomalies, mostly near the +20 to +40 m contour.

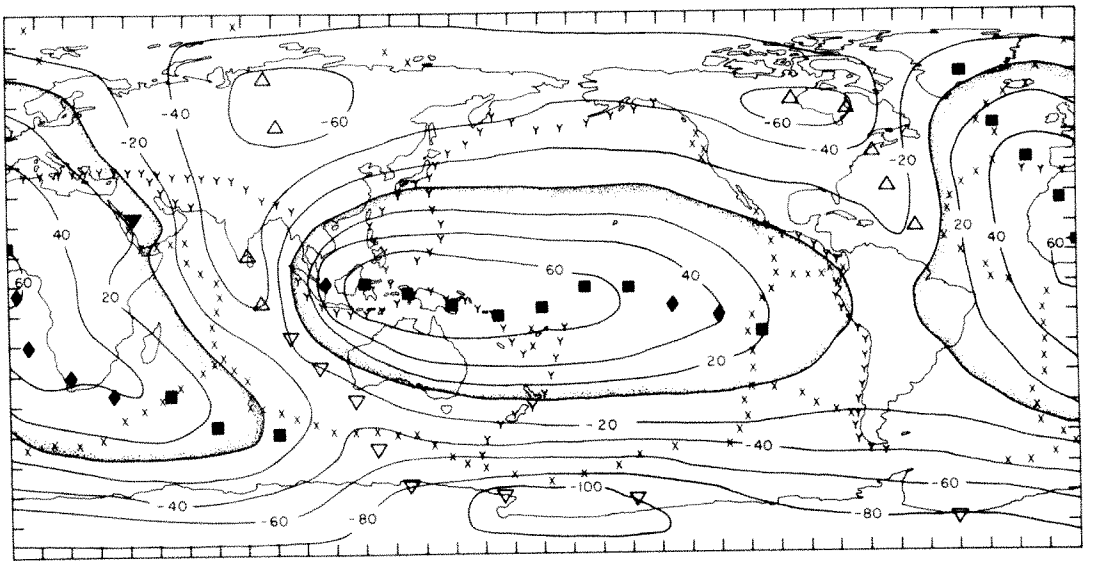

Fig. 4 Model of deep uncompensated point masses designed to approximate residual of Fig. 3. Depths: △, 1,000 km; ▽, 1,200 km; ◇, ◆, 2,000 km; ■, □, 2,900 km. Open symbols, negative point masses; filled symbols, positive point masses. Note the continuity of the anomalies and that the negative masses are all shallow. Centre of mass offset 64 m towards 6° N, 64° E.

slab cannot be removed from near the slab faster than conduction (very slow) or convection permits. This could leave a broad, fairly shallow dense area behind the subduction zone. Note that the residual highs are located where the subduction zones used to be, because all of these trenches move oceanwards in the hotspot frame of reference[27].

Large residual anomalies

The most remarkable features in Fig. 3 are three enormous 60–80-m amplitude geoidal anomalies. There are two positive features—one in the Pacific, stretching from Sumatra to the Galapagos, and the other from south-east of Africa to Greenland—and one discontinuous negative anomaly from Antarctica through India and Siberia to the North Atlantic. Clearly most variation of the geoid from hydrostatic equilibrium is not due to subduction zones.

These three large geoidal anomalies share several characteristics that need explanations. (1) Great size: each of the anomalies is at least 18,000 km in length, and the positive anomalies are more than 6,000 km wide, the negative is about 4,500 km wide. (2) Large amplitudes: all have amplitudes greater than 40 m for much of their length. (3) Lack of correlation to surface tectonic features: all three anomalies cross several plate boundaries with little apparent disturbance. There is no correspondence to type or age of lithosphere. (4) Strong correlation to location of oceanic hotspots: of the 24 selected hotspots marked on Fig. 3, all but three lie within the positive anomalies.

Deep source model

To find maximum source depth, I have constructed a point mass model for the large residual anomalies (Fig. 4). The point sources for the positive anomalies could be placed quite deep, at 2,000 or 2,900 km (core–mantle boundary). This depth is a maximum, because a broad, smooth anomaly can also come from a more gradual density fluctuation at shallower depth. The sources of the negative anomaly could be no deeper than 1,200 km, however. The estimate of excess mass for the features (Table 1) is a close upper limit and not very sensitive to depth of the source mass distribution. The positive anomalies, as well as being broader and possibly deeper in origin, require much more excess mass than the negative one.

This model for the non-hydrostatic part of the Earth's shape includes the excess equatorial bulge. The largest anomaly, the equatorial Pacific high, determines the maximum non-hydrostatic moment of inertia of the Earth, and therefore the position of the rotational axis[28]. Should the African high grow larger than the Pacific high, the whole Earth would shift relative to the axis—true polar wander, with Greenland moving to the Equator!

The observed geoid with the deep source model subtracted is shown in Fig. 5. Subduction-related features are most prominent (compare Fig. 2). There are other anomalies of note: positive anomalies of 2–8 m height over the mid-ocean ridges (see ref. 29); and a 10-m high in mid-Pacific west of the Hawaiian Islands[30]. The broad low in the eastern Pacific may be related to asthenospheric counterflow, as discussed above.

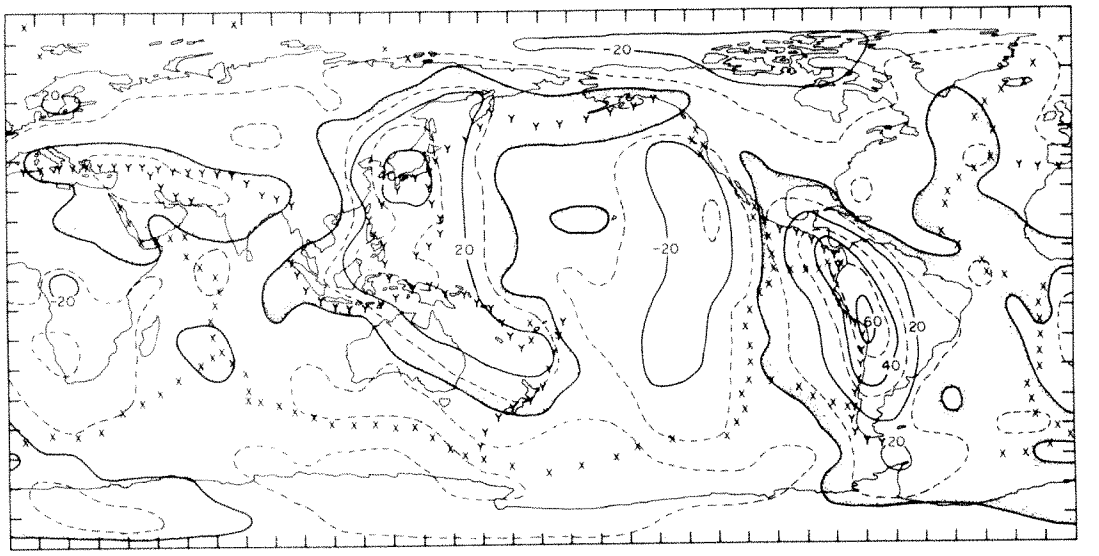

Fig. 5 Observed geoid with deep mass model of Fig. 4 removed. Compare with Fig. 2.

Lower mantle convection?

What, then, is the origin of the large anomalies (Fig. 3) that dominate the non-hydrostatic part of the Earth's geoid? Rocks are not strong enough to support these features, so convective processes must be responsible[3,5,31]. The lack of correlation of the large anomalies to plate boundaries and motions allows a more specific interpretation of where the convection is located: it must be below the flow regime associated with plate tectonics.

Whole mantle convection closely coupled to surface plate motions has been invoked lately[25,32-34], but is clearly not permissible if the large geoidal anomalies unambiguously reflect the location of lower mantle convection cells. Such a geometry could not satisfy mass balance requirements for plate motions[24] and there is no particular relationship to plate motions or interplate stresses[11]. For example, convection associated with the Pacific high should either extend or compress the Pacific plate in a north–south direction, neither of which is observed[11]. Thus the residual geoidal anomalies are direct evidence favouring the model advanced by McKenzie and Weiss[35] of two layer convection with upper and lower mantle circulating separately.

It is not obvious whether the positive anomalies would mark upwellings or downwellings in the lower mantle convection. Analytical[36] and numerical[37] models of mantle convection suggest that deflections of density boundaries will dominate the gravity field in many cases, leading to positive anomalies over upwellings. The tendency of hotspots to occur over geoidal highs may indicate hotter than normal material below. The hotspots themselves imply some interchange of material between lower and upper mantle, if they do originate within a lower convective system. Global heat flow patterns[38] show little correlation with the large geoidal anomalies. Seismic travel times under the North Atlantic[39] resemble the geoidal patterns there, slow travel times corresponding to geoidal lows. Globally, deep travel time anomalies[40] also show some correlation with geoid anomalies in the low degree harmonics. A great deal more work needs to be done on the intriguing possibility that the Earth's gravity field reveals convective patterns hidden at depth.

This work was supported by NSF grant EAR 75-21622. I thank the Earth Science Board, University of California, Santa Cruz for hospitality during my sabbatical when this work was done, and B. Hager and G. Davies for helpful comments.

Specificity of the antibody response of rabbits to a self-antigen

Ronald Jemmerson* & Emanuel Margoliash

Department of Biochemistry and Molecular Biology, Northwestern University, Evanston, Illinois 60201

The demonstration that the antigenic determinants on rabbit cytochrome c that elicit antibodies in rabbits occur in regions of variability among mammalian cytochromes c suggests the existence of an evolutionary process which eliminates genetic specificities for self-determinants.

DESPITE the considerable attention which has been given to the antigenic properties of proteins, we still do not know why certain parts of a protein antigen elicit antibody responses while other regions remain immunologically silent. As the B-cell specificity repertoire that is expressed is limited[1], it follows that not every molecular substructure of an antigen would have a corresponding B cell reactive to it. But what restraints act to limit the B-cell specificity repertoire?

One theory is that, because of the phenomenon of immunological tolerance, antibodies may not be elicited against those regions of an antigen which share structural or chemical properties with self-molecules of the host. Indeed, studies on the antigenicity of cytochrome *c* indicate that the regions of amino acid sequence difference between the cytochrome *c* immunogen and the corresponding host's protein are antigenic[2–5]. For example, one of the six residue differences between horse and rabbit cytochromes *c* is residue 60, where horse cytochrome *c* has lysine and the rabbit protein has glycine. These two cytochromes *c* have 18 other lysyl residues in common. When rabbits are immunised against horse cytochrome *c*, the antibodies directed against the region of lysine 60 comprise 20–40% of the total antibody and the other lysyl residues do not elicit antibody responses[4,5]. It is difficult to explain this observation other than by tolerance. The concept of a particular chemistry inducing antigenicity must be excluded in this instance as only one of 19 lysine residues is antigenic.

Although immunological self-tolerance seems to be a dominant factor affecting the specificity of the immune response to cytochrome *c*, it was early observed that not only did antibodies elicited against a heterologous cytochrome *c* bind the rabbit protein, but also when polymerised with glutaraldehyde[6]

or covalently coupled to bovine γ-globulin[7], rabbit cytochrome *c* itself was immunogenic in rabbits. The finding that antibodies elicited against a foreign cytochrome *c* cross-reacted with rabbit cytochrome *c* is attributed to the more stringent requirements for stimulating a B cell than for binding of an antigen to the cell receptor (antibody)[8,9]. Thus, the observation is not inconsistent with the existence of a state of tolerance in rabbits to rabbit cytochrome *c*. However, the finding that rabbit cytochrome *c*, when in certain molecular forms, does initiate an antibody response is not as readily understood. The quantitatively lower response evoked by the self-antigen, as opposed to heterologous cytochromes *c*, indicates a degree of immunological tolerance to rabbit cytochrome *c* and it may be that modification by coupling to a carrier or by polymerisation may have enabled the protein to trigger a response that would normally not be allowed.

In any case, the ability to elicit an antibody response to a self-antigen indicates that immunological self-recognition is not the only mechanism allowing certain sites on an antigen to remain immunologically silent. We considered that by establishing which sites on rabbit cytochrome *c* elicit antibody responses in rabbits, we might elucidate factors other than lack of self-recognition that would influence the antigenicity of only certain regions of a molecule.

To obtain autoantibodies against rabbit cytochrome *c*, eight adult New Zealand white male rabbits were injected three times over 6 weeks with the glutaraldehyde-polymerised form of the protein (~9 mg total) emulsified in Freund's complete or incomplete adjuvants. The cytochromes *c* used in this study and the glutaraldehyde-polymerised rabbit cytochrome *c* were prepared as previously described[3]. Rabbit cytochrome *c* was chemically fragmented using cyanogen bromide and the peptides (residues 1–65, 66–80 and 81–104) were separated according to the procedure of Corradin and Harbury[10]. Other methods used, including antibody fluorescence quenching titration and modified Farr assay, have been reported elsewhere[3].

Characterisation of the antibody response

All eight rabbits immunised with rabbit cytochrome *c* polymers produced antibodies specific for the monomer, with serum titres between 115 and 230 μg antibody ml^{-1} as determined by immunoadsorption of the antibodies on rabbit cytochrome *c* coupled to CNBr-activated Sepharose 4B. The serum titres were 5–20% of the response observed against heterologous cytochromes *c* differing from the rabbit protein at 6–9 residues out of 104. Clearly, rabbits display a degree of 'tolerance' to their own cytochrome *c*[6].

The rabbit anti-rabbit cytochrome *c* antibodies adsorbed on the insolubilised antigen had an apparent molecular weight of 150,000 based on gel filtration studies on a calibrated column of Sephadex G-150, migrated electrophoretically as a single band

Table 1 Comparison of the amino acid sequences of mammalian cytochromes *c*

	3	3	4	4	5	6	6	8	8	9	10

Beef[17]	–	–	P	–	–	–	E	–	G	E	–
Horse[18]	–	–	P	T	–	K	E	–	T	E	–
Dog[19]	–	–	P	–	–	–	E	T	G	–	K

The single letter code for amino acids is used. Residue positions are given vertically, for example, $\frac{3}{3}$ referring to position 33. Only the residues that differ among the cytochromes *c* listed are shown. – Indicates that the residue is identical to that of the rabbit protein.

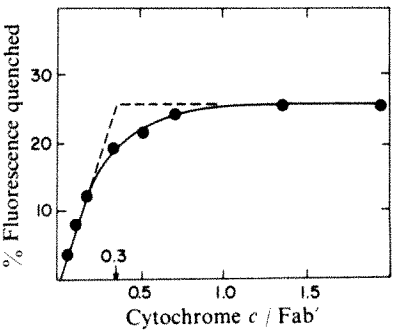

Fig. 1 Fluorescence quenching titration of rabbit anti-rabbit cytochrome *c* Fab' with rabbit cytochrome *c*. The antibodies were isolated from pooled antisera on insolubilised rabbit cytochrome *c*, digested with 2% pepsin for 8 h, then reduced with cysteine and alkylated with iodoacetamide.

in the γ region, and showed precipitation in agarose film with goat anti-rabbit γ-chain-specific but not μ-chain-specific antisera. Thus, the antibodies elicited in rabbits against their own protein were IgG. The stoichiometry of the antibody-binding reaction, as determined by fluorescence quenching assays between the Fab' fragments prepared from the antibodies and rabbit cytochrome *c*, was 3 : 1, indicating the presence of at least three separate antigenic determinants on rabbit cytochrome *c* (Fig. 1).

Modified Farr assays of rabbit anti-rabbit cytochrome *c* sera showed that the antibodies distinguished between rabbit and heterologous cytochromes *c* that differed at two to six amino acid residue positions (Fig. 2, Table 1). Thus, mouse cytochrome *c*, which varies from the rabbit protein at only two positions—residues 44 and 89—did not compete with ^{125}I-labelled rabbit cytochrome *c* for the antibody-binding sites as effectively as did rabbit cytochrome *c*. The dog protein displaced only 30% of the labelled rabbit cytochrome *c*, even though it differs from the rabbit protein at only five residue positions—44, 62, 88, 89 and 103. These results show that the rabbit anti-rabbit cytochrome *c* antibodies are directed against regions of the molecule where the rabbit and the other mammalian cytochromes *c* differ in amino acid sequence.

Identification of the sites of antibody binding

At least one antibody population bound in the carboxyl-terminal segment comprising residues 88–104. Indeed, dog cytochrome *c* was a less effective inhibitor in the modified Farr assay than was the beef protein, which differs from it only at residues 88, 92 and 103. Furthermore, the peptide consisting of residues 81–104 of rabbit cytochrome *c* inhibited the binding of approximately 20% of the labelled rabbit cytochrome *c* when present in a 20-fold molar excess over the latter (Fig. 3). The difference in binding between mouse and rabbit cytochromes *c* may indicate that the antigenic site is in the region of residue 89 as these two proteins differ only at that position and at residue 44. In any case, the data indicate that residue 44 or 89 or both are within antigenic determinants. In contrast to the 81–104 peptide, the 66–80 peptide failed to inhibit any binding of the antibodies to rabbit cytochrome *c*. However, the haem-containing 1–65 peptide displaced 80% of the labelled protein. Thus, the 1–65 and the 81–104 peptides contained the whole of the autoantigenic activity of rabbit cytochrome *c*. Further one of the antibodies binding to the 1–65 fragment was found to be directed against the region of residue 62. Thus, mouse and kangaroo cytochromes *c*, which, like the rabbit protein, carry aspartic acid at that position, were more effective inhibitors of rabbit cytochrome *c* than was guanaco cytochrome *c*, which has glutamic acid (Fig. 2). The only other position at which guanaco cytochrome *c* differs from the rabbit protein is 89, where the former

has a glycine and the latter aspartic acid. Both mouse and kangaroo cytochromes *c* are identical to the guanaco protein at position 89, so that the greater affinity of these two cytochromes *c* for the antibodies must be due to their greater similarity to the rabbit protein at position 62.

As the stoichiometry of the reaction between rabbit cytochrome *c* and its antibodies is three, in addition to the antibodies binding in the carboxyl-terminal segment and in the region of residue 62 there is at least one other antibody population. It probably binds to the amino-terminal segment of the protein represented by the 1–65 peptide, because as already noted, that peptide accounts for a large proportion of the autoantigenic activity of the molecule, and the 81–104 fragment contains another antigenic determinant accounting for the remainder of the activity.

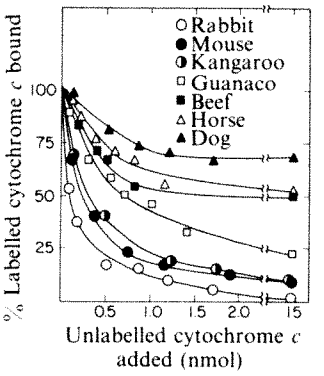

Fig. 2 Competitive binding assays between rabbit and various mammalian cytochromes *c* and antibodies elicited in rabbits against the glutaraldehyde-polymerised form of rabbit cytochrome *c*. Rabbit cytochrome *c* was iodinated with carrier-free ^{125}I by the method of Hunter and Greenwood[20]. The antiserum used was pooled from four rabbits and diluted 1:4 with 6.2 mM sodium borate–boric acid buffered at *p*H 8.6, containing 130 mM sodium chloride. Each reaction mixture contained 1.36 nmol ^{125}I-labelled rabbit cytochrome *c*, 0.20 ml diluted antiserum and amounts of unlabelled cytochrome *c* ranging from 0 to 15 nmol. Antibody–cytochrome *c* complexes were precipitated in 50% saturated ammonium sulphate and washed three times. The amount of radioactivity precipitated was corrected for nonspecific binding using normal rabbit serum. In the absence of inhibitor 0.038 nmol of ^{125}I-labelled rabbit cytochrome *c* were precipitated.

Do specificities for self-determinants tend to be eliminated during evolution?

From the above analysis, two of the three antigenic sites on the self-antigen rabbit cytochrome *c* have been localised to the regions around residue 62 and the carboxyl-terminal segment probably around residue 89. Those two sites correspond to regions on heterologous cytochromes *c* that are antigenic in rabbits. Indeed, the antigenic sites on guanaco and mouse cytochromes *c* were found to be centred around residues 62 and 89 and residues 44, 62 and 89, respectively[3], and those on horse cytochrome *c* were in the regions of residues 44, 60 and 89 or 92 (refs 4, 5). The area around residue 44 in rabbit cytochrome *c* may be the third autoantigenic site of that protein.

What property of these regions of cytochrome *c* makes them antigenic? It is unlikely that the particular amino acid side chains share an antigenic property, as each cytochrome *c* examined with respect to antigenic specificity has different amino acid residues in the immunodominant position and the antibodies elicited by each cytochrome *c* antigen are specific for its own side chains[2–5]. Possibly, the tertiary structure of the molecule in the antigenic regions is such that interactions with cells of the immune system occur more readily. This explanation also seems unlikely as the cytochrome *c* molecule is a tightly folded oblate spheroid and no externally located backbone sequence is particularly better situated than any other for increasing the probability of extramolecular interactions. In this regard, there are no sharp bends in cytochrome *c* as there are in myoglobin that could explain the antigenicity of certain sites on that molecule[11].

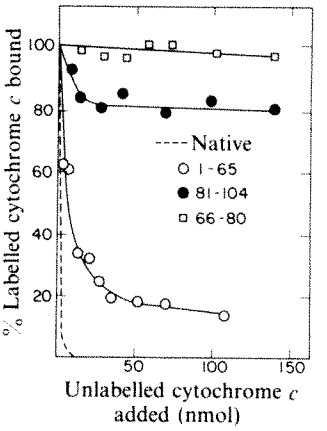

Fig. 3 Competitive binding assays between rabbit cytochrome *c* and cyanogen bromide-cleaved peptides of the protein and antibodies elicited in rabbits against rabbit cytochrome *c*. The assays were carried out as described in Fig. 2 legend.

Notwithstanding any unknown chemical features which of themselves might allow certain regions to be antigenic, it is particularly interesting that the antigenic sites on rabbit cytochrome *c* correspond to the areas on the molecule where other mammalian cytochromes *c* differ from it (Fig. 4) and in fact, a region in which all cytochromes *c* are identical (residues 66–80) was demonstrated not to be antigenic in rabbit cytochrome *c*.

A possible explanation for this is that only certain regions of a self-antigen elicit immune responsiveness because other specificities are absent from the repertoire (not carried in the germ line). Selective pressures against the maintenance of antibody specificities to self-antigens could act during evolution to eliminate specificities for self-antigenic determinants from the antibody repertoire. Because self-antigens would continue to vary structurally in the course of evolution, as selective pressures begin to effect the elimination of the corresponding antibody specificities, those specificities corresponding to the most variable regions of a self-antigen, namely, those most likely to have varied recently, are the least likely to have been eliminated. Selective pressures would be most effective against those antibodies specific for the evolutionarily conserved regions of a self-molecule because of the long exposure time required for evolutionary elimination.

Thus, if this interpretation is correct, antibodies elicited against a self-antigen should correspond to those regions of the molecule which have varied evolutionarily. That seems to be the

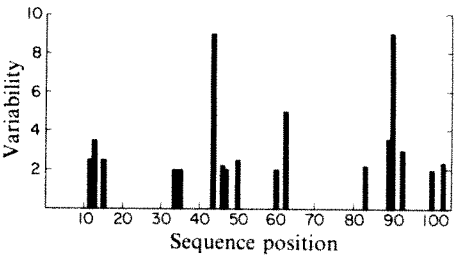

Fig. 4 Variability of mammalian cytochromes *c*. Variability is defined as the number of different amino acids at a given position divided by the frequency of the most common amino acid at that position[21]. Eighteen mammalian cytochrome *c* sequences were used for this[22,23]. The variabilities at residues 11, 12 and 15 are attributable to amino acid substitutions in the later evolving primate cytochromes *c* and thus, the region around residues 11, 12 and 15 would not be antigenic in rabbit cytochrome *c* by the mechanism discussed in the text.

case with the antibody response in rabbits against rabbit cytochrome *c*. One could, therefore, consider that there are at least two biological levels at which an individual is rendered tolerant to self-antigens—at the developmental level, clones reactive with self are aborted or tolerised; at the evolutionary level, genes corresponding to specificities against self tend to be eliminated. Although this is not the only possible interpretation, it would be consistent only with a germ-line or programmed somatic mutation theory of antibody diversity and cannot be reconciled with a theory of diversity involving somatic mutation alone.

We thank Drs Susan Pierce and Norman Klinman for useful discussions. This work was supported by grants AI-12001, GM-19121 and HL-11119 from the NIH.
